Uttarpara Jaikrishna Public Library

same beneficent rule appeared the great Arabian physicians Rhazes, Haly Abbas, and Avicenna.

Arabian medicine was carried into Spain by the Moors, and flourished exceedingly under the generous sympathy of the Cordova Caliphs, producing workers like Albucasis and Avenzour.

Even Egypt had its 'Hall of Wisdom' erected by Hakim Biamrillah in 1005, under the protection of the Cairene Caliphs.

During this period medical instruction was given to scholars in the large hospitals and in the dispensaries, which were numerous.

The features of Arabic medicine which are especially interesting to us are the references to tropical diseases, and these are sufficiently numerous because the Arabic physicians were brought into contact with strangers from various parts of the world who had been attracted to Arabic countries by the wisdom of the Caliphs with regard to learning and liberty. As these strangers often brought with them strange herbs and drugs, so Arabic medicine abounds with references to new remedies for disease.

Associated with Arabic medicine is the appearance of many Jewish medical works, and so much so that it appears to us that this should be held to be *the second period of Jewish medicine*. The reason for this development is because the Caliphs allowed the Jews to live and work in freedom at a time when Christianity as a whole was persecuting them.

The decline of Arabian medicine came in the thirteenth century, with the fall of Cordova in A.D. 1236 and with the Mongol invasion of Bagdad in A.D. 1258, and though it lived for long in Spain, still, its day was over and its scholars were passing to the *School of Salerno*, from which were to come those piercing rays of medical knowledge which were to illuminate the closing years of the Middle Ages.

Before, however, passing on to the consideration of mediæval medicine we will make brief reference to a few of the Arabic works on medicine, which included not merely dictionaries and translations, but original works on general medicine, pharmacopœias, works dealing with natural history, and veterinary matters.

Abû Zakarîya Yûḥannâ ben Mâsawayh or Mesua, was the son of a Christian apothecary in the hospital of Gundeshâpûr. He was appointed by the Caliph Hârûnu-'r-Rashîd to translate Greek works, of which he did many, but he also wrote original treatises—e.g., one upon 'the Curiosities of Medicine.' He died in A.D. 857, and some of his books, as far as we know, were the first medical works to be printed in movable type in 1471. He seems to have been the first to write a medical treatise in tabular form in his 'Kitâbu-'l-Mushajjar,' which comprised treatises on the general rules of medical art and on the diseases of regions and organs, including four books on the diseases of the skin.

Abû Bakr Muḥammad ben Zakarîya-'r-Râzî, or Rhazes, was born at Ray in 'Iraq-i-'Ajam, but did not commence the study of medicine until he was thirty-two years of age, when he was taught at Bagdad by 'Alî ben Rabban at-Tabarî. He was first Director of the Ray Hospital and later of the Bagdad. He died about A.D. 923.

His works are numerous, and we may mention 'Kitâbu-'l Manşûrî' System of Medicine, which is divided into ten chapters. It includes anat diagnosis, ailments and drugs, preservation of health, cosmetics and th of pityriasis, advice to travellers, surgery, poisons, regional diseases, fevers, and also the qualities necessary for a physician, and remarks on quacks and impostors. He gave the earliest accounts of smallpox and measles, which earned for him lasting fame.

A System of Midwifery—'Kitâb u-Tadbîr-al-Habâlâ'—was written in the fourth century by a physician *Abu-'l-'Abbas Aḥmad ben Muhammad ben Yaḥya-'l-Baladî*. This book included the management of pregnancy and the diseases of the fœtus and the infant, as well as the rearing of the child.

Khalaf ben 'Abbâs-az-Zahrawî, or Albucasis, was born at Az-zahrâ, near Cordova, and died probably about A.D. 1013. His great work is 'Kitâbu-'T-Tasrîf,' which is an encyclopædia chiefly valued for its surgical portion, which was translated into Latin in the twelfth century, and for long remained the standard surgery of Europe.

Ophthalmic surgery was considered by *'Alî ben 'Îsâ al-Kuḥḥâl*, or Jesu Haly

Abû 'Alî al-Husayn ben 'Abdullah ben Sînâ, or Avicenna, often called Ash-Shaykh (the Reverend) or Ar-Ra'is (the Chief), was born at Ashainah, in Bukhârâ, in A.D. 980. He was physician to the Sultan of Bukhârâ, but later he retired to Jurjan, where he wrote his celebrated 'Kitâbu'L-Qânûn,' or Book of the Canon. He died in A.D. 1037. His great work is essentially medical, as the surgical portion is poorer than that of Albucasis, and is in many places a treatise on tropical medicine

Hibatullâh ben Zayd ben Hasan ben Ya'qûb ben Ismâ'îl ben Jamî' al Isrâ'îlî, or Ibn Jami Isrâ'îlî was brought up in Old Cairo, and was considered to be the greatest of the Egyptian physicians. He was physician to the celebrated Al-Malik u'n Nâsir Salâh u'd Dîn (Saladin), for whom he made his *Theriac*. He died in A.D. 1198.

The last of the great Arabian physicians, *Dâ'ûd ben 'Umar al-Anṭâkî*, wrote an encyclopædia of medicine, and after living for a [illegible] time in Cairo went to reside in Mecca, where he died in A.D. 1599

Medieval Medicine. Following Garrison, we may date medieval medicine from the time that the *School of Salerno* established its influence in Europe. As to the origin of this epoch-making school, we know nothing, but we do know that it was here that Arabic translations of Greek medical works were turned into the Latin language by scholars from Spain, and we also know that the knowledge so obtained led to great practical results, in that *universities* were founded, the great movement of building *hospitals* was begun, both of which were founded and aided by Church and State alike. Salerno laid the foundations of these advances in medical teaching and care of the sick, and thus prepared the way for modern medicine, especially as it encouraged individual medical talent.

Foundations of Modern Medicine.

The revival of learning was only made possible by the destruction of feudalism, and this was brought about, as Garrison and others have pointed out, by the discovery of gunpowder. To this great act of freedom must be linked the discovery of printing by means of movable type, and the sack of Mainz in 1462, which disseminated the art of printing all over Europe and thus enabled knowledge to be easily preserved and widely distributed.

While these events were stirring the general public, medical men were confronted with new diseases from the East, which came in epidemic form, and these terrible outbreaks compelled them to observe and to record their observations; and, indeed, it is during this period that Girolamo Fracastoro, studying syphilis and typhus, started modern epidemiology by formulating the theory of contagion.

The subject of infection has been recently studied in a most able manner by C. and D. Singer, who have shown that to primitive peoples infection and contagion are in the general order of things, and not to be questioned, but that Hippocrates had no idea as to the spread of epidemic disease by infection. They point out that it was Thucydides (471-391 B.C.), while studying the 'plague of Athens,' who first established spread of disease by contact, and Aretæus the Cappadocian who added conveyance of infection from a distance, facts recognized by some of the Arabians like Haly Abbas, while the School of Salerno clearly stated that disease could be spread by contact, air, and fomites; and Remacle Fuchs (1510-1587) was not merely clear on these points, but wrote about the 'seminaria,' or seeds of disease. All these were, however, merely the precursors of Fracastoro (1478-1553), whose doctrine of disease seeds or germs, foreshadowed in his 'Syphilis' in 1530, is clearly stated in his 'De contagionibus et contagiosis morbis et eorum curatione' in 1546, in which he details different types of infection, by contact alone, by contact and fomites, by contact, fomites, and from a distance. He considers infection to be nothing else than *the passage of a putrefaction from one body to another*. He distinguishes infections from poisons because the former possess seeds which can reproduce their like in a second body. In addition, he was the first to recognize typhus fever and the specific characters of fevers.

These factors—viz., new methods of warfare changing society, new methods of spreading knowledge and apparently new epidemics—were the forces which in our opinion laid the foundations of modern medicine.

The Discovery of the Tropics.—It will be noted that in early times medicine was relatively highly developed in Egypt and India, while it was very primitive in the Temperate Zone, but the question as to the supremacy of East over West was settled by the Battle of Salamis, and thenceforth the general tendency was that learning advanced in the West and languished in the East. But the West knew that there was an East: the question was how to get there. A few travellers lived to return and tell the tale of the overland journeys to the East, and these were sufficient to indicate that the overland route was unsuited for traffic on a large scale, though trade came through gradually.

The problem of finding a way to the East was solved by the Portuguese, who in 1415 established contact with the Atlantic Islands, in 1444 with the West Coast of Africa, and later with the Congo and Angola. In 1486 they reached the Great Fish River, and in the last decade of the fifteenth century the route to India viâ the Cape was made known.

While this was going on in the East, Colombus was tracing a route to America across the Atlantic in 1492, and in 1519 Magellan passed through the Straits to which his name has been given, and showed the route to the East, while still later the complete voyage round the world was carried out successfully.

China and Tibet, however, remained unknown until the seventeenth century and Central Africa until the nineteenth century.

Early Tropical Medicine.—The work of the last section being carried out in ships with more or less numerous crews, it was customary for these vessels to be provided with a surgeon, or, at all events, with a person with some knowledge of medicine and some powers of observation. Later, when intelligent people settled in tropical regions they made records of their experiences, and in this way a curious literature sprang up, partly geographical, partly zoological, partly botanical, partly medical, and partly ethnographical. It is in this literature that we find some of the earliest references to disease in the tropics. The literature itself is sufficiently indicated in the list of works given at the end of this chapter; but being so mixed in its nature, it produced but little effect, and was left almost unnoticed until after the rise of modern tropical medicine.

Foundations of Modern Tropical Medicine.

The discoveries of new lands made as indicated above by voyages, were in due course extended by land exploration, and later by settlements founded by Europeans and their families, and as these grew in number and in size, so the number of medical practitioners also increased.

These medical men studied the diseases of the European settlers and of the natives of the regions in which they resided, and recorded their results in numerous publications, as is indicated in the list of works given at the end of this chapter.

These works naturally reflected the teaching which the author had received in Europe prior to his tropical career, and, therefore, as knowledge in Europe progressed, so information with regard to tropical diseases was amplified.

The factor which was most potent in the foundation of modern tropical medicine was the steady evolution and perfection of the compound microscope. It was this instrument which enabled *Laveran* to discover the malarial parasite, and *Manson* to find the periodicity of the *Microfilaria nocturna*.

These investigators may well be called the *pioneer founders* of modern tropical medicine, and that foundation was secured by the world-wide interest in tropical disease aroused by *Ross's discovery* of the spread of malaria by the mosquito. From the date of these discoveries *modern tropical medicine*, in our opinion, begins, because they opened up the possibility of finding the cause, the treatment, the method of spread, and the prevention of a tropical disease, and, moreover, for some reason or another, subsequent work on these lines has apparently been much more successful in the tropics than elsewhere.

Thus modern tropical medicine was essentially based upon the microscopical diagnosis of the disease, and differed thereby from earlier tropical medicine, which was entirely clinical; yet, in our opinion, clinical and microscopical diagnosis should go hand in hand, and the practitioner should never so depart from the essential of all medical knowledge, the thorough bedside examination of the patient by clinical methods, as to commit the error of entirely trusting to the microscopical diagnosis. If he trusts entirely to the clinical diagnosis errors must occur; if he leans absolutely upon laboratory examinations, which are often negative, he will again find himself in difficulties. The real foundation of modern tropical medicine is the blending together of clinical work with scientific research, thus making a living progressive science of medicine, in which causation, treatment, and prophylaxis of known diseases are associated with State-aided research into the unknown. We will now briefly look at the history of these various points.

Causation of Diseases.—One of the most marked features of modern tropical medicine is the success which has attended attempts to find the causal agent of the various diseases; and to trace the rather romantic history of these discoveries, it is necessary to subdivide the subject into Helminthology, Protozoology, Mycology, Bacteriology, Serums and Vaccines, Entomology, Toxicology, Climatology, and Dietetics.

Helminthology.—We have already noted that the Ebers Papyrus mentioned the presence of worms in the intestines; that Moses not merely knew the guinea-worm, but how to extract it by winding it round a stick; and we have further drawn attention to Agatharchides' description of this worm in 170 B.C. and to the reference to broad and round worms by Paul of Ægina and may, therefore, pass on to more recent work.

Trematodes were first recognized by Jehan de Brie in the form of the liver fluke of sheep, which was afterwards described in 1547 by Gabucinez. This initial work was extended later by Leeuwenhoek (1675), Swammerdam (1752), Rosenhof (1758), Muller (1777), Zeder (1800), who called them 'sucking worms,' and Rudolphi who gave the name Trematode, from τρηματώδης, meaning pierced by holes. Quite recently these worms have been the subject of two great discoveries, which may be briefly summarized.

In 1874 the trematode *Clonorchis sinensis* (= *C. endemicus*) was discovered by McConnell in the liver of a Chinaman, but the method of infection was not known until Kobayashi worked this out in 1912, 1915, and 1917, showing that the encysted stage could be found in twelve varieties of fish, and that kittens produced the adult trematode when fed upon infected fish, and finally that the first intermediate host is a mollusc—*i.e.*, a species of Melania.

In 1851 Bilharz discovered the trematode *Schistosoma hæmatobium* in the portal vein of an Egyptian. Since 1907 Sambon has shown that under this name was concealed, as suggested by Manson, a second parasite, which he called *Schistosoma mansoni*. In 1915 Leiper not merely confirmed the existence of these two distinct parasites, but traced their life-histories through the molluscs to the adult form in mammals. This is indeed a great and valuable discovery, and by no means the first by which this distinguished helminthologist has benefited mankind.

With regard to the Cestoda and Nemathelminthes space does not permit of a history at this point, as this will be given later; but with regard to the latter group Sir Patrick Manson's researches into filariasis were epoch-making.

The detailed history of *Filaria bancrofti* will be given later, and it will suffice to state here that the microfilaria was discovered by Demarquay in 1863, and that Manson discovered its development in the mosquito in the years 1877-1879, while in 1882 he laid stress upon the nocturnal periodicity of the microfilaria, a fact entirely disbelieved when first reported.

The great importance of the discovery of the development of this worm in a mosquito is that it paved the way for Ross's discovery of the spread of malaria by a similar agency.

It is quite impossible here to give even a reasonable list of the workers on this important branch of causation, but references to their discoveries will be found later in this book.

Protozoology. Protozoa were recognized by Leeuwenhoek in 1675, and the first life-history of a protozoon (a vorticella) was worked out by Trembley in 1744-1747.

Among the protozoa parasitic in human beings, one of the first to be discovered was *Balantidium coli*, found by Malmsten of Stockholm in the year 1856, and now known to be often associated with a chronic catarrh and ulceration of the large bowel. *Lamblia intestinalis*, discovered by Lambl in 1859, and *Trichomonas hominis*, found by Davaine in 1854, are considered by many authors (Ebstein, etc.) to be the cause of certain cases of diarrhœa.

In 1875 an ameba was found by Lösch in St. Petersburg, in a peasant who suffered from an ulcerative inflammation of the large intestine, and Sonsino in Cairo also described the finding of large numbers of amebæ in the intestinal mucus of a child who had died of dysentery. Other observers, however (e.g., Grassi, Celli, and Cunningham) found amebæ in persons whose health had undergone no change. Kruse and Pasquale first suggested that there might be two species of amebæ, one pathogenic, the other harmless. Later Schaudinn showed that there were two kinds of amebæ affecting man, viz., *Entamœba coli*, which was non-pathogenic; and *Entamœba histolytica*, described by himself, which was the cause of a certain kind of dysentery (amebic dysentery) and of the abscess of the liver which at times followed it.

The discovery which has had the greatest influence on tropical medicine was that of the parasite of malarial fever by Laveran on November 6, 1880. True, this had to some extent been foreshadowed by Merkel in 1847, and Virchow in 1848, both of whom saw, and the latter figured, protoplasmic masses and pigment. Still, the entire credit for this great discovery is due to Laveran, for the others failed to recognize the parasitic nature of the forms they saw. The development of our knowledge concerning this parasite is due to the valuable researches of Golgi, Marchiafava, Celli, Bignami, and many others. Of great importance was Golgi's discovery of the plurality of species of the malarial parasite. Laveran's discovery and the work of his successors left, however, a great gap in the history of the parasite. They described lucidly its life-history in the human being, but could not explain how man became infected.

Sir Patrick Manson, reasoning on his work on the mosquito and filaria, suggested that there might be a stage of the development of the parasite in the mosquito. Working on Manson's theory, Ross, at that time in the Indian Medical Service, after years of patient hard work, was able to trace the full development of a bird's parasite in Culex, and partially that of the human parasite in the Anopheles, and thus made not merely a great discovery, but one which ought to be in time of lasting benefit to mankind. The full development of the human parasite was found out by Grassi, who also showed that only Anopheles are capable of transmitting the parasite. Ross and Grassi's most important discoveries have been verified and extended by many people—e.g., Marchiafava, Celli, Bignami, Dionisi, Daniels, Stephens, and Christophers, etc.—but the account of their work will be given later. Thus, out of the fevers all classed as malaria there issued a type clearly defined, to which the term 'malaria' must be restricted.

In 1901 Forde and Dutton discovered a trypanosome, called by Dutton *Trypanosoma gambiense*, in a case of a peculiar irregular fever in the Gambia. In 1902 Dutton and Todd observed this organism in several other cases presenting the same type of fever, which became known at the time as trypanosome fever, Gambia fever, or Dutton's disease (Laveran and Mesnil). In 1902 and 1903 Castellani found a trypanosome in the cerebro-spinal fluid of cases of sleeping sickness, and first associated it with the ætiology. Further investigation by Bruce, Nabarro, and numerous observers in various regions of Africa confirmed and greatly extended this work. In 1903 Sambon and Brumpt independently promulgated the hypothesis that the human trypanosome was carried by a tsetse-fly, in all probability the *Glossina palpalis*, and Bruce and Nabarro experimentally proved that the *Trypanosoma castellanii* is in reality introduced into human beings by the bite of *Glossina palpalis*. Bruce and others considered the transmission as purely mechanical, but the researches of Kleine show that the parasite undergoes true development in the body of the tsetse fly. In 1903 Castellani stated that man in analogy with the lower animals might be infected by several species of trypanosomes. In 1909 Chagas discovered a form of human trypanosomiasis in South America, and showed that the trypanosome causing it (*S. cruzi* Chagas, 1909) was carried by a Conorhinus. In 1910 Stephens and Fantham created a new species (*T. rhodesiense*), which Kinghorn and Yorke in 1912 showed to be transmitted by *Glossina morsitans* (Westwood).

Trypanosomes were found in the lower animals long before they were discovered in man. Gruby first used (1843) the term 'trypanosoma' for a flagellate he had found in the blood of frogs in 1842. A similar parasite had been found by Valentin in 1841 in the common trout (*Salmo fario*). Very little progress was made in the investigations of these organisms until 1878, when Lewis, in India, described a trypanosome in the blood of rats, which was named by S. Kent *Trypanosoma lewisi*. In 1880 Evans discovered a trypanosome in animals affected with surra—*Trypanosoma evansi* (Steel 1885). This was a most important discovery, as it showed that trypanosomes were capable of producing disease, while previously it had been believed that these parasites were harmless. In 1894 Bruce discovered the Nagana trypanosome, *Trypanosoma brucei* (Plimmer and Bradford, 1899), and experimentally proved that the organism was conveyed by a species of tsetse-fly (*Glossina morsitans*). Rouget in the same year observed a trypanosome in the blood of horses affected with dourine—*Trypanosoma equiperdum* (Doflein, 1901).

Elmassian in 1901 described a trypanosome observed by him in mal de caderas —*Trypanosoma equinum* (Voges, 1901). Theiler, in 1902, in South Africa found a trypanosome in the blood of cattle affected with a peculiar disease known locally as 'galziecté' The parasite was named by Bruce *Trypanosoma theileri*. Recently several other forms of trypanosomiasis have been described in the lower animals by Dutton and Todd, Cazalbou, Lingard, Ed. and Et. Sergent, Schilling, Martini, Ziemann, and others.

In the meanwhile, Colonel Sir W. B. Leishman, in the year 1900, discovered some peculiar bodies in the spleen of a soldier who had died of what was called 'dum-dum fever,' but did not publish an account of his discovery till 1903, in which year Donovan also found the same parasitic bodies in Madras. This parasite was first considered to be a piroplasma by Laveran and Mesnil, and called *Piroplasma donovani*; but Ross created a new genus for it, using the term *Leishmania*. Wright of Boston found similar bodies in Oriental sore, which he called *Helcosoma tropicum*. The knowledge of these bodies and the diseases they cause has been considerably extended by Christophers and by Martzinowsky and Bogroff, while a great advance was made by Rogers, who in 1904 showed that by artificial cultivation *Leishmania donovani* developed into flagellate organisms. The life-history of *L. donovani* outside the human body has partially been traced by Patton, of the Indian Medical Service, in the bed-bug. In 1904 Laveran and Cathoire discovered a Leishmania in films from the spleen of a child in Tunisia. In 1905, Pianese, in Italy, found a Leishmania in the spleen of children suffering from febrile splenic anaemia. Nicolle completed the study of the parasite, and called it *Leishmania infantum*. Gabbi, and later Cardamatis, Feletti, and others, have emphasized the frequency of this disease in the Mediterranean littoral and islands. Gabbi considers the disease to be identical with Indian kala-azar.

In 1903 peculiar parasitic bodies, certainly protozoa, were discovered in rabies by Negri of Pavia. Negri's important discovery has been confirmed by many authors, and in the tropics by Cornwall.

In this section may be described the discovery of the causes of disease due to spirochaetes, the nature and relationship of which are not yet clearly known. Obermeyer, as far back as 1873, described the spirochaete of relapsing fever, which was thought to be spread by the bed-bug. In 1904 Nabarro, Ross, and Milne, in Uganda, discovered a spirochaete in the blood of persons suffering from tick fever—i.e., a fever supposed to be due to the bite of *Ornithodoros moubata*—and independently in the same year Dutton and Todd, working in the Congo, described a spirochæte causing tick fever. This spirochaete has been proved by Breinl and Kinghorn to be distinct from the *Spiroschaudinnia recurrentis*, and in 1906 they gave it the name of *S. duttoni*, in honour of the late Dr. Dutton, of the Liverpool School, who had done so much for Tropical Medicine, and who himself had fallen a victim to this disease. Novy and Knapp had a little time previously assigned the name *Spirillum duttoni* to the same parasite. In 1914 Inada and Ido discovered a spirochæte in Weil's disease, which they called *S. icterohæmorragiæ*. In 1918 Noguchi cultivated from cases of yellow fever a spirochæte which he has named *Leptospira icteroides*. Other spirochætæ have recently been described, as will be mentioned later.

In 1905 Schaudinn discovered the presence of a spirochæte-like organism in syphilis, which he called *Spirochæta pallida*. Later he created for the organism a new genus—Treponema. In the same year Castellani demonstrated the presence of a spirochæte or treponema in yaws, and named it *Spirochæta pertenuis* (*Treponema pertenue*), and in 1906 described Bronchospirochætosis.

Reference must here be made to the discovery of a small protozoan parasite in sheep suffering from a disease called 'carceag' by Babès in Roumania in 1888. The name applied to this parasite—viz., hæmatococcus—could not be maintained, as it was already used in botany, hence the generic name of Babesia was given to the group by Starcovici in 1893. The term 'piroplasma,' which should be used, was introduced by Patton in 1895. It is, however, mostly due to the work of Smith and Kilborne on red-water in cattle that Piroplasma has become well known, together with the fact that it is spread by a tick. The parasite *Piroplasma canis*, discovered by Piana and Galli-Valerio in 1895, has been thoroughly described by Celli in 1900 and Nuttall in 1904, and the life history in the tick has been worked out by Christophers. At the present time, thanks to the researches of Koch, Theiler, França, and others, several species of Piroplasma especially affecting cattle are known.

As to whether a Piroplasma is the cause of the tick or spotted fever of the Rocky Mountains appears open to grave doubt, although it has been described by Wilson and Chowning in 1902, and supported by Westbrook and Cobb in the same year, and Anderson in 1903, because other observers have failed to find any such organism. There is, however, strong evidence in favour of a tick being the spreader of the disease.

Mycology. Pathogenic mycology takes its origin in 1677 with Hooke's description and illustration of fungi causing the blighted or yellow specks on the leaves of the damask rose, and by his illustration of the blue moulds. This pioneer work is continued by Malpighi (1686), Ray (1706), Plukenet (1720), Micheli (1729), and their discoveries were systematized and extended by Linnæus (1753), Persoon (1801), Fries (1821), Link (1824), and so on to the days of Saccardo, Vuillemin, and last, and by no means least, Pinoy; but more detailed information with regard to this history will be given later.

Special attention must be drawn to the discovery by Gruby, in 1844, that ringworm was due to a parasitic fungus, and to the extension of that discovery by Malmsten in 1845, and to the great list of investigators of this particular feature down to the classical work of Sabouraud.

This work by Gruby produced world-wide interest in parasitic mycology, and for a time it made great progress, but fell back into a second-rate place when bacteriology came forward, and is only now being rescued from this position thanks to the labours of Manson, Blanchard, Böllinger, Eyre, Carter, Vincent, Nocard, Pinoy, and Brumpt.

Bacteriology. From the most remote times the suspicion that the mysterious cause of contagious and epidemic diseases must be sought in living entities has flashed through the minds of many observers. Columella, a contemporary of Seneca, records the belief, apparently popular in his time, of the living nature of miasmata and contagion. The idea of a *contagium vivum* was not extinguished even in the darkness of the Middle Ages. Thus, for instance, in a book written in the twelfth century, and wrongly stated to be by St. Hildegard, the abbess of a convent, we find notices of minute animals which produce disease.

Fracastoro's sixteenth century work is considered above, while in 1641 Athanasius Kircher, a friar, stated that he had observed minute living organisms in the blood of a patient during an epidemic of plague. Linnaeus supported the theory that disease was due to minute forms of life by inserting papers on the subject in his 'Amœnitates Academicae.' But the first to promulgate scientifically a bacterial theory was Agostino Bassi, a country practitioner of the north of Italy in the early nineteenth century. At that time a peculiar disease was destroying the silkworms, bringing ruin to the country in which the silk industry was paramount. Bassi, by means of the microscope, discovered the germ which is the cause of the disease. The organism received later the name of *Botrytis bassiana*. From analogy, Bassi believed and stated that human diseases were also due to micro-organisms. Bassi's work was not appreciated by his contemporaries.

In 1849 Pollender, and in 1850 Davaine, noted the *Bacillus anthracis* in the blood of sheep suffering from anthrax, but it was not until Pasteur, in 1857, had shown that fermentation was due to a yeast and that butyric acid fermentation was due to a bacillus, that Davaine, in 1863, considered that the rodlets which he had seen in the sheep's blood were the cause of the disease.

In 1882 Koch discovered the tubercle bacillus, and from 1877 to 1911 he introduced and improved methods for the separation and pure culture of bacteria, and laid down the proofs required to demonstrate that a given bacterium is the cause of a disease; and acting on these lines, Hansen in 1879 discovered the so-called bacillus of leprosy, Eberth in 1880 that of typhoid fever, Nicolaire in 1884 that of tetanus, Koch in 1884 that of cholera, Bruce in 1886 that of Malta fever, Yersin and Kitasato in 1894 that of plague, Shiga in 1898 and Kruse in 1900 that of bacillary dysentery.

The discovery of the typhoid, paratyphoid, and allied organisms has been of importance in enabling the differentiation of fevers previously massed together into a chaotic group labelled 'malaria.'

Serums and Vaccines.—The discovery of the immune serums, and their application to the treatment of disease, marked a great step forward in the history of medical science.

Still more important are the labours of Roux, Haffkine, Wright, Strong, Lustig, Galeotti, and others, in perfecting and applying vaccines to the prevention as well as to the treatment of disease.

Those of greatest tropical importance are Haffkine's plague vaccine, the same worker's cholera vaccine, and Wright's monovalent typhoid vaccine and his pyogenic vaccines.

A further advance was the introduction of Castellani's multiple vaccines for the prevention and treatment of disease. For long it was thought that a vaccine must be monovalent, but Castellani's triple vaccine for typhoid and the paratyphoid fevers has now been used on a very large scale for the British and other armies with success, and the tetravaccine typhoid, para A, para B, cholera has been adopted by the Serbian Army since 1916. He has also prepared tetravaccines, which include undulant or Malta fever, and has prepared and advocated the use of penta- and hexa-valent vaccines.

Entomology. It is obvious from the preceding sections that insects play a great part in the spread of protozoal diseases, and the same holds good for worms and bacteria.

Filaria can be spread by Culex, Stegomyia, or Anopheles; malaria by several species of the Anophelinae; Piroplasma and spirochaetes by ticks; *Leishmania donovani* perhaps by bugs; *Leishmania infantum* probably by fleas; trypanosomes by tsetse-flies, and possibly by some kind of flies.

But apart from these diseases, of which we know the cause, there are two infections the unknown agent of which is carried by mosquitoes. Thus Finlay, in 1881, formulated definitely the hypothesis that yellow fever was spread by a mosquito, which in 1900 was proved by Reed, Carroll, Agramonte, and Lazear to be a fact, the mosquito being *Stegomyia fasciata*, now *Stegomyia calopus*.

With regard to dengue fever, Graham of Beirut, in 1903, thought that he had discovered a protozoon in the red corpuscles of persons suffering from this disease, and that this parasite underwent development in *Culex fatigans* (Wied). Doubt has been thrown upon Graham's parasite, but the idea that *Culex fatigans* (Wied) is responsible for the spread of dengue fever has been strongly supported by Ashburn and Craig in 1907.

Turning now to bacterial diseases, the work of the Indian Plague Committee, published in 1906-1908, proves that the rat-flea (*Xenopsylla cheopis*) is the main means of the spread of plague. With regard to typhoid, it was conclusively proved in the army concentration camps of the United States in the Spanish-American War of 1898 that flies were great spreaders of the disease, a fact already emphasized by Celli and others; and this has been further supported by the work of Firth and Horrocks (1902), Chantemesse, and numerous other observers. Dysentery may also be spread by flies.

A knowledge, therefore, of ticks, biting flies, and other insects is of the greatest importance to the doctor who is to practise in the tropics. We refer the reader interested in this subject to the classical work of Nuttall on insects as carriers of disease in the Johns Hopkins Hospital Reports, 1899.

The idea that the house-fly and its allies are capable of spreading disease originates from the time of Mercurialis, who in 1577 suggested that the virus of plague might be disseminated by this means. In 1666 Sydenham remarked that the presence of numerous flies in the summer indicated that there would be much sickness in the autumn, while in 1808 Crawford stated that he believed insects to be the carriers of infection. In 1853 Moore referred to flies as the possible carriers of cholera, typhoid, tuberculosis, anthrax, and leprosy. In 1869 Raimbert performed the first experiments, showing that anthrax could be disseminated by flies. Tizzoni and Cattani made observations on the spread of cholera by the same means, Grassi and later Stiles demonstrated the possibility of the carriage of parasitic worms, and one of us the transference of the *Treponema pertenue* by the same means. Gayon in 1903 indicated the possibility of the dissemination of fungi by flies.

Toxicology.—Micro-organisms are not the only causes of disease to be found in the tropics, for poisons from plants and animals are also of the greatest importance.

It has been shown that the most primitive peoples have definite knowledge of poisons, and it has already been mentioned how early the study of snake and other animal venoms began.

It will suffice here to indicate that the scientific study of snake-venom, begun by Prince Lucien Bonaparte in 1843, has been extended by Fayrer, Martin, Lamb, Calmette, Noguchi, and many others, and leave a fuller description of this and the history of other poisons to a later chapter.

Climatology.—Tropical medicine does not confine itself to diseases caused only by parasites and poisons, for there are such conditions as heat-stroke, which are entirely due to physical causes, and also there is the important question of the influence of tropical climates on man, which must be dealt with in a later chapter.

Dietetics.—But little work has so far been done with regard to this important subject in the tropics, though pioneer struggles have been undertaken most successfully by McCay in India, and his example deserves to be followed.

Clinical Medicine.—Clinical researches into the diseases affecting Europeans and natives in the tropics began with the earliest modern travellers, non-medical as well as medical, and the earliest references to tropical diseases are to be found in these early works on travel. Thus, as Singer has pointed out, De Oviedo in 1526 gives a reference to a disease bubas, which we now know to include *Frambœsia tropica*, a form of Leishmaniasis, and probably a form of Blastomycosis. In 1558 Thevet described the jigger as a little worm called '*Tom*,' which entered into the feet, and wrote descriptions of *Frambœsia tropica* under the term 'Pians.' In 1598 G. W. wrote an account of Calenture (heat-stroke), and Tabardillo, which is derived from the Spanish word *Tabardo*, a cloak, and was applied to the typhus fever epidemic in Spain in 1557; and therefore G. W. may have meant typhus by this term, though it is possible that he also included yellow fever under the same name. He also describes

Espinlas, possibly due to the bite or sting of some venomous animal; Cameras de Sangre, or dysentery; erysipelas, which probably included filariasis: and Tiñoso, or scurvy. In 1642 Bontius wrote his work, 'De Medicina Indorum.' Chalmers and Archibald have drawn attention to the description of dracontiasis, dermatophiliasis, epidemic gangrenous rectitis in South America; simple continued fever, malarial fevers, dysenteries, smallpox, climatic bubo in India; malaria, endemic yellow fever, dengue, smallpox, filariasis, diarrhœas, dysentery, and yaws in West Africa, as indicated by D. L. F. in 1726 and by Aubrey in 1729; but these and many others are briefly mentioned at the end of this chapter under the heading 'Special Works on Tropical Medicine,' and need not be further described here.

It is not possible for us to trace out in detail the history of treatment, but we may briefly mention a few points with regard to quinine, arsenic, antimony, thymol, and emetine.

Treatment--*Quinine*.- In the seventeenth century the epoch-making discovery of the value of cinchona-bark in the treatment of malarial fevers took place.

In 1638 the Countess of Chinchon, wife of the fourth Count, Viceroy of Peru, after nine years' residence in that country, was seized with tertian malarial fever. Don Lopez de Canizaries, the Corregidor of Loxa, hearing of this, sent her a parcel of the bark of a tree called by the Indians of Loxa 'quina-quina.' The duplication of the name of the tree is said to indicate that it has medical properties.

The value of this bark in the treatment of fever appears to have been only known locally, but was understood by the Spaniards in Loxa as far back as 1600. How the Indians became acquainted with the bark is not known, and the tales of the curing of their fevers by drinking the water of a lake into which a cinchona-tree had fallen, or of a sick puma chewing the bark, are considered to be myths invented later in Europe.

Dr. Don Juan de Vega administered the bark to the Countess, who quickly recovered, and four years later returned to Europe with a large supply of it, which she distributed to persons suffering from fever on her estates near Madrid. Hence the bark was often known as *Pulvis comitissæ*. In 1670 Jesuit missionaries sent some of the bark to Rome, whence it was distributed throughout Europe by Cardinal de Lugo. Hence the names 'Jesuit's' or 'Cardinal's' bark.

Linnæus named the tree after the Countess, but spelt her name wrongly, calling it *Cinchona officinalis*. A curious strife now rose in Europe as to whether fever should be treated by bark or not, but the labours of Morton and Sydenham, together with the dramatic cure of the Grand Dauphin, enabled its true value to be known. The tree has since that time been introduced into several parts of the world, and grows well in India, Ceylon, and Java.

Finally in 1820 Pelletier and Caventou prepared the alkaloid quinine from cinchona-bark. For further particulars see Chapter XL. on Malaria.

Arsenic and Antimony.—Thanks to Morgan's work it is possible to give a brief history of these two metalloids, which belong to the nitrogen group of the fifth vertical series of the periodic classification, and are related to the non-metals phosphorus and nitrogen and to the metal bismuth.

Arsenic occurs in nature in combination with cobalt, as smaltite and cobaltite, both of which are included under the term *cobalt*, which was found by a German artist to be capable of making *sympathetic ink* when acted upon by aqua fortis, the action of which was studied in 1737 by Hellot and in 1760 by Cadet de Gassicourt, who produced a highly inflammable stinking fluid therefrom, and this Thenard concluded was a *complex acetate containing arsenic*.

During the years 1837-1843 Bunsen isolated this complex, to which Berzelius gave the name *cacodyl*, and in 1858 Baeyer, having first made *primary methyl arsenicals*, produced methylarsenic acid, the soluble salts of which are employed medicinally as new cacodyl and arrhenal. In 1860-1863 Béchamp made the *first aromatic arsenical*, and in the seventies Michaelis, in collaboration with other workers, not merely extended this knowledge, but prepared the *first aromatic antimony compounds*. In 1902 Béchamp's compound was first tried in medicine by Thomas and Breinl for sleeping sickness, being called *atoxyl* because of its comparatively non-toxic action, and it is the drug which has been used with such success in sleeping sickness in the Sudan. Atoxyl was shown in 1907 by Ehrlich and Bertheim to be the sodium salt of *p*-arsenilic acid, being a derivative of quinquevalent arsenic.

Atoxyl,  $NH_2C_6H_4AsO\begin{matrix}ONa\\OH\end{matrix}$ contains from 25·05 to 20·78 per cent of arsenic according to the amount of water of crystallization. Mono-acetylated atoxyl is  $CH_3CONHC_6H_4AsO\begin{matrix}ONa\\OH\end{matrix}$.

According to Mesnil and Nicolle's experiments, and the observations of Nierenstein, it is not the arsenic in these compounds which is to be looked upon as the effective agent, but the amido group, which may possibly be the effective agent in trypan red, afridol blue, afridol violet, and parafuchsin, which do not contain arsenic but possess amido-groups, and affect trypanosomes in a similar manner to atoxyl. According to Ehrlich, Levaditi, and Yamanouchi, atoxyl undergoes a reduction in the animal tissues. Ehrlich has prepared two derivatives of atoxyl, one of which, already mentioned (arsenophenylglycin), is very effective in mice on atoxyl-resistant trypanosomes. Levaditi and Yamanouchi have also prepared an active derivative of atoxyl, which they call trypanotoxyl. Nierenstein thinks that atoxyl is oxydized in the tissues, and it is only in the nascent state that it becomes efficacious.

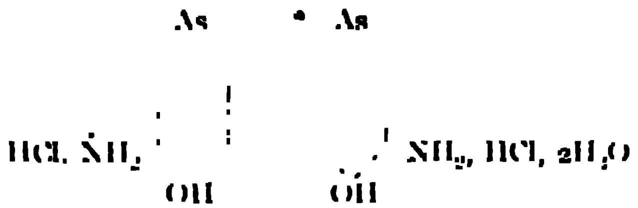
Owing to the fact that large doses of atoxyl lead to such unpleasant results as optic atrophy, gastro-intestinal inflammation, and peripheral neuritis, other arsenical preparations have been recommended; and the firm Burroughs and Wellcome has introduced, under the trade name of *soamin*, a preparation somewhat similar to atoxyl, but said to be less poisonous. It is given in the same doses as atoxyl, but the therapeutic results do not appear to have been very successful. *Soamin*, according to the published formula, is $C_6H_4NH_2AsO(OH)(ONa)5H_2O$.

Atoxylate of mercury was introduced by Uhlenhuth, but is less satisfactory than atoxyl.

Combinations of Mesnil's afridol and atoxyl, Ehrlich's parafuchsin and atoxyl, picric acid, safranin, trypaflavin, and other dyes and atoxyl, have been suggested in the treatment of trypanosomiasis, but in man the results have not been so successful as in the lower animals.

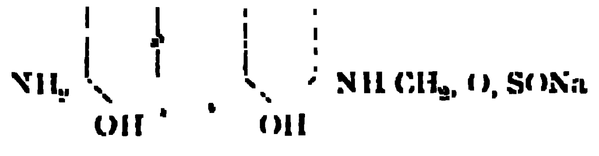
Mercury was first introduced in 1902 for the treatment of sleeping sickness by Low and Castellani, using intravenous injection of Baccelli's sublimate solution (hydrargyri perchloridi, 0·10 gramme; sodii chloridi, 0·50 gramme, aquæ destillatæ, 100·00 c.c.; 1 to 4 c.c. per intravenous injection), in association with arsenic and quinine by the mouth. A fall of the temperature was observed in some cases, but the fatal course of the disease was not influenced. Moore, Nierenstein, and Todd have used mercury and atoxyl in combination or alternation, with the idea that mercury might act upon the latent form of the trypanosome, while atoxyl would influence the active form. In man this combined treatment has apparently not given any better results than atoxyl alone. This combined treatment, consisting of atoxyl and an inorganic salt of arsenic such as orpiment has been recommended by Laveran and Thiroux and has already been used in man with good results. The orpiment should be given in pills, in the dose of 2 grains of orpiment two or three times daily. The administration of orpiment frequently causes diarrhœa. Thiroux therefore incorporates in the orpiment pills some opium.

Ehrlich observed that the aromatic compounds of tervalent arsenic were more efficacious in attempts to kill protozoan parasites, and after 605 attempts in 1909 he evolved *Salvarsan, or 606, also known as Kharsivan and Arsenobillon*, which is a pale yellow powder soluble in dilute hydrochloric acid or aqueous sodium hydroxide or carbonate. Its formula is the hydrochloride of 3 : 3'-diamino-4 : 4'-dihydroxy-arseno-benzene-*i.e.*:—



On account of its phenolic and feebly basic properties Salvarsan fails to give neutral salts, and the free base is very insoluble in water or in normal saline solution; therefore an approximately neutral solution has to be prepared immediately before use, which is inconvenient, and led to the search for a compound with soluble salts giving a neutral reaction in solution. Such a preparation had been foreshadowed by Ehrlich's 418 Spirarsyl, or the sodium salt of arsenophenylglycine, which was the most successful of the arsenic compounds prior to Salvarsan.

It was found that Salvarsan dihydrochloride could be made to produce a compound called Ehrlich's 914, or Neosalvarsan, also called Neokharsivan, Novarsenobillon, Novarsenobenzol, or Sodium 3 : 3'-diamino-4 : 4'-dihydroxy-arsenobenzene-N-methylene sulphurate:—



This is a pale yellow powder, with (commercially) generally small proportions of inorganic salts. It is soluble in water and the solution is quite neutral, but its arsenical content is lower than that of Salvarsan, and hence its average dose is larger, and the efficacy of the preparation should be tested by intravenous injections into rabbits.

Galyl, discovered by Mouneyrat, is 4 : 4'-dihydroxyarsenobenzene-3 : 3'-phosphamic acid, and forms a neutral solution when added to aqueous sodium carbonate, and is useful in syphilis and also kills spirochætes and trypanosomes. It is very slightly toxic. Ludyl is a complex disulphonamide discovered as

1,151 of Mouneyrat's series, and like galyl is given intravenously and for the same conditions.

We have already referred to *Spirarsyl*, and we may mention that *Arsenophenylmethylglycine* has been used experimentally by Oechslin to kill *Trypanosoma evansi* and *T. rhodesiense* in experimental animals.

In 1913 Ehrlich found that Salvarsan and other derivatives of arsenobenzene could join with salts of copper, silver, gold, and platinum, forming combinations which could be administered intravenously and in which the heavy metal appeared to aid the arsenic in its germicidal action. Luargol is an example of this type of chemical body

Further new types of compounds of organic arsenicals with antimony, selenium, etc., are being tried. Especial attention is said by Morgan to be directed at the moment to certain partly methylated hexaminoarsenobenzenes, which give stable solutions with soluble bicarbonates, and so the final word has yet to be said with regard to these compounds, which the chemist is preparing for trial by the physician.

With regard to the organic antimony derivatives, the salts of antimonyl tartaric acid, in the form of lithium antimonyl tartrate, were first used in the experimental trypanosomiasis of mice by Plimmer and Thomson in June, 1907. Their results were confirmed by Mesnil and Brimont in January, 1908, while in March, 1908, Manson used it on man, giving it by the mouth. Also in 1908 Boosten and Rodhain used tartar emetic in human trypanosomiasis.

In 1913, Tsuzuki introduced potassium ammonium antimonyl tartrate, as *antiluetin*, and in the same year Vianna and Machado gave tartar emetic intravenously in cases of espundia, with good results, which have been confirmed by Terra da Silva, Carini Carwalho and Christopherson, and by Low. For the same complaint Ludeberg tried trioxide of antimony intramuscularly, and Martindale prepared an *injectio antimonii oxidi*, which Morgan considers to contain, probably, a glyceryl antimonite, and this has been reported in 1917 as curative of American Leishmaniasis when used subcutaneously, intramuscularly, and intravenously.

Also in 1913 Vianna and Aragão reported that tartar emetic was useful in the treatment of ulcerating granuloma.

In 1914 Castellani used tartar emetic, together with other drugs, in a case of Indian kala-azar, with satisfactory results, and came to the conclusion that the drug was the cause of the striking result, and therefore he recommended it for routine treatment. In the previous year he had originated his yaws mixture (now generally called Castellani's mixture), which contains tartar emetic, potassium iodide, and both carbonate and salicylate of soda.

In 1915 Di Cristina and Caronia reported the cure of eight cases of infantile Leishmaniasis by antimony therapy, and later Rogers confirmed and extended this use of tartrate of antimony in kala-azar, a line of treatment well accepted at the present time.

Emetine.—For many years it was known that ipecacuanha and emetine were valuable in the treatment of certain cases of dysentery, and this was crystallized down to the treatment of amœbic dysentery, and more especially to the presuppurative stage of amœbic hepatitis by Rogers from 1909 onwards. Later Vedder in the Philippine Islands studied its action on entamœbæ, and Rogers devised the clinical application of the drug by subcutaneous injection, which to-day is used as the correct treatment of that form of dysentery and its complications.

Thymol.—Bozzolo, in 1880, was the first to introduce this drug for the treatment of ankylostomiasis. He obtained satisfactory results which have been confirmed all over the world.

Prophylaxis.—The knowledge of the causal agent and its method of dissemination have enabled reasoned and scientific methods of prophylaxis to be devised and carried out, of which perhaps the most striking is that performed in Panama by Gorgas.

It is to be hoped that in years to come these methods will be extended, and that many diseases at present hampering civilization will cease to be terrors; indeed, the present war has amply proved the wisdom of prophylactic and sanitary measures, especially the polyvalent prophylactic treatment against the enteric fevers, cholera, and other diseases, and it is to be hoped that now the war is over international action will be taken all over the world to combat disease

Research. Notwithstanding the fact that so much has been done to elucidate disease, still there is a great field for research, and one of the direct blessings of the recent war will be the stirring up of Governments to provide funds for this work, which should never be left, as it used to be, entirely, or almost entirely, to individual generosity.

The State and Tropical Medicine. Tropical medicine has been fortunate in that at the commencement of modern tropical medicine there was at the head of the British Colonial Office a far-seeing and exceedingly wise statesman Mr. Joseph Chamberlain - who clearly realized the duties of the State in regard to the formation of Schools of Tropical Medicine in London and Liverpool, and of the foundation of laboratories in British Colonies. This policy, continued and extended under the auspices of the Advisory Committee of the Tropical Diseases Research Fund, has produced the *Tropical Diseases Bulletin* and other publications of great value.

The example set by the British Government has been followed by those of other countries, and to-day all over the world the State supports tropical medicine.

In many tropical countries, however, it appears to us that the State should exercise more authority over the medical practitioner, native or modern trained; that registers of such practitioners should be kept, and that this should not be confined to medical practice only, but also to dental and veterinary work.

The War and Tropical Medicine.—The recent war has disseminated tropical diseases in such a manner that many of them may become cosmopolitan. The Anophelines of England have now a chance to become infected with malaria, and, in fact, cases of endemic malaria have already occurred, but we doubt whether there is any real danger of an epidemic. Bilharziosis has the opportunity to spread from Egypt to other countries. Are sufficiently strong measures being taken to combat the spread of these diseases and many others like them, *e.g.*, amœbic dysentery?

Another point which the war has brought into prominent notice is that so-called tropical diseases exist in abundance in Europe—*e.g.*, in the Balkans and that agents like lice are as prone to spread disease in the Temperate as in the Tropical Zone.

Certainly the massed formations of medical knowledge at work in the recent war at the study, treatment, and prevention of disease will produce results which would have been but slowly evolved in years of peace.

It is not possible to close this history without acknowledging the debt which tropical medicine owes to the officers of the Royal Army Medical Corps, of the Royal Navy, the Indian Medical Service, the Colonial Service, and to their training schools, as well as to the officers of the Medical Services of the armies and navies of France, Italy, and the United States of America.

MODERN JOURNALS.

The very excellent *Tropical Diseases Bulletin* enables the tropical practitioner to keep himself abreast of the day as regards current events in tropical medicine while the *Tropical Veterinary Bulletin* permits him, if he so desires, to obtain the same up to date information with regard to the diseases of animals. Both these publications are issued by the Tropical Diseases Bureau, the Imperial Institute, London, S.W. 7.

If he desires more information with regard to bacteriological work he may find this and much more in the *Bulletin de l'Institut Pasteur* which is issued by that Institute in Paris.

If he wishes more detail with regard to Japanese medical work, he will find a review in English, written by the Research Staff of the Severance Union Medical College, Seoul, Korea, published in *The China Medical Journal*. The names of some of the Japanese medical journals are as follows:—

Chugai Iji Shimpo, or Home and Foreign Medical News, *Juzenkai Zasshi* or Journal of the Perfection Medical Society Alumni of Kanazawa Medical School; *Nisshin Chiryo* or Modern Therapeutics, *Taiwan Igakukai Zasshi*, or Journal of the Formosa Medical Society, *Tokyo Iji Shinshi*, or Tokyo Medical News, *Tokyo Igakukai Zasshi* or the Proceedings of the Medical Society of Tokyo; also *Acta Scholae Medicinalis Universitatis Imperialis* in Kioto, *Japanische Zeitschrift für Dermatologie und Urologie*, *Kyoto Igakukai Zasshi*, *Mitteilungen aus der Medizinischen Fakultät der Kaiserlichen Universität zu Tokyo*, *Sei-i-kwai* (*Medical Journal*) of Tokio, *Tokyoer Medizinische Wochenschrift*, *Mitteilungen aus der Medizinischen Fachschule zu Keijo*.

If resumes of German literature are desired, they can be found in the *Archiv für Schiffs- und Tropenhygiene* and in the *Archiv für Bakteriologie*.

Apart from these the following journals usually contain original papers dealing with tropical medicine:—

1. Annali di Medicina Navale e Coloniale (Rome).
2. Annales d'Hygiène et de Médecine Coloniales (Paris).
3. Annales de l'Institut Pasteur (Paris).
4. Annali d'Igiene (Turin).
5. Anales del Instituto Médico Nacional (Mexico).
6. Annales Paulistas de Medicina e Cirurgia (San Paulo).
7. Annals of Tropical Medicine and Parasitology (Liverpool).

8. Annual Reports of the Principal Medical Officers of British, French, Italian, and Dutch Colonies.
9. Archives de Médecine et Pharmacie Navales (Paris).
10. Archives de Parasitologie (Paris).
11. Archiv für Protistenkunde (Jena).
12. Archiv für Schiffs- und Tropen-Hygiene, and separately 'die Beihefte' (Leipzig).
13. Arquivos de Hygiene e Pathologia Exoticas (Lisbon).
14. Archivos do Instituto Bacteriologica Camara Pestana (Lisbon).
15. Archives de Médecine (Athens).
16. Archivos Brasileiros de Medicina (Rio di Janeiro)
17. Archives de l'Institut Pasteur de Tunis (Tunis).
18. Atti della Società per gli Studi della Malaria (Rome).
19. Australian Institute of Tropical Medicine, Collected Papers (Townsville).
20. Boletin del Instituto Nacional de Higiene de Alfonso XIII. (Madrid).
21 Boletin de la Association Médica de Puerto Rico (San Juan)
22. Brazil Medico (Rio di Janeiro)
23. British Guiana Medical Annual (Demerara).
24. Bulletin de l'Office International d'Hygiène (Paris)
25. Bulletin de la Société de Pathologie Exotique (Paris).
26 Bulletin de l'Académie Royale de Médecine de Belgique (Brussels)
27 Bulletin de la Société Portugaise des Sciences Naturelles (Lisbon).
28 Bulletin de la Société Medico-Chirurgicale de l'Indochine (Hanoi and Haiphong).
29 Bulletin de la Société Médicale de l'Ile Maurice (Mauritius)
30 Bulletin of Entomological Research (London).
31. Bulletin de l'Institut Pasteur d'Algérie (Algiers).
32. China Medical Journal (Shanghai).
33 Cronica Medica (Lima)
34 Cronica Medica Mexicana (Mexico).
35. Commonwealth of Australia. Quarantine Service Publications (Melbourne)
36. Folia Microbiologica (Delft).
37. Gaceta Medica de Caracas (Caracas).
38. Geneeskundig Tijdschrift voor Nederlandsch Indie, Rijswijk (Batavia).
39 Grèce Médicale (Athens)
40. Illinois Biological Monographs (Urbana).
41. Index Medicus (Washington)
42. Indian Journal of Medical Research (Calcutta).
43 Indian Medical Gazette (Calcutta)
44 Interstate Medical Journal (St. Louis)
45. Journal of the Ceylon Branch of the British Medical Association (Colombo).
46 Journal of Comparative Pathology and Therapeutics (Edinburgh;
47 Journal of Hygiene (Cambridge)
48. Journal of Pathology and Bacteriology (Cambridge)
49. Journal of the Royal Army Medical Corps (London).
50. Journal of Tropical Medicine and Hygiene (London)
51. Journal of Parasitology (Urbana).
52. Kitasato Archives of Experimental Medicine (Tokio)
53. Lister Institute, Collected Papers (London)
54 Malaria e Malattie dei Paesi Caldi (Rome)
55. Malay Medical Journal.
56. Malariologia (Naples).
57. Medicina Contemporanea (Lisbon).
58. Mededeelingen van den Burgerlijken Geneeskundigen Dienst in Nederlandsch-Indie (Batavia)
59. Medical Journal of South Africa (Johannesburg).
60 Memorias do Instituto Oswaldo Cruz (Rio di Janeiro).
61 Monthly Health Reports of the Department of Health of the Panama Canal (Washington).
62. Pacific Medical Journal.

63. Panama Canal Record (Balboa Heights Canal Zone).
64. Parasitology (Cambridge).
65. Philippine Journal of Science, Section B. Philippine Journal of Tropical Medicine (Manila).
66. Proceedings of the Canal Zone Medical Association (Mount Hope, Canal Zone).
67. Proceedings of the Society for Experimental Biology and Medicine (New York).
68. Records of the Egyptian Government School of Medicine (Cairo).
69. Review of Applied Entomology, Series B, Medical and Veterinary (London).
70. Revue de Médecine et d'Hygiène Tropicales (Paris).
71. Revista Medica de Yucatan (Yucatan).
72. Repertorio de Medicina y Cirugia (Bogotá).
73. Revista Clinica (Colombia).
74. Revista Medica de San Paulo (San Paulo)
75 Revue Médicale d'Alger.
76. Riforma Medica (Naples).
77 Sanidad y Beneficencia, Bolito de l'Secretaria (Havana)
78 Southern Medical Journal (Nashville, Tennessee)
79 South-Western Medicine El Paso (Texas).
80. Sperimentale (Florence)
81. Studies from the Institute for Medical Research (Federated Malay States).
82. Transactions of the Society of Tropical Medicine and Hygiene (London).
83. Texas State Journal of Medicine (Fort Worth).
84. Veeartsenijkundige Bladen voor Nederlandsch Indie (Batavia).
85 Zeitschrift fur Chemotherapie (Leipzig)
86 Zeitschrift fur Hygiene und Infektionskrankheiten (Leipzig).
87. Zeitschrift fur Immunitätsforschung und Experimentell Therapie (Jena).

The following journals have, from t [illegible] time, valuable papers on Tropical Medicine and Parasitology:—

1 Arbeiten aus dem Kaiserlichen Gesundheitsamte (Berlin).
2. Archives of International Medicine (Chicago).
3. British Medical Journal.
4. Boston Medical and Surgical Journal (Boston).
5. Bulletins and Reports of the United States Departments concerned with:— (*a*) Animal Industry; (*b*) Hygienic Laboratory, (*c*) Public, Health (Bulletins and Reports separately), (*d*) Naval Medical; (*e*) War Department (Washington).
6. Canadian Medical Association Journal (Toronto)
7. Collected Studies from the Research Laboratory, Department of Health (City of New York).
8. Comptes Rendus de la Société de Biologie (Paris).
9. Deutsche Medizinische Wochenschrift (Berlin).
10. Johns Hopkins Bulletin.
11. Journal of the American Medical Association (Chicago).
12. Journal of Experimental Medicine (New York).
13. Journal of Infectious Diseases (Chicago).
14. Journal of Laboratory and Clinical Medicine (St. Louis).
15. Journal of Immunology.
16. Journal of Medical Research (Boston).
17. Journal of the Royal Naval Medical Service (London).
18. Lancet (London).
19. Medical Journal of Australia (Sydney).
20 Münchener Medizinische Wochenschrift (Munich).
21. New Zealand Medical Journal (Wellington).
22. Policlinico (Rome)
23. Presse Médicale (Paris).
24. Proceedings, Series B, and Transactions of the Royal Society of London.
25. Quarterly Journal of Microscopical Science (London).
26. South African Medical Record (Cape Town).

JOURNALS WHICH HAVE CEASED PUBLICATION.

Since the appearance of the second edition of this book the following journals have either ceased to be published as separate entities or have stopped publication altogether:--

1. *American Journal of Tropical Diseases and Preventive Medicine.* This is now included in the New Orleans Medical and Surgical Journal. Three volumes were issued 1913-1916.
2. *Journal of the London School of Tropical Medicine.* Two volumes were issued 1911-1913.
3. *Journal of Tropical Veterinary Science, Calcutta.* Seven volumes appeared 1906-1912.
4. *Paludism, Simla.* There are five numbers only, 1910-1912.
5. *Scientific Memoirs by Officers of the Medical and Sanitary Departments of the Government of India.* New Series, Calcutta. These are exceedingly valuable publications, and numbered some sixty volumes from 1902-1913. Their place and that of *Paludism* is taken by the *Indian Journal of Medical Research.*
6. *Yellow Fever Bureau Bulletin, Liverpool.* There are three interesting volumes in existence which appeared from 1911 to 1915. Its work is carried on by the *Annals of Tropical Medicine and Parasitology.*

No *Reports of the Wellcome Tropical Research Laboratories, Khartoum,* have appeared since 1911. In the meanwhile much of the original work performed during the last five years has been published in medical, chemical, and entomological journals. Up to date four reports and two reviews of tropical literature have appeared between 1904 and 1911.

SPECIAL WORKS ON TROPICAL MEDICINE.

(*In Chronological Sequence.*)

De Oviedo, F. (1526). Hystoria Natural de las Indias (Toledo). (1547). Coronica de las Indias (Madrid). (Accounts of Yaws and Jiggers.)

Thevet, F. A. (1558). Les Singularitez de la France Antartique autrement nommée Amerique. (Jiggers, Yaws, and Native Practice.)

Da Orta, G. (1563). Coloquios dos Simples e Drogas da India. (This book is the first European work published in India, and contains descriptions of many Indian plants and their application to the treatment of Cholera, Dysentery, etc.) Garcia de Orta was physician to Dom Marten da Sousa, Governor of Goa, with whom he travelled in India and Ceylon in 1534. Antwerp, 1567, translation by Clusius into Latin. The English translation (1913).

W., G. (1598). The Cures of the Diseased in Remote Regions (London) Heat Stroke, Typhus, Yellow Fever (?), Erysipelas (Filariasis?), Espindas Dysentery, and Scurvy. (1916) Reprinted at Oxford.

Bontius, J. (1642). De Medicina Indorum (Lugduni, Batavia). (Remarks on drugs, preservation of health, treatment, and morbid anatomy.)

Alpinus, P. (1645) De Medicina Ægyptiorum (Parisiis). (The first book contains articles on the state of Egyptian medicine, on diseases endemic and epidemic, including plague; the second on blood-letting; the third on scarification, extraction of stone from the bladder, baths, and friction; the fourth on medicines.)

Pison, G. (1648). Historia Medica Brasiliæ (Lugduni, Batavia). (This work is divided into two parts, of which the first treats of Brazilian climatology; the second, of Brazilian diseases—*e.g.*, catarrhs, diseases of the eyes, spasm, stupor of the members, obstructions of the viscera, hydropsy, fluxes, tenesmus, colic, dysentery, liver troubles, worms, syphilis, ulcers, etc.)

PISON (GULIELMUS) ET GEORGIO MARCGRAVO DE LIEBSTAT (1648). Historia Naturalis Brasiliæ

PISON, G. (1658). De Indiæ Utriusque de Natura et Medica (Amsterdam).

CLEYER, A. D. C. (1682). Opuscula Medica ad Mentem Sinensium (Francofurti).

SLOANE (1707-1725). A Voyage to the Islands of Madeira, Barbadoes, and Jamaica, to which is prefixed an Introduction wherein is an Account of the Inhabitants, Air, Water, Diseases, Trade, etc., of that place.

KAEMPFER, E. (1712). Amœnitatum Exoticarum Politico-Physico-Medicarum Lemgoviæ. (This well-illustrated book, dealing with Persia, India, and Japan, is composed of five fascicles, of which the first is political; the second antiquarian, the third physico-medico containing descriptions of the Torpedo, *Dracunculus persarum*, Asafœtida, Hydrocele, Hypersarcosis ulcerosa pedum malabaricæ genti vernacula—i.e. Madura-foot, acupuncture, cauterization; the fourth and fifth are botanical.)

F. D. L. (1720). Traité des Maladies Particulières aux Pays Orientaux (Paris). (Bound with Luillier's Voyages; contains descriptions of Sea-Sickness, Scurvy, Colic, Venereal Disease, Fever, Guinea Worms, Jiggers, Serpent Bite, Smallpox, etc.)

AUBREY, T. (1729). The Sea Surgeon, or the Guinea Man's Vade-Mecum (London). (Contains accounts of Fevers, Erysipelas, Diarrhœa, Cholicks, Yaws, Negroes and their Food, etc., as seen on the Coast of Guinea.)

ATKINS, J. (1734). The Navy Surgeon (London). (Contains an appendix on 'The Sleepy Distemper in the Negro.')

ATKINS, J. (1737). A Voyage to Guinea, Brazil, West Indies. 2nd edition 1810.

PERRY, C. (1743). View of the Levant, particularly Constantinople, Syria, Egypt, and Greece in four parts, containing information with regard to Medicine and Surgery in the East.)

BROCKLESBY, R. (1764). Observations on Camp Diseases, with an Appendix on the Climate and Diseases in Africa (London).

LIND, JAMES (1768). Essays on Diseases incidental to Europeans in Hot Climates (London). (Other editions 1771, 1777, 1788, 1808, 1811. Translated into German 1773. Also edition 1792.)

HILLARY (1752). Observations on the Changes of Air, etc., in the Island of Barbadoes (London). 1766.

HISTORY OF TROPICAL MEDICINE.

The most excellent book is Garrison (1918), 'History of Medicine,' 2nd edition, Philadelphia, and the important periodicals are 'Annals of Medical History,' commenced in 1917, and published in New York; and the 'Archiv für Geschichte der Medizin,' started in Leipzig in 1908, and Janus, as well as the Transactions of the 'Medical Historical Section' of the Royal Society of Medicine.

Neuberger (1910), 'History of Medicine,' vol. i., English translation by Playfair, gives good accounts of Byzantine and Arabic medicine; and Elliott (1914), 'Outlines of Greek and Roman Medicine,' London, is most interesting.

Anderson (1908). Third Report. Wellcome Tropical Research Laboratories, 310; (1911) Fourth Report same Laboratories, 248 (London). These are most valuable observations upon Primitive Medicine in the Anglo-Egyptian Sudan.

Berdoe (1913). The Origin and Growth of the Healing Art (London). (Contains articles on the Medicine of Primitive Man of Egypt, Judea, Chaldea India, Persia, Mexico and Peru.)

Castellani (1916). British Medical Journal, ii., October 21 (London). (Tartar Emetic and Protozoal Diseases.)

Chalmers and Archibald (1913). Two early eighteenth century treatises on Tropical Medicine, Royal Society of Medicine. (Contains Dracontiasis, Dermatophiliasis, Epidemic Gangrenous Rectitis, Malarial Fevers, Cholera, Dysenteries, Smallpox, Climatic Bubo (?), Endemic Yellow Fever in West Africa, Filariasis, Diarrhoea, Yaws.)

Chalmers and Maloof (1918). A Sudanese Arabic Medical Manuscript, Royal Society of Medicine. (Gives an account of the method of treatment of disease in the Anglo-Egyptian Sudan some 200 years ago.)

Charaka. English translation (Calcutta).

Chemin (1913). Archives de Médecine et Pharmacie Navale, January February, etc. (Paris). (Remarks upon the History of Japanese Medicine.)

Dabry (1863). La Médecine chez les Chinois (Paris).

Dorothea Singer (1916). Transactions Royal Society of Medicine (London). (Plague Tracts.)

Gimlette (1915). Malay Poisons and Charms (London).

Hessinger (1840). Geschichte der Indischen Medicin, Sach's Medicin.

Jee (1896). A Short History of Aryan Medical Science (London).

Keegli (1887). Superstition in Native Medicine (Ceylon Medical Journal).

Lepage, F. A. (1813). Récherches historiques sur la Médecine des Chinois. Thèse (Paris).

Low (1916). Transactions of the Society of Tropical Medicine and Hygiene, vol. x., pp. 37-42 (London). (History of Tartar Emetic.)

Macdonald (1879). Historical Sketch of Medicine (Edinburgh). (Contains a translation of some palm-leaf manuscripts, without date, by Burmese physicians.)

Morgan (1918). Organic Compounds of Arsenic and Antimony (London).

Oribasius (1557). Opera Basileae.

Rho, F. (1909). Dal Vecchio al Nuovo in Patologia Esotica (Roma).

Roth, W. E. (1897). Ethnological Studies among the North-West Central Aborigines (Brisbane). (Contains a chapter on Disease, Accident, and Death.)

Ross (1910). Catalogue of the Arabic and Persian Manuscripts in the Oriental Public Library at Bankipore. (Vol. iv. contains the Arabic medical works, and is very interesting and useful to us.) (Calcutta.)

Rush (1818). Medical Inquiries and Observations. (The first volume contains an account of medicine amongst the North American Indians.)

Seligmann, C. G. (1902). Journal of the Anthropological Institute (London). (The Medicine, Surgery, and Midwifery of the Sinangolo, an inland tribe inhabiting the Rigo District of British New Guinea.)

Singer (1912). Annals of Tropical Medicine and Parasitology, vi. 8; 379 (Liverpool). With D. Singer (1917). Annals of Medical History, I., i. 1, New York. (Facastoro and Infection.)

Suśruta. English translation (Calcutta), also a Latin translation about 1837 in Berlin.

Wijesinghe (1889). Mahawansa, pp. 44, 125, 156 (notes), 158.

Wise, T. S. (1867). Review of the History of Medicine (London). (Deals with medicine among the Hindus and Chinese.)

Whitney (1885). History of Medical Progress in Japan. Transactions of the Asiatic Society of Japan (Yokohama).

CHAPTER II

TROPICAL RACES

The Tropics—Tropical Races—Primitive man—Classification—Caucasic division—Ethiopic division—Mongolic division—Amerind division—References.

THE TROPICS.

SUPAN suggested that climates should be classified as follows:—

1. *Tropical or warm climates*, extending from the Equator to the mean annual isotherm of 20° C. or 68° F.

2. *Temperate climates*, extending from lands possessing a mean annual isotherm of 20° C. or 68° F. to those which have a temperature of 50° F. for the warmest months of the year.

3. *Cold climates*, lying polewards of the isotherm of 50° F. for the warmest months of the year.

In Fig. 1 we have depicted the tropical or warm climates as delineated by Supan's lines marked B B., indicating the mean annual isotherm of 20° C. or 68° F. in north and south latitudes. Both lines are very wavy, the northern being situate about 35 degrees north latitude, and the southern at rather less than 30 degrees south latitude. This region Supan has divided into two zones, the *Tropical Zone* and the *Subtropical Zone*, by lines indicated on Fig. 1 as A.A., which represent isotherms of 20° C. or 68° F. for the coldest months of the year in both northern and southern latitudes.

These lines A.A. correspond more or less to 23½ degrees north and south latitude—*i.e.*, more or less to the Tropics of Cancer and Capricorn.

1. **The Tropical Zone.**—Examining the map a little more in detail, it will be noticed that, starting in the extreme west and travelling eastwards, the isotherm both north and south of the Equator is nearly the same as the latitude 23½ degrees north or south, but as the coast of America is reached it dips a little to the south in the Northern Hemisphere, and considerably to the north in the Southern Hemisphere. This variation is caused by cold currents in the sea running along the west coast of America, the more important of which (marked I. on the map) is the cold current from the Antarctic.

Tracing the line farther eastward, it will be noticed that it rises towards the north in the Northern Hemisphere, and falls towards the south in the Southern Hemisphere. In the Northern Hemi-

FIG. 1.—THE WORLD, SHOWING WARM CLIMATES AS DELINEATED BY SUPAN'S LINES.

sphere this is due to the warm Equatorial Current (II.), and in the Southern Hemisphere to the warming effects of the land and to the warm Brazilian Current (IV.).

With reference to the different effect of land and sea, it is necessary to remember that though 25 per cent. of the heat of the sun's rays which fall on the outer limit of our atmosphere are absorbed, still these rays do not really warm the air to any appreciable extent. The real warmth of the air is obtained from the dark heat radiated from land and sea.

Land not only absorbs the radiant heat from the sun more quickly than water, but also more readily gives off the dark heat to the air; therefore the presence of a large area of land upon which the sun's rays fall more or less vertically at noon all the year round will raise the temperature of the air, and will tend to extend the area of the warm climates. Hence the land may become extremely hot--incredibly high temperatures have been mentioned by authors—while water never becomes very warm. The reason of this is that water, being a liquid, by convection and by currents tends to keep at a more even temperature than land, though, as already noted, the currents, cold and warm, have a marked influence on the climate.

Turning again to the map, and tracing the isotherm eastwards towards the west coast of Africa, it will be noticed that again both the northern and the southern isotherms approach the Equator, and again this is due to cold currents- in the north to the North Equatorial Current (V.); and in the south to the cold Antarctic Current (I.). Crossing the continent of Africa, the effect of land is seen, and on passing into the Indian Ocean the effect of the Mozambique and the South Equatorial Currents may be noted, and finally, to the west and east of Australia the cold Antarctic Currents produce effects.

Thus the Tropical Zone is alternately decreased and increased in area, the most marked diminutions being on the west coast of America and the west coast of Africa.

It will be observed that this zone includes Central America, a large portion of South America, the West Indies, a large portion of Africa, Madagascar, a portion of Arabia, India, Ceylon, Indo-China, Sumatra, Java, Borneo, the Philippine Islands, New Guinea, and a portion of Australia, and many other smaller islands.

2. **The Subtropical Zone.**--The Subtropical Zone lies between the isotherms of 68° F. (20° C.) for the temperature of the coldest month, and the same isotherms for the mean temperature of the year.

It is depicted in Fig. 1, and will be noticed to include a portion of North America and considerable portions of South America, Africa, Asia Minor, Arabia, Persia, North India, China, and Australia.

Another method of subdividing warm climates, based upon the winds, rainfall, and altitude, will be given in the next chapter.

TROPICAL RACES.

It is now desirable to inquire very briefly into the races of mankind inhabiting these tropical or warm climates as defined above, in order that the tropical practitioner may understand the racial relationship of the peoples amongst whom he is working: and for this purpose we give the following very condensed account, starting with primitive man.

PRIMITIVE MAN.

From geological, zoological, and botanical considerations there can be little doubt that in early tertiary times there existed an Indo-African continent where, at present, the Indian Ocean lies. This continent, embracing the Deccan, Madagascar, and South Africa, is more extensive than Sclater's Lemuria, and is now known as Gondwanaland.

This Indo-African continent may, for many reasons, have been the site of the primitive home of the human race, and indeed it was in Java that Dubois found those remarkable teeth, calvarium and femur, which to-day are recognized as belonging to *Pithecanthropus erectus* Dubois 1891, which, geologically, belongs more probably to the early Pleistocene rather than to the Tertiary Pliocene, as was at one time considered possible. These remains belong either to a very early form of man or to an immediate precursor.

Once evolved, there can be no doubt that the main factor in man's further evolution has been the development of the brain, and this may have been stimulated by his remarkable migrations, for, driven by food requirements, geological or meteorological disturbances, man migrated from his primeval home and spread westwards into Africa, where, in the then fertile and well-watered northern regions of the Sahara, Caucasic man probably evolved. He also migrated northwards into Asia, evolving there the common ancestor of Mongolic-Amerind man, which eventually formed Mongolic man in Asia, while the further migration into America gave rise to Amerind man. Migrations from the south were easier in those days, because the Himalayas were much lower than they are to-day.

In the meanwhile the non-migrating common ancestor may have evolved into Ethiopic man, who was eventually compelled by the subsidence of the land to migrate westwards into Africa and eastwards into Oceania.

With regard to these early migrations, it must not be forgotten that the climatic conditions were probably very different from those of to-day, and, as it was a warm interglacial period, were distinctly favourable to these movements; while the abundant land connections of Africa to Europe, Asia to America, and America to Europe, of those days materially facilitated them. Neither must it be forgotten that these migrations, as well as subsequent migrations, were not single, but multiple, taking place in successive waves, and spread over a long space of time.

When considering the different divisions of mankind in greater detail, it will be noted that they spread from their original homes in various directions and at various times, until the whole world was populated.

The first dispersal of man over the globe must have resembled the migrations of animals in that it must have been performed unconsciously under the influence of the factors just mentioned, though it is possible that the food factor was the most potent, because, as Seligmann has pointed out, the hunting man of to-day requires a relatively large area in which to obtain his food, and it is equally possible that primeval man soon found that a given district was unable to feed his rapidly increasing family or tribe. Under these circumstances the family or tribe in question would move into a more suitable region. When man became more evolved migrations would still take place under compulsion as described above, but might also have taken place under the influences of attraction or expulsion, by which one means that a powerful tribe might be attracted to an area held by a weaker tribe, which latter would be compelled to submit to the conquerors or to migrate to some other area. If the weaker tribe remained with the stronger, there would possibly be a race fusion, as has so often taken place all over the world, and a new mixed race would appear, or the two races might live together with little fusion. During these early times must have appeared many of the diseases, especially the infectious diseases, which to-day afflict mankind, but what part the disease factor played in these migrations we do not know. What part epidemic parasitic diseases have played in evolution cannot be stated, but that they must have played some part in the extinction of animals seems possible; and it appears also possible that parasites transferred from animals to man at this period by the agency of blood sucking insects, etc., may have formed the basis of certain of the diseases of man to-day.

These migrations must have been delayed or stopped by meeting with natural barriers, such as deserts, dense forests, or broad expanses of water; and probably at these places settlements would be made, from which reflux migrations into parts originally occupied, or passed through, might arise, due again to the influence of the factors above mentioned.

In this way tribes, now modified by selection, environment, etc., re-entered the districts through which they had originally passed, and, finding them more or less occupied by differently evolved peoples, brought about fusion of the early divisions and subdivisions of mankind. And thus at an early period arose the first of these race fusions which are ethnologically so confusing to-day. One factor in these early refluxes must be mentioned, and this is the changed meteorological conditions brought about at the Glacial period or periods, for during these man must have been driven towards the Equator, while in the intervals he could wander polewards.

These early migrations and refluxes must have acted as potent stimuli to the already rapidly evolving brain of man, but this evolution does not appear to have gone on equally all over the world; in fact, it is in the so-called *Culture Zone*, situate between 25° and 50° north latitude, that brain development began to be highly specialized. In the eastern part of this region arose the Accadians, the Egyptians, and the early Cretans, from whom all the culture of Europe, Asia, and Africa evolved; and separately in the west the Mexicans, Peruvians, Columbians, and inhabitants of Yucatan, whose advance was ended once for all by the Spanish conquests, leaving only the culture of Accadian, Egyptian, and Cretan origin to supply the world with knowledge.

In other regions man has lagged far behind; indeed, in New Guinea and in other places we have the native peoples just emerging from a contemporary Stone Age side by side with the newly migrated and highly cultured Caucasic.

The tropical regions of to-day have therefore a most curious and most complex congeries of mankind. First, the indigenous inhabitants or natives of the land in question, together with the descendants of peoples arising from the intermingling of the original native race with other races brought thither by migrations of long ago; secondly, peoples whose native habitat is a temperate or cold climate, and who are derived from the quite recent and still continuing Caucasic migration; and, thirdly, the half-castes, derived from the intermingling of these Caucasic races and the native races

From the above it will be comprehended that the study of the ethnology of man in the tropics is indeed complex, but some elementary knowledge of the origin and relationships of the people among whom he is to work may be of use to the practitioner in the tropics, and therefore we give the following brief classification, leaving anyone interested in this subject an opportunity of further study by means of the works mentioned in the references at the end of the chapter.

Classification.- All classifications are more or less artificial, and based upon the generally accepted knowledge of the day, and are therefore ephemeral, and the various classifications, suggested by Bernier in 1684, Linnæus in 1735, 1740, and 1758, Blumenbach in 1775, Virey in 1801, Des Moulins in 1825-26, Bory de Saint-Vincent in 1827, Agassiz in 1850 and 1853, Isidore Geoffroy Saint-Hilaire in 1858, Pruner Bey in 1863, Haeckel in 1873, Broca and Topinard in 1885, Flower in 1885, Deniker in 1889, and, finally, Keane in 1895, form no exception to this rule.

The most useful classification is that of Keane, in which the human species is divided into four divisions--viz.:--

The Caucasic Division.
The Ethiopic or Negroid Division.
The Mongolic Division.
The Amerind Division.

We will now briefly consider these divisions.

Caucasic Division.

This division of man is thought to have evolved in Northern Africa at a time when the Sahara was a well-watered and inhabitable region.

Characters.—The characters of Caucasic man are:—*Height*, average or above the average; *colour*, florid or pale; *hair*, long, wavy, soft, and flaxen, or long, straight, wiry, and black, in either case oval on transverse section; *skull*, dolichocephalic or brachycephalic; *eyes*, moderately large, straight, blue or black; *nose*, straight or arched leptorrhine; *cheek-bones*, small; *jaws*, orthognathous; *teeth*, small; *beards*, full. Three types are recognized of these physical characters: the Nordic, with cephalic index 74-79, and blue or grey eyes, fair hair, and height 5 feet 8 inches to 6 feet; the Alpine, with cephalic index 80-90, brown or black eyes, dark hair, and height 5 feet 5 inches to 5 feet 6 inches; the Mediterranean, with cephalic index 72-78, black eyes, black hair, and height 5 feet 4 inches to 5 feet 6 inches. *Speech*, inflecting—*e.g.*, the Hamitic, Semitic, and Aryan languages—except in some instances, when it is agglutinating—*e.g.*, Basque; *temperament*, active, enterprising, and imaginative. *Medicine* varies from the highly evolved European medicine to the primitive Oceanic medicine.

Migrations. From his Saharic home the primitive Caucasic man wandered in Palæolithic and Neolithic times eastwards into the Valley of the Nile and on into Asia, where he met Mongolic man, and later into Southern Asia, and so into Oceania, reaching, as we shall presently see, its farthest islands. He also wandered northwards in successive migrations across the bridges between Africa and Europe, where he was succeeded by the early race to which belong the Cannstadt cranium found in 1700, the Neanderthal cranium found in 1856, the Spy cranium found in 1886, the skeleton of *Homo primigenius* found in 1908 in the Valley of Vézère, and the various skeletons and skulls found in 1909. All these skulls belong to the type called 'Neanderthaloid,' after their best-known member, and are considered by some authorities as not belonging to *Homo sapiens*, but to a separate species—*H. primigenius* (*H. neanderthalensis*)—which is approached to-day most closely by the Australian type. This earlier type was followed by more highly evolved Caucasic types, as, for example, the Cro-Magnon race of the French anthropologists found at Les Eyzies in Périgord. It is almost certain that these early peoples did not speak an Aryan language, but more probably a language allied to that of the Berbers, and therefore to the present Basque language. In Asia a fusion took place of certain Caucasic races with Mongols, forming the Turkoman and many Tatar peoples, such as the Uzbeg Tatars.

In both prehistoric and historic times there have been migrations of Semitic Caucasians from Asia into Africa, of which the most important were the Arabic migrations, which have produced a great impression on the peoples of Northern and Eastern Africa.

In recent times migrations of the highly evolved types of Caucasians have taken place from Europe into America, Oceania, Asia, and Africa, and to-day new races are arising from the fusion of native races with Spaniards and Portuguese in America, with Dutch in South Africa, and with French in Indo-China. It is, however, a curious sociological trait of the Anglo-Saxon not to amalgamate with the aborigines of the land into which he has migrated.

Population.—At the present time the Caucasic division is estimated to number 770,000,000 of the 1,570,000,000 of peoples which are supposed to inhabit the world, but there can be no doubt that this division is rapidly increasing in numbers. These 770,000,000 are distributed as follows:

Europe, 355,000,000; Asia, 280,000,000; America, 115,000,000; Africa, 15,000,000; Oceania, 5,000,000.

Classification.—Ethnologically, Caucasic man may be classified into the Xanthochroi and the Melanochroi, while an early wave passing across Asia gave rise to the Indonesians, which type is difficult to define, though Haddon considers that its least modified representatives are to be found among the dolichocephalids of the forests of Borneo.

THE XANTHOCHROI, or fair subdivision, is characterized by possessing light hair and light-coloured eyes. It contains the modern Europeans, who can be subdivided into the Teutonic branch, consisting of Germans, Dutch, Anglo-Saxons, and Norse races, and the Slavic branch, consisting of Russians, Poles, Serbs, Bulgars (in part), and Croats. It is the Teutonic branch which has supplied many of the peoples of the recent Caucasic invasion of the tropics.

THE MELANOCHROI, or dark subdivision, has long, straight, wiry black hair, black eyes, and only average height, while their characters are fiery, impulsive, and fickle. For the present purposes the Melanochroi may be subdivided into Hamites, Semites, Hindus, and Dravidians.

The Hamites may be further divided into a western division and an eastern division. The Western Hamites are the Berbers, sometimes referred to as Libyans, who are spread from the Canary Isles in the west to the Oasis of Siwa in the east, and from the Mediterranean in the north to the Senegal River and southern boundaries of the Sahara in the south.

The original strain of the Berbers has become altered by admixture with Arab blood in the north and negro blood in the south. In the north they have suffered much from the irruptions of Phœnicians, Romans, Greeks, Vandals, Arabs, and the European nations of to-day.

Two important sections of the Berbers must be recognized—the Agriculturists, as, for example, the Kabyles of Mauretania, who live settled lives, and the Nomads, represented by the Tuaregs of the Sahara. Tracing the various groups of true and mixed Berbers from west to east, there are first of all the Guanches, or original inhabitants of the Canary Isles, who show an affinity to these peoples; then the Trarza and Brakna of the Coast Sahara just north of the Senegal River, who have a negro strain. The Moors of Morocco must be considered to be Berbers with a strong Arabic strain. The principal groups of these are the Riffians of the north of Morocco, the Brábers of the Atlas, the Shluh of Western Morocco, the Sus between the great and small Atlas and the Tafilat to the south of the Atlas; but the last two have a negroid strain, as have the Wargla. East of these come the Kabyles of Jurjura and the Shauia of Aurès, who are interesting because, according to authors, some of them have chestnut hair and grey eyes. The Uled-Naïls of the Biskra district are mixed Berbers and Semites.

South of the territories of these peoples are the interesting veiled Tuaregs, with their centre in the *Haggar* Mountains, and their division into Asgers (Asjars) in the east, Haggars (Ahaggars) in the west, and Kelowis in the south; and Awelimmiden on the Central Niger. The veil, or *litham*, is used to protect them from the wind-blown sand of the desert. In the south of Algeria there are mixed Berbers, Arabs, and negroes, such as the Beni-Mzab, the Wargla, and other inhabitants of the oases. The Shaamba are Berbers between the south of Tunis and the west of Tripoli. In Tripoli itself there are Berbers mixed with Semites. South of these and east of the Tuaregs lies Tibesti, the headquarters of the Tibus, who are now Mohammedans with a slight mixture of Paganism. Far south there are the Fulahs, who are Berbers with a great admixture of negro blood, who are dispersed among the Sudanese negroes. They took their origin on the Senegal, but later invaded the Hausa States and formed the Empire of Sokoto.

The eastern division of the Hamites includes the Egyptians, the Abyssinians, and the so-called Ethiopians or Nubians. The Egyptians of to-day exist as the Christian Kopts and the Mohammedan Fellahîn. The Ethiopians include the Bejas or Bisharû, of the land between the Red Sea and the Nile; the Afar or Danakil, between Abyssinia and the Gulf of Aden; the Somals of Somaliland, who are much intermingled with negroes, Arabs, Afars, and Abyssinians; the Gallas or Ilm'Orma, in Southern Ethiopia or Gala-land proper; and the Masai of Masailand intermediate between the Galla and the Wahuma or Wahima, who are dispersed among the Bantu peoples of the great lakes, and are believed by some to be the originators of the Bantu dialects

The Semites have their primeval home in Arabia, from which they wandered in various directions e.g., the Himyarites or Southern Arabs to Abyssinia, the Arabs proper to North Africa and to the east coast of Africa, producing profound effects They may be classified into South Arabians, including Himyarites and their derivatives, certain tribes of the Abyssinians and the Northern or true Arabs, the Assyrians, Amorites, and Canaanites, which included the Hebrews and Phœnicians, both of which have produced effects upon man in Africa, where to day the Jew is found in numbers in Tripoli and Algeria.

The Hindus. The Aryans are thought by Keane to have arisen as a fusion of many Caucasic and some Mongolic elements with an original xanthochroid basis, and to have lived in a Eurasian home, probably in the steppes between the Ural and Caucasian Mountains and in the Aral-Caspian depression and the regions of Turkestan; for, as he points out, in Neolithic times this region was very suitable for human life, being then well watered, but the gradual drying of Asia would compel these primitive Aryans to wander westwards into Europe, and south-eastwards into the Iranian plateau and India, and it is with this last migration that we are at present concerned. In this extent there is only one non-Aryan survival- viz., the Brahui of Eastern Baluchistan. The important groups are the Hindus, Bengalis, Punjabis, Kashmiris, Gujaratis, and Sinhalese.

The Dravidians include a vast congeries of tribes, which, if the so-called Pre-Dravidian jungle peoples be excepted, form everywhere in India the basis of the population. The pure Dravidian

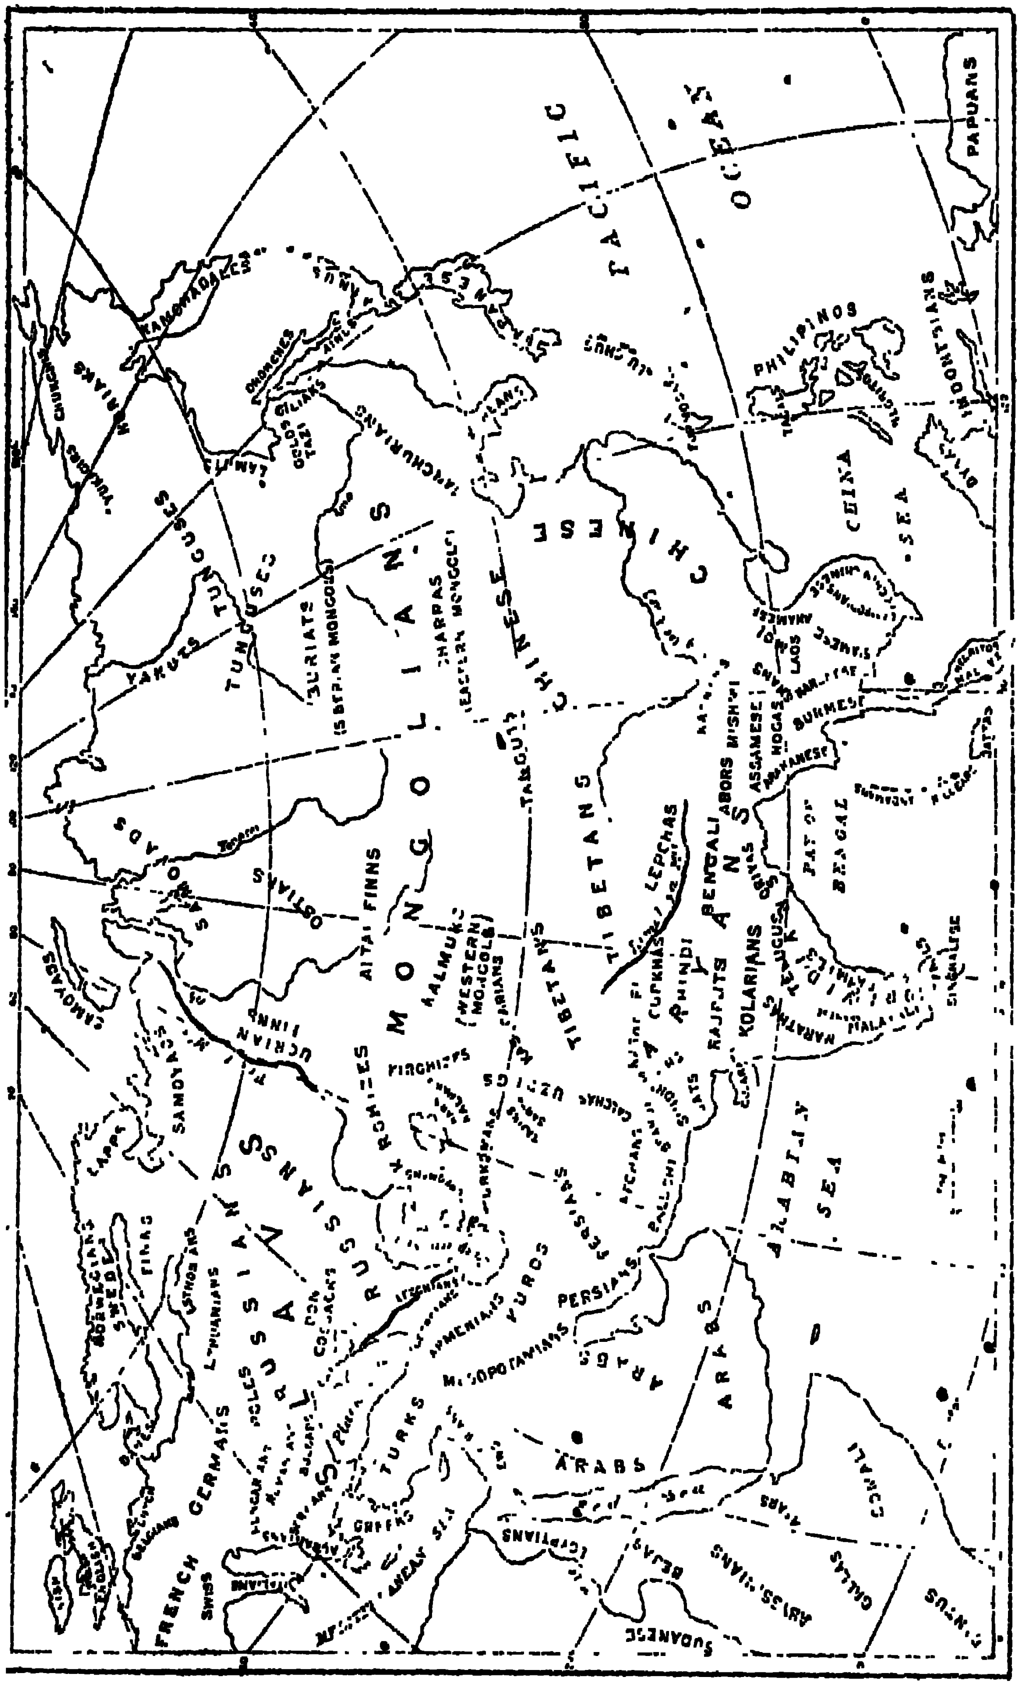

FIG. 2.—THE RACES OF ASIA.
(From Hutchinson's 'Living Races of Man.')

stock is represented by the short, dark, broad-nosed, dolichocephalic peoples (recalling the noseless Daezu of the invading Aryans), but they have everywhere been modified by fusion with immigrant peoples, giving rise to the Aryo-Dravidian, Scytho-Dravidian, and the Mongolo-Dravidian types. The Aryo-Dravidian type is principally found in Northern India and Ceylon, its upper strata being exemplified by the Hindustani-speaking Brahman of Northern India and the Tamil-speaking gentleman of Northern Ceylon, while its lower strata are exemplified by the Chamar. The complexion of these people varies from medium brown to very dark, and their noses from medium to broad. The Scytho-Dravidian type of Western India is characterized by a fair complexion, with little or no hair on the face, with broad heads and moderately fine noses. Riseley considers that this type is a fusion between Dravidians and immigrant Scythians, and Haddon suggests that it is a fusion with the Alpine race from the hills of South-West Asia in prehistoric times. The Mongolo-Dravidians are best represented by the inhabitants of Lower Bengal and Orissa. They are of medium stature, and usually of dark complexion with abundant hair on the face, with broad heads and broad or medium noses.

INDONESIANS.—The greatest divergence of opinion is found with regard to the inhabitants of Malaysia and Oceania. It would appear probable that the earliest inhabitants belonged to the undifferentiated negroid type, of which the negritoes gave rise to the Andamanese, the Semangs of Malaysia, the Aëta of the Philippines, and the pygmies of New Guinea, while the negroes formed the Tasmanians, the Papuans, and the majority of the Melanesians. In among these peoples came the brachycephalic Mongols, called by Haddon the Proto-Malays, who were to be found first in the Peninsula, and later, driven south by the Caucasic migrations to be presently described, in the islands.

Earlier migrations still, perhaps of lowly developed Caucasian stocks, may have given rise to the Pre-Dravidian jungle tribes of India and Ceylon, and perhaps to the Kakhyens of Northern Borneo and the Sakai of Malaysia, and to one element in the Australian race.

An early migration fused with the Proto-Malays, forming the Proto-Polynesians of Haddon, who migrated into the Western Pacific, and, fusing with the early black peoples, gave rise to the Melanesians; while others, passing through or round Melanesia, went on to Tonga and Samoa, and later to Tahiti and Raratonga of the Cook Islands, spreading later to Hawaii and the Marquesas, and still later to New Zealand. These migrations or voyages are supposed to have begun by a migration to Java as late as 65 B.C., and did not cease till A.D. 1350. In this way the mixed populations of many of the islands of the Pacific arose.

(From Hutchinson's 'Living Races of Man.')

Ethiopic Division.

It is possible that this division took its origin in the Indo-African continent.

Characters.—The characters of Ethiopic man are.—*Height*, either above the average (negro) or dwarfish (negrito); *colour*, blackish or yellowish brown; *hair*, short, frizzy, flat in section, or reddish-brown and woolly; *skull*, dolichocephalic (negro) or brachycephalic (negrito); *eyes*, large, round, prominent, black, with yellowish cornea; *nose*, flat and broad, platyrhine, *cheek-bones*, small; *jaws*, prognathous; *teeth*, large, *beards*, absent or small; *speech*, agglutinating, with prefix and postfix types, or inflectional. In negroid Africa there are numerous languages in the Sudan and West Africa, but in the east, centre, and south there are only variants of the Bantu stock language; in the far south there are the Hottentot and Bushmen languages. In Madagascar and Oceania the Malayo-Polynesian stock language is prevalent. In America the speech of the negroes has approached that of the European languages. *Temperament*, indolent, sensuous, passionate, and cruel. In Africa there is a lack of self-respect, thus readily permitting slavery. The development of the mind is believed to be arrested at puberty by the closure of the cranial sutures, and there is also a belief that the negro, left to himself, without Caucasic migrations, would have retrograded enormously, some stating that he would have retrograded to the condition of an animal (these statements may be received with caution). *Religion*, fetishism, nature and ancestral worship, *medicine*, primitive, being closely associated with religion, and therefore with the fetish priest, and therefore with magic, charms, invocations, and sacrifices; but there is a knowledge of poisonous plants, which are used in trials by ordeal, in hunting, fishing, and war.

Population.—Ethiopic man is guessed to number some 175,000,000 of persons, of whom perhaps 155,000,000 are in Africa, 3,000,000 in Madagascar, 20,000,000 in America, and 2,000,000 in Oceania.

Migrations.—From his Indo-African home Ethiopic man wandered westwards into Africa and eastwards into Oceania.

Africa.—One of the first of the westward waves must have been that caused by Palaeolithic man migrating into Africa, wherein he spread north and south. Another very early wave was that of the pygmies, who gave rise to the Bushmen and negritoes or negrillos, and spread along the whole east side of Africa from the Mediterranean to the extreme south. With, or perhaps not long after, the pygmy migration came the taller negro, who possibly wandered into East Africa and through the forests, together with the pygmies, to the west coast, and possibly northwards as far as the northern shores of the Mediterranean; but these migrations of Ethiopic man in Northern Africa were stopped by the evolution of Caucasic man, who not merely drove the negro southwards, but made some remarkable race fusions with him. Thus, for example, the Hottentots are believed by some to be of Hamitic-Bushmen origin, although others consider it safer to place them as intermediates between the Bantu peoples and the Bushmen. These Hottentots were stronger than the Bushmen peoples, but not so strong as the Bantu peoples, by whom they were eventually driven into Southern Africa.

Another remarkable race fusion is that which produced the Fulani, who are believed to have been originally Berbers (Caucasics), but who have intermingled with the negro races among whom they have migrated. Thus their residence on the Senegal River is traced by the Wolofs of the Senegambia, who are a negroid Fulani race; and along the Niger by the Mandingoes, who possibly have also Tuareg and Arab infusions. These Mandingoes, driven by Fulani migrations, have to-day approached the coast south of the Senegal River, displacing the Krus and Kpwesi, who now live in Liberia. Migrating farther inland, these Fulanis compelled the Ashantis and Fantis to travel coastwards, and then settling in the Hausa States, and forming the Sokoto Empire, they compelled the Hausas to move southwards and to force the Yorubas to approach the coast, who in their turn drove the weaker indigenous

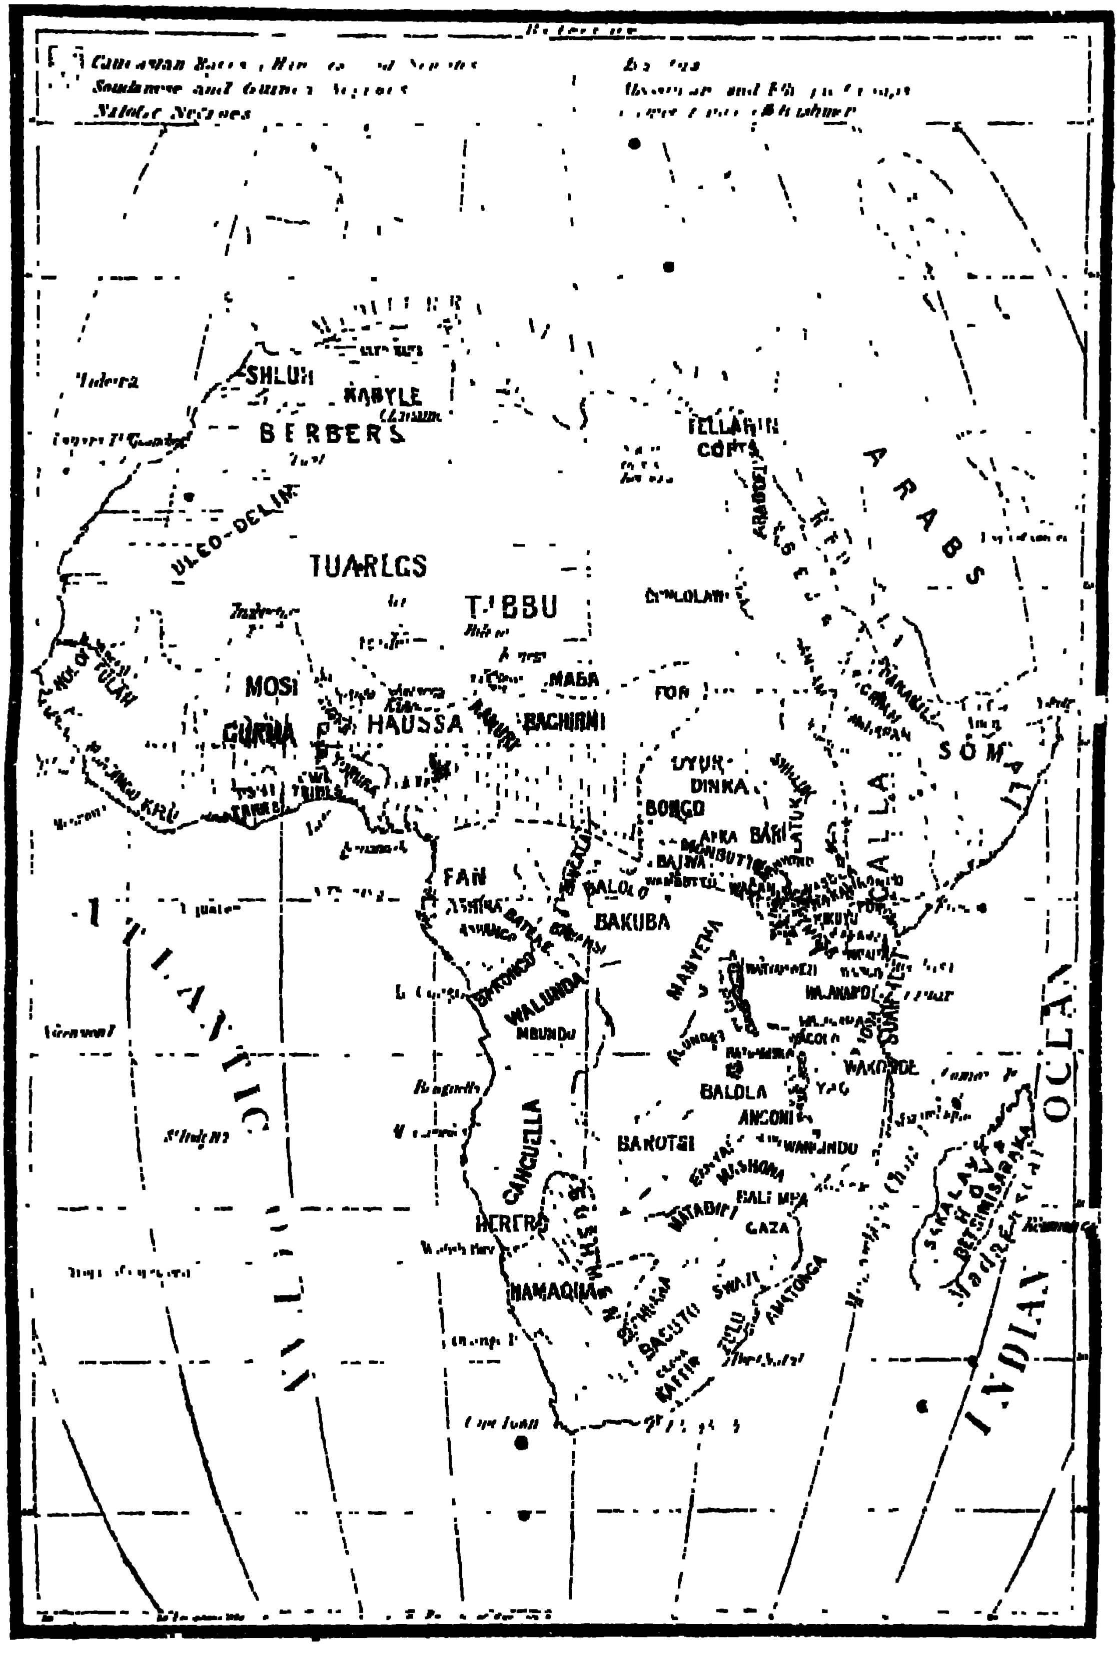

FIG. 4.—THE RACES OF AFRICA.
(From Hutchinson's 'Living Races of Man.')

tribes into the unhealthy delta of the Niger. The Fulani can also be traced by their language right across Africa to Dar-Fur.

All these negroes, pure and mixed, living in that region of Africa which is called the Sudan, from the Arabic *Belad-es-Sudan* (Land of the Blacks), speak languages of various stocks, but very different is the language of the Bantu speaking peoples of the portion of Africa south of a line approximately drawn eastwards from the Rio del Rey River, near the northern boundary of the Kamerun, which separates the Bantu peoples from the Sudan peoples.

It is quite impossible here to mention the many changes which have been brought about in the position of the various Bantu tribes by the slave-trade, migrations of local tribes, as well as those of Caucasians; but these influences have produced many changes even during the nineteenth century, of which some are known, particularly in South Africa.

The slave raids began with the expeditions of the ancient Egyptians, and continued until quite recently, when the last Arabic raiders were checked by the Caucasic migration.

Locally, movement of Congo tribes southwards, and southern tribes northwards and interior tribes coastwards, have caused much confusion; but perhaps of all the movements, those of the Ama Zulu and their descendants, the Zulu especially under Chaka, together with those of the Barotse and the Mantati, and the Ova Herero, are the most remarkable or best known. Curious causes have called forth these migrations. First of all, the physical features of Africa have had a great effect upon the occupations, and hence upon the migrations of its people; secondly, the urgent need for salt in vegetable-feeding peoples, driving them coastwards; and, lastly, the endemic and epidemic disease factor, which is demonstrated by the weaker tribes being driven into the most unhealthy regions. The Caucasic migrations of the Dutch and English in South Africa have also had great effect in driving the native tribes northwards and in exterminating them.

Oceanic. The eastward or Oceanic migration of Ethiopic man is extremely difficult to follow, and may have taken place largely on foot over land bridges, which at that time existed, and later in canoes by water.

The negritoes, or pygmies, are represented to-day by the Andamanese, the Semangs of Malaysia, the Aeta of the Philippines, and the pygmies of New Guinea; while the Oceanic negroes gave rise to the extinct Tasmanians and the Papuan people, the latter forming the ground-stock of Melanesia.

Classification. Ethnologically, the Ethiopic millions are classified into two principal sections—the Western or African, and the Eastern or Oceanic, section.

The stature of the Ethiopics of the Oceanic section is less than that of the Africans, the hair is more wiry, the nose is large and straight, the lips are not so thick, and are not everted as they are in the Africans. The Oceanics are more savage, but they show artistic taste and execute wood carving.

The Western or African Section contains negritoes and negroes. The negrito is dwarfish, with yellowish-brown colour, reddish-brown woolly hair, and brachycephalic skull; while the negro is tall, of blackish colour, with jet-black frizzy hair and dolichocephalic skull.

The African negro may be subdivided into negroes living north of the Equator and not speaking the Bantu dialects, which include the West and Central Sudanese, the Welle River groups, the Nilotic groups, and the Nubas of Kordofan, and into groups living south of the Equator and speaking the Bantu dialects; while in the extreme south are found the Hottentots and Bushmen.

The Eastern or Oceanic Section contains also negritoes and negroes, distinguished as above mentioned.

Mongolic Division.

Mongolic man probably evolved in the Tibetan Plateau of long ago.

Characters.—The characters of Mongolic man are: *Height*, rather under the average; *hair*, black, lank, coarse, round on transverse section; *skull*, brachycephalic; *eyes*, small, black, oblique, with outer canthus slightly higher than the inner, and with a vertical fold of skin over the inner canthus; *nose*, very small, mesorrhine; *cheek-bones*, prominent laterally; *jaws*, mesognathous; *teeth*, medium; *beard*, slight or absent, but moustache present; *speech*, agglutinating, with postfixes, the families being Ural-Altaic, Tibeto-Indo-Chinese, and Malayo-Polynesian; *temperament*, reserved, sullen, and apathetic in the Mongols, industrious in the Chinese, and indolent in the Malays; they are all gamblers; *religion*, animism, Shamanism, Lamaism, Buddhism, Mohammedanism, Confucianism, Taoism, etc.; *medicine*, mostly theurgic, associated with invocations, but in China there has been an attempt to evolve a higher state of efficiency. The Hungarians have the usual highly evolved modern medicine.

Population.—The total number of Mongols is estimated to be 540,000,000 persons, of whom 380,000,000 are believed to reside in China, 55,000,000 in Japan and Korea, 35,000,000 in Indo-China, 30,000,000 in Malaysia, 10,000,000 in Mongolia and Manchuria, 6,000,000 in Tibet, 7,000,000 in Turkestan and Siberia, 13,00 in West Asia, and 4, elsewhere, but estimates vary very much.

Migrations.—The common stock of Mongol-Amerind man, migrating from the primeval home in the Indo-African continent, passed into Asia, and while the Amerind division travelled through that continent into America, it is probable that the Mongolic division made its home in Tibet. This would be in later Pliocene times, when the Tibetan Plateau would not be the elevated region which it is to-day.

In Tibet to-day the original type is best preserved among the Drupa, who are about 5 feet 4 inches in height, with light brown skin, somewhat resembling that of the Amerindians, with brachycephalic skulls, long black hair, brown eyes, slightly prominent cheek-bones, depressed nose, wide nostrils, and large ears. They are semi-nomadic pastoral peoples, living at a height of about 14,000 feet above the sea-level. The other groups in Tibet are the Bodpa, the dominant peoples, who are of mixed descent, and the Tanguts, predatory peoples along the north-east boundary.

From this Tibetan home Mongolic man wandered westwards, giving rise to the celebrated Akkads and Sumerians of Babylonia, and much earlier entered Europe, giving rise to the many Asiatic invasions of that continent. With regard to the Akkads and Sumerians, it may be stated that they early evolved a form of culture which grew and flourished after their fusion with their early Semitic conquerors, thus laying the foundations of one of the most ancient forms of human civilization. According to some authorities (though by no means proved), the Chinese took their origin from early Akkadian emigrants.

Another migration from Tibet was southwards along the valleys of the Irawadi, Salwin, and Mekhong Rivers into Indo-China, giving rise to the Mishmi, the Abors (with whom there has been trouble recently), the Kuki, the Luohai, the Chins, the Nagas, the Karens, the Khas, and the Moi, who, though perhaps not the makers of the stone implements recently discovered in the Irawadi Basin, may be looked upon as the aborigines of these regions, because there is at present no evidence as to who these earlier peoples were. The above-mentioned tribes have remained in a primitive condition, but others have developed, under Hindu influences, a high degree of civilization—as, for example, the Burmese. An immigration from the north brought the Malayans and the Tai race, which, coming from Central China about the Yang-tse-Kiang, gave rise to the Shans, the Laos, and the Siamese; while yet another migration, this time from the valley of the Si-Kiang and South-Eastern China, gave rise to the Annamese, Tongkinese, and Cochin Chinese.

In Oceania, taken in its widest sense to include all the islands of the Indian Ocean, as well as what is generally known as Oceania, the Mongol peoples are often known under the term 'Malays,' which is, properly, only applied to the Mohammedan tribes of Malay Peninsula, who are the Malays proper. These Malayans are found in Sumatra, Java, Borneo, Celebes, Bali, Lombok, Billeton, Bangka, the Spice Islands, and the Philippines, but are much mingled with other races—*e.g.*, with the negroes of Bantu origin in Madagascar, and the Caucasic Indonesians in Malaysia generally.

Keane says that the term 'Malay' was originally applied to the Orang-Maláyu, a small tribe of the Menangkabau district of Sumatra, who rose into prominence about a thousand years ago and spread over the archipelago, and whose language is the chief medium of intercourse throughout Malaysia.

Reverting to the primeval home of the Mongols, there are still further offshoots to mention—viz., the Hyperboreans of Northern Siberia and the Mongol-Túrki. These latter, who are often called Mongol-Tatars, from two words—'Mongol,' meaning 'brave,' and 'Tatar,' the plural of 'Tata,' 'an archer' (while 'Turk' is an Aryan word meaning 'swift'), which, again, is often spelt 'Tartar'—spread in two directions—eastwards and westwards. The eastward-migrating Mongol-Túrki gave rise to the Mongols proper, who include the Kalmuks, Sharras, Buryats, Tunguses, and Manchus, and the Mongoloid Koreans and Japanese. The Tunguses of the Amur Basin and East Siberia are interesting because the great bulk of them are Shamanists, their Shamans being medicine men, often called 'priests,' who heal by magic, uttering oracles by which they establish communication with the invisible world, and thus are able to coerce good spirits and evil spirits to work for the good of the patient, and even to expel devils. The Manchus are the celebrated imperial caste of the Chinese Empire. The Koreans, so called after the powerful Koryo dynasty of A.D. 918-1392, are of mixed Caucasic and Mongolic origin, and are the precursors of the Japanese, who are of mixed Caucasic origin from the Aïnus, Mongolic origin from the Manchus and Koreans, and Malayan from the Malays coming through the Philippine Islands and Formosa.

The westward-migrating Mongol-Turki need not detain us, except to state that they gave rise to the Túrki proper, the Samoyedes, the Lapps, the Magyars and Finns, and the Bulgars, probably only in part.

Classification.—The Mongolic division (*vide* Figs. 2 and 3) may be classified into:—

1. *Mongols*, who include the Mongols proper, the Tunguses, the Manchus, the Koreans, and Japanese.
2. *Túrki Peoples*, who are the Yakuts, Kirghizes, Turkomans, Anatolian Turks, and Osmanli Turks.
3. *Ugro-Finns*, comprising the Finns, Lapps, Samoyedes, Mordvins, and Magyars.
4. *Tibeto-Chinese*, with the Tibetans, Burmese, Nagas, Shans, Siamese, Annamese, and Chinese.
5. *Malayans*, who are classed into the Malays proper, the Javanese, including the Sundanese, Madurese, and Javanese proper; the Achinese, Rejangs, and Passumahs of Sumatra; the Bugis, Mangkassaras, and Minahasans of Celebes; the Tagalas, Bisayas, etc., of the Philippines, the Dyaks of Borneo, the Formosans, and the Hovas of Madagascar.

Amerind Division.

The Amerind or American-Indian division of mankind has a twofold origin—from Europe and from Asia. From Europe dolichocephalic Caucasic peoples made their way in Pleistocene times along land bridges connecting Britain with the Orkneys, the Shetlands, the Faroë Islands, Iceland, Greenland, and Labrador. These peoples, making their way across the continent, met with later and more numerous arrivals, the brachycephalic peoples of Mongol-Amerind stock, arriving from Asia by the land connections about the Behring Straits and the Aleutian Islands. These two races fused and formed the Amerind division of man. These Palæolithic races were apparently uninterrupted by any Caucasic, Mongolic, or Ethiopic migrations until the discovery of America by Columbus, after which all three divisions made their migrations thereunto. Therefore all the culture of the Mayas, Aztecs, and Incas, etc., was an inbred culture, not dependable for its origin on outside sources. Hence the absence of the ordinary animals and plants of Asia, Africa, and Europe, and the presence of peculiar animals and plants. Hence, also, the presence of only stone and copper ages until the introduction of iron by the Caucasians, and also the possible source of certain peculiar diseases, such as yellow fever, and perhaps Frambœsia tropica, and, according to some authors, syphilis, which, when introduced into Europe, Asia, and Africa, produced such ravages.

Characters.--The characters of Amerind man are --*Height*, above the average; *colour*, coppery or yellowish, *hair*, long, coarse, and black, on section round; *skull*, mesaticephalic; *eyes*, small, round, black, sunken, and straight; *nose*, large, bridged, or aquiline mesorhine, *cheek bones*, moderately prominent; *jaws*, mesognathous, *teeth*, medium, *beard*, absent; *speech*, divided into a very large number of linguistic families, said to number more than those of the rest of the world, but peculiar to America by being polysynthetic or holophrastic *i.e.*, sentences made from single long words. The most important of these linguistic families from a tropical point of view are the Ut-Aztecan, the Mayan, Carib, Arawak, Quichuan, and Guaranian. The Ut-Aztecan speech is used by the Shoshoneans, or Snakes, who include the Utahs and the Nahuas, who also include the Aztecs, while the Quichuan comprises the Incas. *Religion*, Shamanism in the north, Nature-worship, and polytheism; *medicine*, very primitive, especially when associated with Shamanism, but was somewhat more advanced among the Aztecs and Incas. Cinchona bark was a native Ecuador remedy.

Population.--There are believed to be some 10,000,000 Amerinds and 13,000,000 to 40,000,000 half-breeds, but the numbers are by no means easy to estimate even approximately. It is clear, however, that the Amerinds are rapidly dying out in Canada and the United States.

Migrations.--The brachycephalic peoples whom we have already noticed proved superior to the dolichocephalic people from Europe, and drove them northwards, where they became Eskimo, and southwards, where they became the Tehuelche or Patagonians and the Fuegians. The brachycephalic peoples then evolved the North American Indians, of whom we are only concerned with the members of the Ut-Aztecan linguistic family, because the Aztecs are members of this family in common with the Shoshoneans, and it is probable that the Nahuan family to which the Aztecs belong migrated southwards from the district of British Columbia.

Coming to Mexico proper, it is found that the archaic peoples—the Popolcans, Mixe, Chinantecs, Zoque, Mazatec, Cuicatecs, Chocho, and Magahua—have all been pressed by the migrations presently to be mentioned into secluded valleys, where alone traces of them can be found at the present time. The Mexicans proper are the Otomi, who are related to the Magahua, and are still to be found in the valley of the Upper Moctezuma and in Guanjuato.

A northern immigration may have brought the Tarascos of Michoacan into Mexico, or they may belong to the primitive Mexicans. In either case, they are to be found to-day in Guanjuato; with these may be joined the Ulmecs, Xicalancas, Mestecs, and Zapotecs among the early tribes of Mexico. Of all these, the most important would appear to be the Mistecâ-Zapotecâ family, because they are known to have evolved a degree of civilization before the days of the Mayas. This culture is exemplified by the monuments of Mitla and of Monte Alban in Oajaca.

The Maya people are variously believed to have been immigrants into Yucatan, from which they spread into Guatemala, Salvador, and Honduras, or to have been original settlers therein. Be that as it may, there is no doubt that they extended into Mexico, both along the coast, where one of their tribes, the Huantecs, were found about Tampico, and into the plateau. They very early produced some degree of civilization, and constructed the celebrated monuments of Guatemala and the pyramid of Cholula in Mexico, on the top of which was the temple of Quetzatcoatl They invented picture-writing and an almanac. They were divided into the Mayas proper of Yucatan, the Choulats of Mexico, the Quichés, the Pocomans of Guatemala, the Chortes, and the Huantecs of Tampico.

Such must have been the constitution of the tribes of Mexico when the Nahuans broke their way in. This tribe is allied to the Shoshonics, who occupy the wide tract from Oregon to California and New Mexico, and are believed to have come from the region of British Columbia. They moved down to the west of the Rocky Mountains, and spread as far south as Oajaca and eastwards to the Atlantic between Vera Cruz and Coatzacoalcos. The first waves may have been the Toltecs, but there is great doubt as to who these people were. The Alculhuaques and the Tepanecs followed, while the last immigration was that of the powerful Aztecs, who, though probably but little civilized when they entered Mexico, soon became so, and remained the masters of that part of America until subdued by the Caucasic migration.

Enumerating, therefore, the tribes from the north to the south, there would be first the Shoshonies in the west and south-west of the United States, extending into Mexico; the Yumas of Arizona and the Pueblo-Indians, characterized by their curious rock structures; then would come the Otomi, Totonacs, and Zapotecâ, with their Nahuan conquerors, especially the Aztecâ, all in Mexico. In Central America the Maya people would be found in Yucatan, Guatemala, and Honduras, along with the Xicaks of Northern Honduras, the Leukas and Guatusos of Central Honduras. Farther south would be the Choulats of Nicaragua, the Soumoo, the Micos of the Mosquito Reservation, the Moscos of the Blewfields Lagoon, and the Rinos of an island therein.

Passing into South America, there is the great linguistic family of the Chibcha of Colombia, whose empire extended southwards until it met that of the Incas. These peoples, as well as the Incas, are Andeans—that is to say, are peoples belonging to the highlands of the Andes. It is curious that all the South Amerind civilizations should have developed in these highlands, but it is probable that the lakes and rapid streams were suitable for the extension of agriculture, and thus led to the settlement of peoples, for without a permanent abode any great degree of civilization is impossible. The Chibchas, also called 'Muyscans,' influenced the whole Panama region as far north as the northern boundary of Costa Rica.

South of the Chibchas comes the ancient empire of the Incas, extending from Quito as far south as the Rio Maule in Chili. It would appear from the megalithic remains and the ruins of Tiahuanacu that there was an early civilization in this region, especially about Lake Titicaca. Who these people were we do not know, but they must have been conquered by the Quichuas or Aymaras, who are allied to them, as both speak derivatives of the Quichuan language.

At the same time there existed near Truxillo the Chimu people, speaking Mochica, a language quite different from Quichuan. They reached to a degree of civilization, but both they and the Quichuans were conquered by

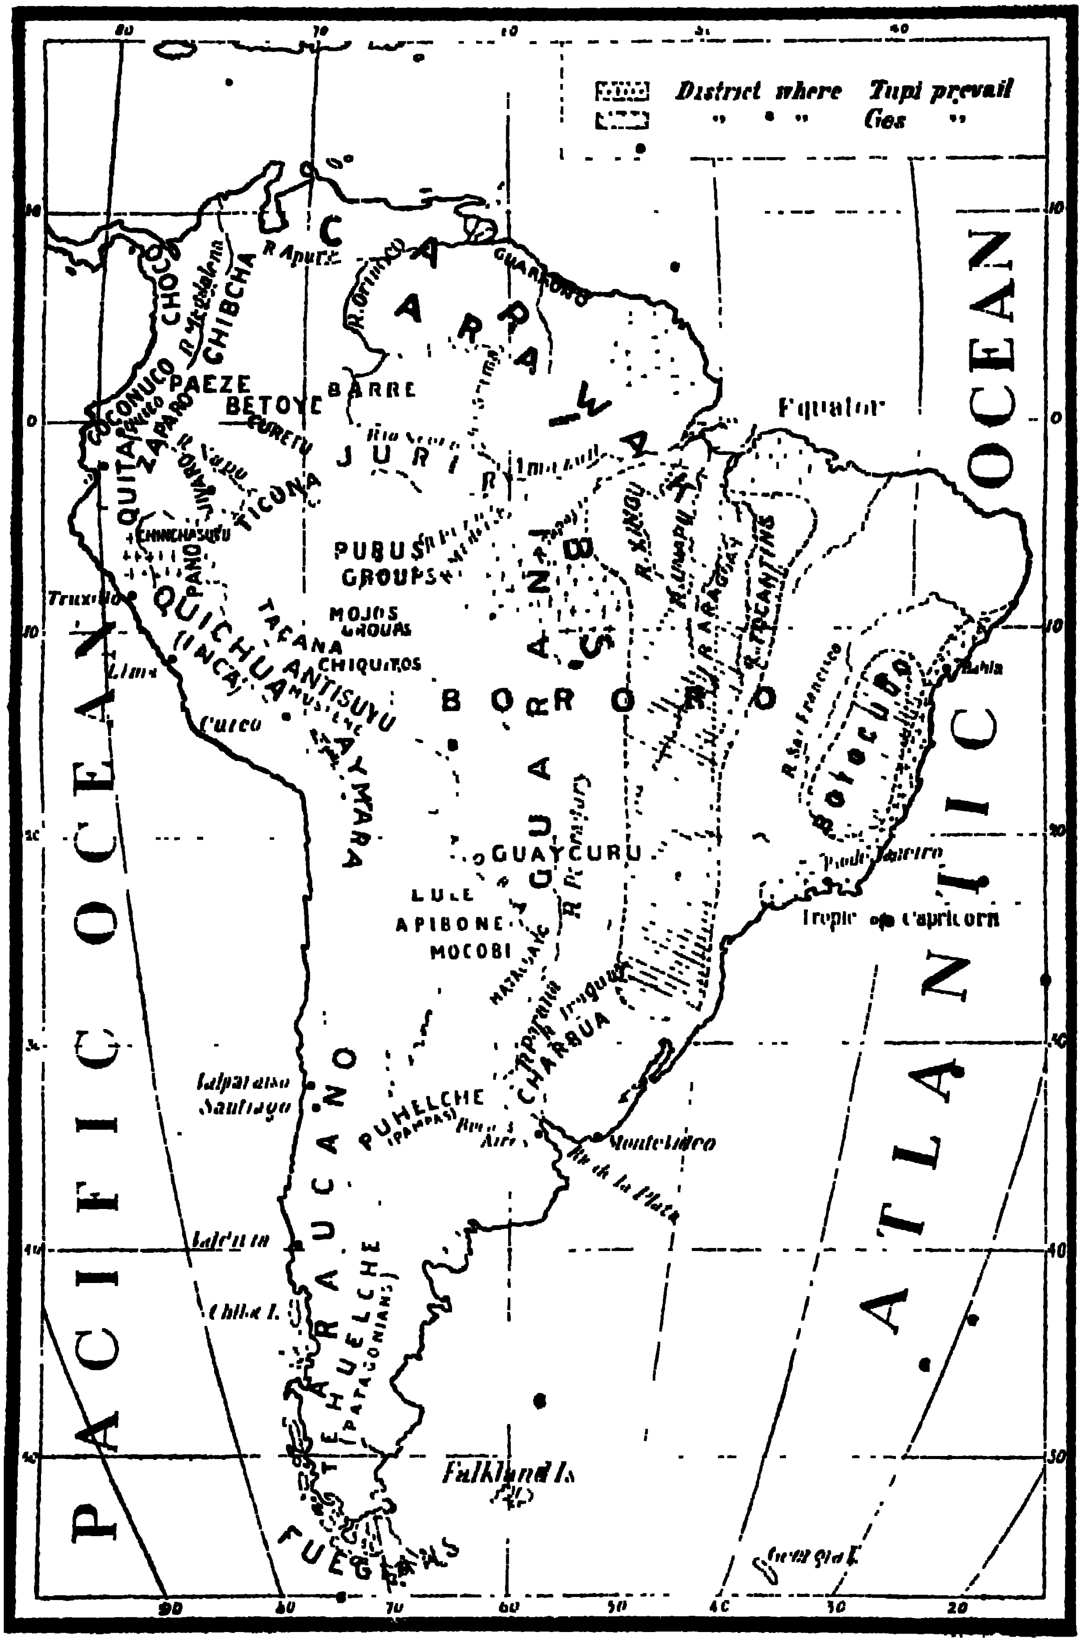

FIG. 5.—THE RACES OF SOUTH AMERICA.
(From Hutchinson's 'Living Races of Man.')

the Incas. To-day the descendants of the Chimu are called the 'Yuncas,' and live along the coast from 5 degrees to 10 degrees south latitude. In the provinces of Catamarca, Tucuman, and Salta of the Argentine lived a civilized race, now extinct, called the 'Calchaqui,' who were also subdued by the Incas.

The Incas are possibly the descendants of the unknown peoples of the early civilizations who, defeated by the Quichuan peoples, fled into the Apurimac region, whence they subsequently issued forth to subdue their ancient conquerors. Their rule was very despotic, and their subject peoples were very carefully divided into tens, fifties, five hundreds, and ten thousands, the last being under a chief taking orders direct from the Inca. Their system was very artificial, and absolutely without any freedom for the individual, and hence the easy Spanish conquest. They possessed no written language, everything being preserved by oral information handed down from generation to generation.

Except in the Andes, there are no civilizations in South America, and the peoples whom we now come to consider were all backward in their culture evolution at the time of the advent of the Spaniards. They are the members of the linguistic families called 'Arawak,' 'Tapuya,' 'Tupi,' and 'Carib,' in the regions lying east of the Cordilleras as far south as the Rio de la Plata, while farther south lived the Pampeans and Fuegians, with whom we are not concerned.

The Arawak would appear to be the original inhabitants of the low-lying lands to the east of the Cordilleras, and it is possible that they originally spread to the north-east, the east, and the south-east from a primeval home on the eastern slopes of the Bolivian Cordilleras; but their most important migration appears to have been that to the north east, where they populated the, until then, vacant valleys of the Orinoco and Amazon, especially along the north bank and up the Xingu River. In the east of Brazil, from the Xingu River to the coast, lived the Tapuya, who were probably the aborigines of these regions. They include the Ges and Botocudos of to-day, of which the latter are degraded savages.

The Caribs, according to Van der Stein, took their origin about the sources of the Xingu and Paranatiga Rivers, where the Caribbean tribes called 'Bakairi' and 'Nahuqua' live. From this source they travelled, probably by water, along the Amazon, meeting with the Arawak, till they reached its mouth, when they turned northwards, probably because they met the Tupi people coming from the south, and spread through Guiana to Venezuela, where their progress was checked by the civilized Chibchas, though some of them entered the valley of the Magdalena River. From the north of South America they proceeded to the Antilles, into which they were still migrating when stopped by the arrival of the Spaniards.

The Tupi people had their primitive home, according to Haddon, in the northern portion of the basin of the Rio de la Plata, down which they spread to the mouth, and then, migrating northwards along the coast, reached the mouth of the Amazon, meeting there the Arawak and possibly the Carib peoples, and, travelling westwards along the southern bank of the Amazon, reached the Xingu River, up which they went, founding the Kamayura and Aneta tribes in its upper basin. They went still farther westwards, forming the more civilized Omagua between the Putumayo and Caqueta Rivers, and the Cocama peoples at the junction of the Amazon with the Ucayali River.

In Uruguay and Paraguay the Tupi peoples are called 'Guarani,' or 'Warriors,' and hence the whole family is called the 'Tupi-Guaranian family.'

Into the races mentioned above penetrated the great Caucasic migration, headed by Columbus, in the fifteenth century of our era, which, though stopping the autochthonous evolution of civilization in America, introduced the more highly evolved culture of the Old World at the cost of millions of lives of the Amerindians.

The Latin races of this migration have fused with the aborigines to a great extent, and thus have laid the foundations of the new Latin-Amerindian races which are arising to-day.

The Anglo Saxon in North America did not fuse with the Amerind, who to-day is rapidly approaching extinction.

The negro migration was compulsory, as the negroes were introduced as slaves, but it suited the race, which is rapidly increasing in numbers. The Mongolic migration is at present very small, and of quite recent date.

Classification.—The Amerinds may be classified for our purposes into those belonging to the Northern Section, to the Central Section, and to the Southern Section of America, but only the two last need concern us here.

The Central Section is formed from Mexico and Central America as far south as the northern boundary of Costa Rica. It contains the Opata-Pima linguistic family, composed of the Pimas and Papajos of the Gila Valley, where the Gila Monster (*Heloderma suspectum* Cope 1869) lives, the Capitas, Coras, Yumas, and Torahumeras, though these last are mixed with Caucasic blood. The Nahua or Aztecs come next, and include the Aztecs proper, the Pipils of Guatemala, the Niquirans, and the Chichimecs.

The Huaxtecan group, often called the Maya-Quiché group, includes the Huaxtecs of Tamaulipas and Vera Cruz, the Mayas of Yucatan, the Choulats of Mexico, the Mopans of Northern Guatemala, the Quiché farther south in Guatemala, the Pocomans around the city of Guatemala. The Mayas proper are divided into the Itzas and the Lacandons. The Chortegans include the Chorti living around the ruined city of Copan as well as the Bribri and others.

In the Southern Section are the nations which we have sufficiently described above, viz., the Chibchas, Quichuas, Chimus, Calchecaquis, and Incas, all of whom were civilized, and the Arawak, Tapuya, Carib, and Tupi peoples, who were far more primitive and savage, as well as the Pampeans and Fuegians, which are not tropical races.

CHAPTER III

TROPICAL CLIMATOLOGY

Preliminary remarks — Climate — Tropical climates — Temperature and humidity — Pressure — Winds — Electrical conditions — Sun's rays—Moon's rays—Acclimatization—References.

PRELIMINARY REMARKS.

We have delineated the tropics by Supan's lines, as this appears to us to be the most suitable method of bounding warm climates, and we have noted the characters of the races of mankind which occupy the lands so defined. These, we may incidentally mention, amount to a little less than one-half of the surface of the earth, and now we must consider what is meant by the terms 'climate' and 'tropical climates,' and then turn our attention to the effects of these climates on mankind.

CLIMATE.

Climate may be defined as the combined effects of the sun, the atmosphere, and the earth upon living objects at any one place on the earth's surface. The factors which produce a climate are therefore threefold—viz., the sun, the atmosphere, and the earth; and the living object with which we are concerned being man, we must study the effects of these factors upon him, but we restrict our attention to mankind as seen on that portion of the earth's surface called the tropics.

TROPICAL CLIMATES.

In the previous chapter we have noted Supan's simple division of warm climates by isotherms, but there is a better subdivision given by Ward, and based upon wind systems and their control over rainfall (*vide* Fig. 7).

Around the Equator lies the region of equatorial calms, called the doldrums (Fig. 7), while north and south of this region are the trade winds (Fig. 6). These zones of calms and winds are not stationary; on the contrary, they move so as to reach a maximum extension northwards of some five to eight degrees of latitude in July and a maximum extension southwards of some three to four degrees in January.

These movements are dependent upon the changes in the inclination of the axis of the earth towards the sun, but are not coincident with these changes.

A locality may therefore lie entirely in the equatorial belt, or it may lie entirely in the trade-wind belts, or it may be polewards of these belts; but with the movement of the system polewards, as indicated above, some of the places in a trade-wind belt must come into the equatorial belt, while others usually situate polewards to the trades must be included in these belts.

Were the tropics flat this classification would suffice, but there are high mountain ranges in tropical lands, and therefore it is necessary to make a division to include these, because it is possible in the high lands of the tropics to pass through every degree of temperature, if you ascend high enough, as if you proceeded from the Equator to the Poles.

There are therefore four divisions of warm climates—viz.:

I. The Equatorial Belt.
II. The Trade-Wind Belts.
III. The Monsoon Belts.
IV. Mountain Climates.

I. **The Equatorial Belt.**—Localities situate within a few degrees of the Equator are always more or less subject to rain and cloud, because the heated air is full of aqueous vapour brought by the trade winds from the sea; and as aqueous vapour is lighter than air in the ratio of 0·623 to 1·0, it can rise to high and cold altitudes, and there be condensed into small droplets of water forming cloud or larger droplets forming rain.

As the capacity of air to hold water is doubled for every 27° F. increase in temperature, and as in air saturated at 85° F. and then cooled to 60° F. every cubic foot yields 7 grains of water, the excessive violence of these equatorial and tropical rains is easily understood.

This belt is subject to alternate seasons of wind and calm—*e.g.*, in January it will be subject to the north-east trades, followed by a period of calm; and in July to the south-east trades, succeeded by another period of calm. There are, therefore, two maximal and two minimal temperatures after the two zenithal and solstitial positions of the sun, and two short wet seasons and two short dry seasons.

Such places are Southern India, Ceylon and Java in Asia, Columbia in South America, and in Africa parts of the Valley of the Nile. and the Gold Coast.

With the inclination of the North Pole towards the sun, which begins on March 21 and ceases on September 22, the shifting of calms and trades northwards begins some time after the first date and lags behind the last date, and during this period a locality may be in the equatorial belt for six months in the year and have six months' drought and six months' rain. Such places are Bengal, portions of the Nile Valley, Northern Australia, and Central America. The Sudan receives its rains when the equatorial belt is passing northwards—*i.e.*, from May to August—and its vegetation grows rapidly, but when it is in the trade-wind belt, from November or December to March or later, the climate is dry.

It is the northern migration of the Equatorial Belt which brings the heavy rains to the Uplands of Abyssinia, and causes the rise of the Blue Nile and the Atbara, which produce the rise of the Nile.

The same features are to be noted in the movement southwards; thus rain comes on the pampas of Brazil in the months from October to April, while the dry season lasts for the rest of the year.

Some few places—*e.g.*, Wady Halfa—show only one maximum and one minimum temperature—*i.e.*, the so-called tropical type of temperature variation.

II. **Trade-wind Belts.** The lands which lie just outside the polar boundaries of the equatorial or rain belt are situate some 20° to 35° north or south latitude, and are among the driest in the world, except in India, where the south west monsoon brings a little rain into the dry regions of the Punjab and Sind.

The worst places are the dry zones of California and other parts of North America, the Sahara and Nubian Deserts, parts of Arabia and Persia, Argentina, Eastern Patagonia, South-West Africa, and the interior of Australia. The only rain these regions are likely to get will come from the extension equatorially of the polar winds.

We may, therefore, summarize the character of the trade-wind belts as very regular annual and diurnal ranges of temperature, with a complete absence of rain or with slight showers at infrequent intervals. The range of temperature in the desert is often very great; thus during the day the temperature may be very high, with dry winds carrying dust and sand, and the nights, with the clear sky free from cloud allowing active radiation, may be cool if not cold, or even at times very cold.

III. **Monsoon Belts.**—The word 'monsoon' is believed to be derived from the Arabic word *Mausin*, meaning 'a season.'

The monsoons (Fig. 6) are classifiable into three groups:—

1. North-East and South-West Monsoons.
2. North-West and South-East Monsoons.
3. West Monsoon.

1. **North-East and South-West Monsoons.**—These are typically met with in the Indian Ocean and its coasts.

Dove's explanation of these monsoons is generally accepted—viz., that, owing to heating of the great plains of Asia, where the air ascends in the months of May, June, July, and August, the south-east trade-wind, which is blowing south of the Equator, is drawn northwards, at the same time being deflected to the west, thus forming the south-west monsoon. Conversely, when the plains cool in November, December, January, February, and March, there is a breeze from the north east towards the Equator, which, though called the north-east monsoon, is really a trade-wind.

The interval between the two monsoons is characterized by changeable winds, which blow alternately in opposite directions—north-east and south-west.

The south-west monsoon is laden with moisture, and on it Southern India largely depends for rain, and a failure will mean a famine, because a large portion of the population is agricultural, for the natives depend for food upon

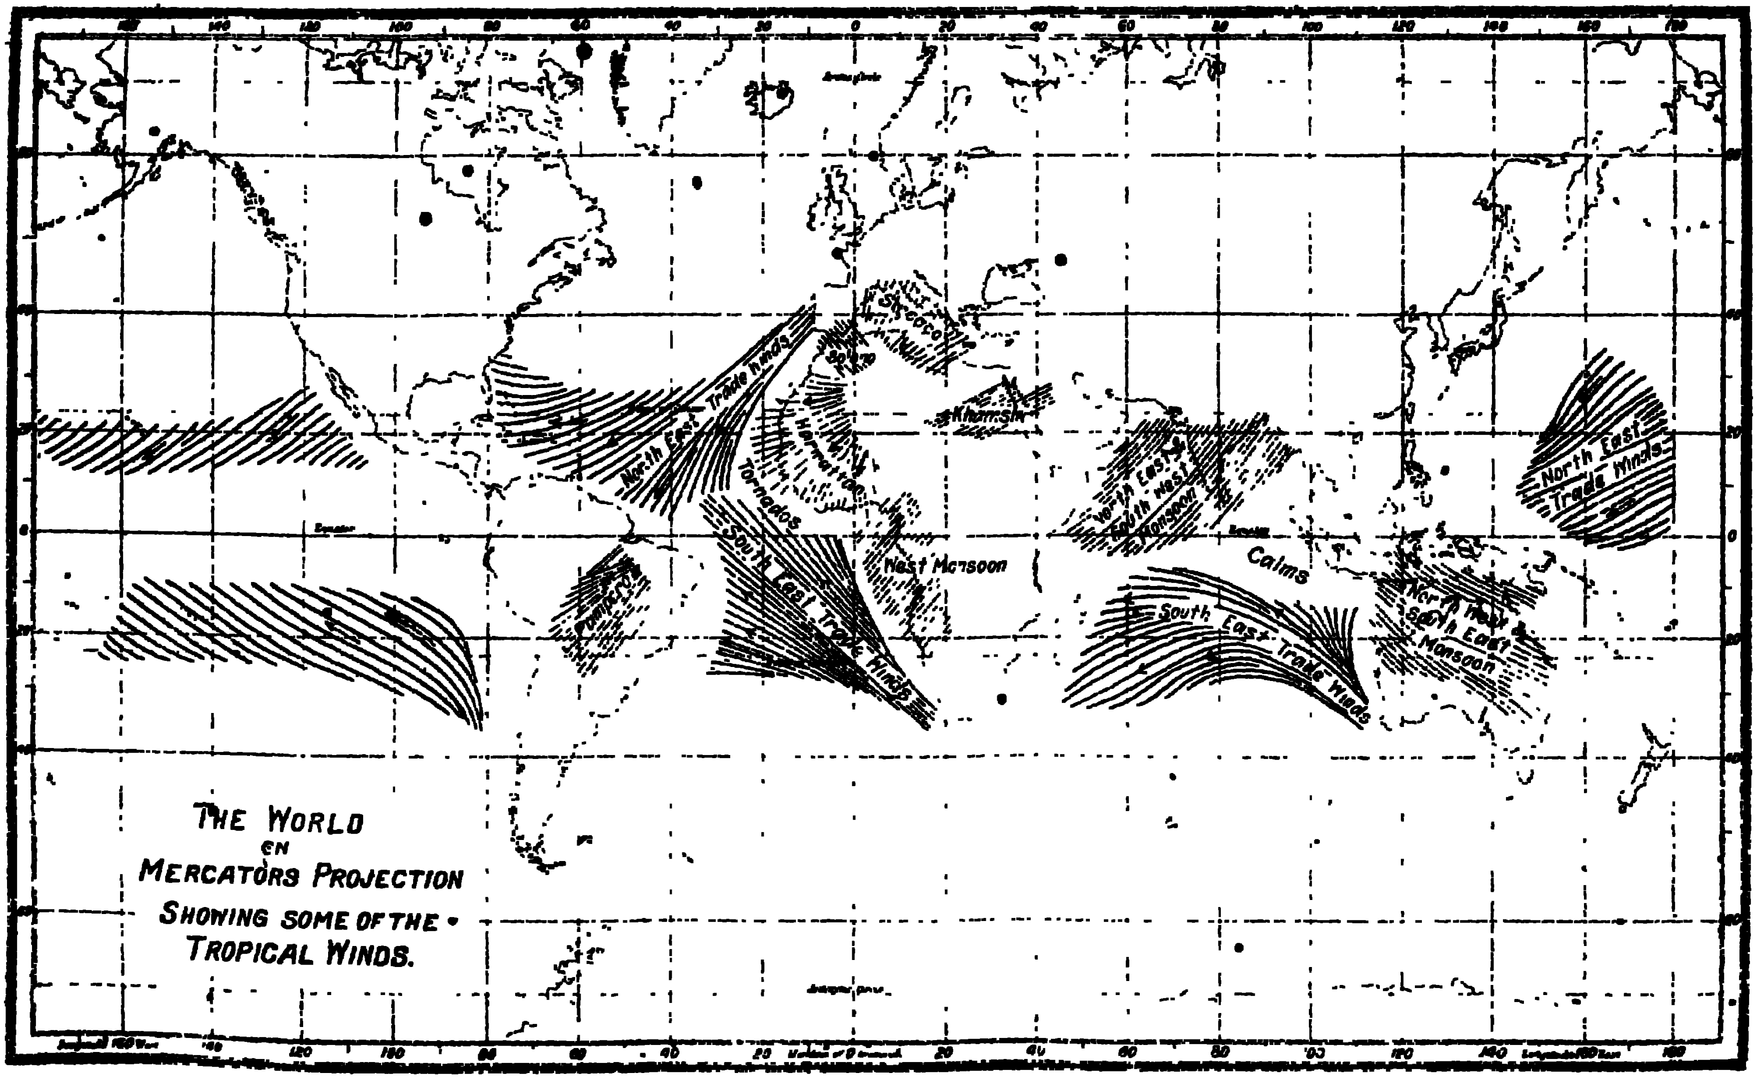

FIG. 6.—TROPICAL WINDS.

their own cultivation; and so densely are they placed that a failure to produce their own crops results in a most severe famine, which can only be coped with by the most energetic action of the Government.

2. **North-West and South-East Monsoons.**—These are to be found in the Southern Hemisphere, and are depicted in Fig. 6 in the region of Australia.

3. **West Monsoon.**—Dove described as the west monsoon of the line a wind which blows in a south-westerly direction along the coast of Africa from Cape Verde down to Walfisch Bay. These winds, however, are variable, and in the Gulf of Guinea are interrupted very often by calms.

Some people describe the winds along the eastern and western coasts of South America as monsoons, but they hardly come under this term.

In typical monsoon regions the rains follow the vertical sun, and the type of temperature is the so-called tropical type, with one maximum and one minimum.

It must be admitted that this simple classification, like all classifications, fails to explain everything, and there are numerous exceptions showing combinations of equatorial, trade-wind, and monsoon types.

IV. **Mountain Climates.**—We have already pointed out the effect of altitude in lowering the temperature, and, indeed, Herschel, many years ago, showed that for every 300 feet of increase in altitude there was a decrease of 1° F. in temperature, and for every 180 metres a decrease of 1° C. These statements are only partially correct, for the temperature at a given altitude depends upon the expansion and humidity of the air, the clearness of the atmosphere, together with the quantity of earth at the given locality, and the nature of the wind blowing at the time of the observations. Perhaps of all these the most important is the expansion of the air, for, as is well known, it expands when heated—*i.e.*, the energy represented by heat is converted into motion, and hence the temperature falls. This will in part be counteracted by the heat produced by the condensation of aqueous vapour, even at high altitudes, and upon this condensation and cloud-formation will depend how much of the heat, radiating from the earth into the air, is retained. The lessened amount of earth in high altitudes is also a factor, as there is less earth to retain heat, and hence less heat is given off into the air. It is obvious that movements of the air—the winds—must have a great effect, depending upon their origin from warm or cold sources. Hence, though in general the rule mentioned above as to a relationship between temperature and altitude holds good, it is only approximate, as the connection between the two is complex, not simple.

In the tropics, therefore, the low country possesses the true tropical climate, while the climatological conditions of the hills are quite different. Indeed, as Ward has said, the climates of many tropical plateaus and mountains have the reputation of having a perpetual spring, but though that may be so at certain latitudes, if considerable elevations are reached a perpetual winter exists, with snow all the year round, even on the Equator.

The great blessing of these elevations in the tropics is that they provide cool hill stations to which the resident of the plains may resort during the hottest months, and in which sanatoria may be built for the treatment of persons convalescent from lowland complaints.

This brief sketch of tropical climates must suffice for our present purpose, and we now turn to consider the various climatic factors and their effects upon man; but the reader interested in this subject may find it useful to consult Chapter II., pp. 28 to 58, in our second edition, in which more details will be found.

TEMPERATURE AND HUMIDITY.

Heat derived from the sun is capable of traversing the atmosphere surrounding the world, and thus reaching the earth, because this atmosphere is diathermanous to rays with short wave-lengths coming from so hot a body as the sun. Dry air is diathermanous for all rays, but aqueous vapour is almost athermanous for infra-red rays, though largely diathermanous for other rays.

In passing through the atmosphere, about 25 per cent. of the heat which has entered it is absorbed before it reaches sea-level.

The position of the sun is, however, of the utmost importance with regard to the quantity of heat reaching the earth. If the sun is quite vertical, probably only 20 per cent. is lost; whereas, if the beam is nearly horizontal, probably none reaches the earth.

The heat rays falling upon the earth are absorbed and converted into dark heat—that is to say, into frequencies with longer wave-lengths—and these are radiated back into the atmosphere (terrestrial radiation). This dark heat is absorbed by the atmosphere, which is, as already stated, almost athermanous to this kind of energy. This atmospheric heat is one of the most important factors in determining the nature of a climate, and shows daily and annual periodic variations, of which the first is due to the sun's rays heating the earth, and therefore this disappears at sea or during an arctic winter, while the second depends largely upon the inclination of the world's axis as it passes round the sun in its yearly orbit. As the sun is vertical in the sky at noon twice a year in the tropics, there is or ought to be a wet season at these times, and in their intervals a dry hot season.

It is impossible, however, to consider the effects of temperature upon man without at the same time taking into account the humidity of the atmosphere.

Man can bear very high temperatures easily, provided the air is dry, but not if there is much moisture or humidity in it. The humidity of the atmosphere is, in fact, of the utmost importance in the study of climatic effects upon man. This humidity is due to aqueous vapour, caused by the constant evaporation which takes place from the surface of all collections of water.

The humidity of the atmosphere presents three problems: atmometry, or the measurement of the quantity of water being taken into the air; hygrometry, or the determination of the quantity of aqueous vapour present in the air at any given time; and hyetometry, or the quantity of water being condensed from the atmosphere.

Evaporation takes place most quickly in hot dry air, and causes a considerable amount of heat to be rendered latent. This fact can be made use of in hot climates, where it is a common practice to wrap flannel or felt round a bottle of water, and after damping the flannel, to hang the bottle in the breeze, so that the contents may become cooled by the evaporation of the water from the flannel. The same principle applies to the porous stone or earthenware basins which are commonly used in Ceylon, Uganda, Egypt, and other parts of the tropics to filter and cool water. Hence, also, the value of collections of water in keeping the temperature of places equable.

The amount of aqueous vapour in the atmosphere is generally spoken of as the humidity. Two kinds of humidity are recognized: absolute humidity, which is the weight of aqueous vapour actually present in a definite volume of air at a given temperature; and relative humidity, which is the ratio of the weight of water actually present in a known volume of air to the weight of water which is required to saturate the same volume of air at the given temperature, and is generally expressed as a percentage.

We have already stated that the humidity of the air is of the greatest importance in considering the effects of a tropical climate on man. The most trying climate would be one with a high air temperature and a high relative humidity, for it is obvious that when the air is full of aqueous vapour, evaporation from the surface of the human body must be considerably diminished; and as this is one of the methods of regulating the bodily temperature, it is apt to rise and cause great discomfort, as will be described later.

A warm place with a high humidity is less bearable than a much hotter but drier place. A fairly high relative humidity can, however, be borne if there is a breeze, without which a much lower humidity is most unbearable. In fact, Giles points out that Abusher, in the Persian Gulf, in August, with a mean maximum temperature of 96·5° F. (35·7° C.), and a relative humidity of 65 per cent., with no rainfall during the month, and little or no breeze, constitutes one of the most unbearable climates in the world, though neither the temperature nor the humidity by themselves are high.

When the aqueous vapour in the atmosphere condenses, the result may be dew, fog, mist, cloud, rain, hail, or snow, of which the two last are rare in the tropics. Clouds in the sky prevent to a great extent the heating of the earth during the day, and at the same time they prevent radiation of heat from the earth during the night, and even reflect this back to it. Hence cloudy nights may be very hot in the tropics.

Effects.

We must now consider briefly the effects of high air temperatures with and without high atmospheric humidity upon man, and we will commence with a consideration of its effects upon the bodily temperature.

Normal Temperature.—The normal temperature of man is the resultant between the heat produced by the oxidation of foodstuffs in the muscles, glands, and other organs and tissues of the body, and the heat lost by warming the urine, fæces, and expired air, by evaporation from the lungs and skin, and by radiation and conduction from the skin. In other words, the temperature of the body is controlled both by chemical and by physical heat regulation.

1. **Chemical Heat Regulation.**—By this is meant regulation of the bodily temperature by increased or diminished production of heat, which can be brought about by alterations in metabolism. Diminished heat production is, however, rare, being usually pathological, though it is possible that it occurs more frequently in the Tropics than in the Temperate Zone, owing to the lessened disposition for muscular or mental work.

2. **Physical Heat Regulation.** The body temperature is usually regulated by increasing or diminishing the loss caused by radiation, convection, and evaporation. According to Hill, a man weighing 70 kilogrammes loses 77·1 per cent. of his heat by radiation and convection and 22·0 per cent. by evaporation. This regulation is brought about by the dilatation of the cutaneous vessels bringing more blood to the skin and by the increased perspiration. The loss of heat caused by radiation and convection depends upon—

1. Temperature and conductivity of the skin.
2. Temperature and radiation from the skin.
3. Temperature of the air.
4. Rate of motion of the air.

Clothing may, however, affect the loss of heat from the skin, for, as a rule, it is composed of substances which are bad conductors of heat, and hence the loss may, according to Rubner, be diminished no less than 47 per cent. Wet clothing, on the other hand, is a good conductor, because of the water in its interstices, and hence the danger of chills while wearing damp clothes. This latter fact is well known to the old resident of the tropics, who has generally learnt its danger by personal experience.

Radiation takes place best when the air is still, dry, and cold, conduction when it is damp. Convection is only of importance when the air is in motion, in which case the loss of heat is proportionate to the square root of the velocity, and is more marked when atmospheric humidity is high.

With regard to evaporation, Rubner has shown that it is best at medium, greater at low, and still greater at high temperatures, as is shown by the following table taken from his book of an observation on a man of 58 kilogrammes weight lightly clad:—

Air Temperature.	*Grammes of OH_2 per Hour.*	*Grammes of CO_2 lost per Hour*
2° C.	37	29·8
10° to 15° C	28	25·1
15° to 20° C	19	24·1
20° to 25° C	23	25·0
25° to 30° C.	43	25·3
30° to 35° C.	84	23·7
35° to 40° C.	112	21·2

This evaporation is very markedly diminished by humidity, as is shown in the following table:—

Temperature in Centigrade.	*5 to 8 per Cent. Humidity.*	*81 to 89 per Cent. Humidity.*
15·0°	30·3	9·0
20·4°	54·1	15·3
25·3°	75·5	23·9
28·9°	105·0	—

It is also diminished by a moderately strong wind, but is increased by the sun's rays and by work in a hot climate.

To determine accurately the temperature of a man in the tropics is not the easy matter which most people consider it to be, and the principles applying thereto should be understood even by those *not likely to be deceived by an air temperature so high that a maximum thermometer rises and keeps above normal without any reference to the patient*, a fact which we have seen lead to curious mistakes. Under such conditions, the thermometer must be kept and examined in cold water.

The temperature of man, being the resultant between the heat produced and the heat lost, must vary considerably under many circumstances, and there is no doubt that it varies in different individuals.

In investigating the temperature of the body, one ought to seek that which most nearly represents the temperature of the blood, for though the different organs of the body manufacture or lose heat in different proportions, the circulation of the blood tends to bring about a mean internal temperature for the whole body.

The possible methods of investigating the temperature of the body are by placing the thermometer—

1. In the axilla,
2. In the mouth,
3. In the rectum,

to which might be added placing the thermometer in the stream of issuing urine; but this method is only open to limited application, and there may be considerable loss from evaporation and radiation, and, therefore, though it is an excellent method when used with care, will not be further considered.

If the thermometer is placed in a *dry, well-closed axilla,* and kept there long enough, the result will be not unlike that in the *mouth;* but if it is thought that any resemblance to the internal temperature of the body is to be obtained by placing a thermometer in a perspiring axilla for half to one minute, then the greatest mistakes as to the real temperature of the patient are possible. In our experience it has not been unusual in the tropics to find several degrees of difference between the axilla and the mouth.

As a rule, it may be stated that the axilla is not a good place in which to take thermometric observations which are meant to indicate the true temperature of the body.

With regard to the mouth temperature there has been a great deal of discussion, but the most careful observations are those of Pembrey and Nicol, who have shown that the mouth temperature is apt to vary considerably, and that it is not a reliable indicator of the internal temperature of the body in cold weather or after exercise. Haldane, in his valuable experiments to be quoted presently, finds that it varies greatly with the individual.

In warm and moist air, however, the mouth temperature approaches the rectal temperature.

The reason why the mouth temperature is apt to be lower than the rectal and the real temperature of the body is apparently the cooling owing to the proximity of the skin, and possibly of the nasal cavity, and therefore in warm air this difference frequently does not exist. In India Crombie found in fifteen carefully taken observations that the mouth temperature was 0·22° F. below that of the rectum, whereas Pembrey found it as much as 4·5° F.—*i.e.*, 2·5° C.—below that of the rectum in cold weather in England. It is possible, therefore, that it is a better site for thermometric observations in the tropics than in Europe.

Rectal temperatures under ordinary conditions give the highest readings and are the truest indicators of the internal temperature of the body; but this is not a method open to clinical use, except in children and in states of coma.

The conclusion is that if care be taken that neither hot nor cold articles have been recently placed in the mouth, and particularly if the mouth has been kept closed for a short time, the temperature from the thermometer placed under the tongue is, without doubt, the most accurate for ordinary clinical work in the tropics, for in that position the thermometer is as completely as possible protected from the influence of the nose and the skin.

A thermometer, however quickly it reacts to its surroundings, must be left a reasonable time in the mouth, by which is meant two or three minutes, so that the temperature of the closed mouth may approach that of the rest of the body. Crombie gives the time for the accurate recording of the temperature in India as:—

Ten minutes in the well-closed and dry axilla.
Eight minutes in the mouth.
Three to four minutes in the rectum.

The mean daily temperature of man for the hours 8 a.m. to 12 midnight in the Temperate Zone is as follows:—

98·45° F. (36·90° C.) in the axilla.
98·36° F. (36·87° C.) in the mouth.
98·96° F. (37·20° C.) in the rectum.

The so-called normal temperature of man in the mouth may be placed at 98·40° F. (36·90° C.) or 98·6° F. (37° C.), and was determined as the mean temperature from 8 a.m. to 12 midnight by John Davy in 1837, and by some mistake it has been interpreted into the mean temperature for the twenty-four hours, which is different, being probably lower.

Crombie gives the following as the means of the observations of Ogle, Allbutt, Casey, and Rattray:—

Mean Morning Temperature.	*Mean Afternoon Temperature.*	*Mean Twenty-four Hours' Temperature.*	*Maximum Daily Range.*
97·763° F.	98·341° F.	98·084° F.	1·41° F.

But at present there are insufficient data upon which to base a definite conclusion as to the mean temperature of human beings for the whole twenty-four hours.

The average temperature in the mouth varies from between 96° F. and 97° F. to a little under 99° F., and the rectal temperature from 97·2° F. (36·28° C.) between 2 to 5 a.m. to 99·4° F. (37·45° C.) between 4 to 7 p.m.

Pembrey gives the mean daily temperature as being 98·6° F. (37° C.), the maximum 99·5° F. (37·5° C.), and the minimum 96·8° F. (36° C.)

Effect on Temperature.—Having now defined what we mean by a normal temperature in man, it is necessary to inquire into the effects of high atmospheric temperatures and varying humidity upon man.

The experiments of Lining (1738), Ellis (1758), Blagden and Fordyce (1775), established the fact that a normal man, suitably clothed, can regulate his temperature so that with high air temperatures it still remains within the normal limits, if the atmospheric humidity is low, and these experiments have been well borne out by life in the tropics.

It is, however, quite otherwise when the atmospheric humidity is high: as far back as 1775 Blagden and Fordyce noted that in a damp room with a temperature of 124·5° F. (51·4° C.) their bodily temperature rose to 100° F. (37·8° C.). Haldane observed that there was no abnormal rise of the bodily temperature until the wet bulb thermometer indicated 88° F. (31° C.), provided that the experimenters were stripped to the waist or clad in light flannel. If, however, the wet bulb exceeded this temperature by even one degree, then the bodily temperature rose hour by hour in proportion to the rise of the wet bulb thermometer above 88° F., but the bodily temperature increased more rapidly when high wet bulb temperatures were reached than when they were relatively low. With the abnormal rise of bodily temperature was associated increase of the pulse rate by about twenty beats per minute for each degree Fahrenheit and thirty-six for each degree Centigrade. All these bodily temperatures were taken in the rectum and with the patient standing. When this rectal temperature reached 102° F. hyperpnœa was observed, while other symptoms associated with the rise of the bodily temperature were profuse sweating and a general feeling of exhaustion and discomfort.

It was observations like these that caused Tyler to attempt to correlate personal sensations with meteorological data, and to formulate his 'hyther' degrees, by which he meant the degree of discomfort caused by high air temperatures associated with high relative humidity.

Haldane's experiments have often been repeated by ourselves on normal people by placing them alongside the condensers in the engine-room of steamers in the Red Sea during very hot months. Near the condensers one can usually find a corner where there is no obvious movement of the air, which is nearly saturated with aqueous vapour, and where there is a high atmospheric temperature. Placed in such a corner and clad only in loose pyjamas, the skin of the body flushes and burns, the perspiration rolls downwards in streams, and the temperature after a short pause commences to rise and goes on rising until the experiment is broken off, usually about 103° F.

This is not a pathological rise, though associated with throbbing vessels, etc., but is simply due to atmospheric conditions acting upon a normal man, and all symptoms disappear rapidly after removal to cooler air.

If such a climate existed no human being could live therein, but no such place is known, and although conditions of high atmospheric temperatures may produce fever, yet these are pathological and not physiological, and depend upon factors which will be discussed later.

From the time of Davy in 1839, observations have been made into the temperature of healthy men during the passage from the temperate to the tropical zone, during their residence in the tropics, and during the passage from the warm to temperate climates. In previous editions of this work we gave the known data, and anyone who cares to look at the pages from 91 to 97 in the second edition of this book will observe how confusing and contradictory are the results, while they will be struck with the relative paucity of these results. The truth is that the earlier observers omitted to take into consideration the atmospheric humidity, and this alone vitiated their conclusions.

Our own observations agree with those who have failed to show any change in the bodily temperature in passages to and from the tropics and in residence therein, provided that the individuals observed were normal.

Further, we have failed to observe any difference in the temperature between well-nourished healthy natives and Europeans, and with due allowance for individual and seasonal differences and the effects of exercise and clothing.

In previous editions we have consumed much space with discussions as to the pulse-rate, and so as not to weary the reader, we may say that we do not believe that there is any change in the pulse-rate of normal Europeans on entering or residing in the tropics, nor is there any appreciable difference between them and natives.

Bussière recently has invited attention to the action of cold on tropical natives brought straight to temperate climates, which tends to produce attacks of malaria, liver troubles, and inflammation of the bronchi and lungs. He especially lays stress on temporary albuminuria yielding to treatment in some one to three weeks

Effect on Respiration. As we have no personal experiments to record with regard to respiration, we give the work of other observers.

Rattray studied very fully the influence of tropical climates on respiration, and gives a table showing their effect on the capacity of the chest, as indicated by the spirometer, on a voyage from England to Bahia and back. The average of twelve observations is as follows (hygrometer indicates the difference between the wet and dry bulb of a Mason's hygrometer):—

Number of Persons, 12	*Temperature* 65° F., *Hygrometer* 2·5° F.	*Temperature* 78° F., *Hygrometer* 1° F.	*Temperature* 83° F., *Hygrometer* 4° F.	*Temperature* 65° F., *Hygrometer* 1·5° F.
Capacity of the chest as shown by spirometer ..	256·083	280·75	287·416	260·25
Gain or loss ..	—	+24·833	+6·5833	−26·333
Percentage gain		9·24		

The increased capacity, according to Rattray, is not due to any actual increase in the capacity of the size of the chest, but to a diminished quantity of blood in the lungs, which he considers has been diverted to the excited and congested skin and liver.

His results may be summarized by saying that the vascularity of the lungs is reduced by 23 fluid ounces, and owing to diminished number of respirations 7·5 per cent. less air is used daily, and 1·1 ounces less carbon, and 4·5 per cent. less aqueous vapour excreted.

With regard to these observations of Rattray, he is apparently supported by all observers as to the increase in capacity when Europeans enter the tropics. Jousset, however, states that this is only temporary, and disappears after acclimatization.

Rattray maintained that there was a diminution of capacity when a native of the tropics went to the Temperate Zone, and gave the following table:—

Condition.	*Race.*	*Temperature 79° F.*	*Temperature 78° F.*	*Temperature 32° F*
B. C., aged twenty-one; height, 5 feet 5½ inches	Native of Sierra Leone	210	207	185
J. C., aged twenty; height, 5 feet 4 inches	Native of Sierra Leone	171	166	156
J. W., aged thirty-one; height, 5 feet 4 inches	Half-caste	[illegible]	162	

He found that the frequency of respiration was slower in the tropics, as is shown in the following table:—

Climate		*Mean Shade Temperature*	*Highest Number of Respirations*	*Lowest Number of Respirations*	*Average Number of Respirations.*
England	Summer	62° F	18	13·5	15·08
	Winter	42·25° F	17·5	15	16·50
Equatorial doldrums	Outward..	78·74° F	14·5	11	12·74
	Homeward..	78·60° F	15	12	13·71

Jousset, Plehn, and others controvert Rattray's statement that the respirations are slower, believing, on the contrary, that they are augmented before acclimatization.

This shows clearly that the question is far from settled, and, in fact, requires reinvestigation.

Effect on Circulation.—Rattray investigated the pulse-rate carefully, and gives the following table:—

Time	*Number of Observations.*	*Tropics.*				*Temperate Zone.*
		Lowest	*Highest*	*Range.*	*Average.*	*Average.*
9 a.m. ..	53	66	112	46	86·4	91·7
3 p.m. ..	53	66	108	42	86·8	88·1
9 p.m. ..	49	73	110	37	87·3	90·5
Averages	—	—	—	—	87·5	90·1

He gives the following conclusions:—

1. The average pulse is lower by 2·5 beats in the Tropics than in the Temperate Zone.
2. This change holds good for the average morning and evening pulse.
3. The average afternoon pulse is higher in the Tropics than in the Temperate Zone, probably because the solar heat is greatest then.
4. The morning pulse has the greatest and the evening the lowest range.

He considers that this reduction in the pulse-rate is related to the diminished respiratory function. Parkes, Jousset, Crevaux, Feris, and Plehn, according to Huggard, maintain, on the contrary, that the pulse is increased by ten beats per minute. Plehn says, however, that on acclimatization the pulse-rate sinks to normal.

There is said to be a lowering of tension (associated, according to Huggard, with the dilatation of the peripheral vessels), as well as increased elasticity and dicrotism, all of which probably pass away on acclimatization.

Chamberlain in the Philippine Islands concludes that the average blood-pressure, measured by a Cook's modification of a Riva-Rocci's apparatus and a 12·5 centimetre armlet, in Filipinos and Americans of the same age dwelling in those islands, does not appreciably differ from one another, nor from that of similar Americans in the Temperate Zone, but that the pulse-rate of active Filipinos and Americans is a few beats above the usual standard of 72 per minute.

In our experience, in Europeans coming to the Tropics, the pulse-rate is *occasionally* slightly increased. This disappears after acclimatization, and the pulse-rate becomes the same as in Temperate Zones. We have never noticed dicrotism of the pulse in normal individuals.

As regards natives of the Tropics, it is stated by some authorities that their pulse is quicker than in the inhabitants of Temperate Zones, but we are unable to confirm this, and find it to be the same as in Europeans.

Effect on the Blood.—Mitchell, as the result of his work in the Persian Gulf, considers that damp heat *of itself* frequently produces anæmia, but gives no details of the blood examinations. In 1916 W. M. Strong, noting that persons who had lived for long in the Tropics became anæmic-looking, investigated this point, and concluded that the pallor was not due to deficiency in hæmoglobin nor to ischæmia of the cutaneous capillaries, but to pigment deposited in the epidermis, which becomes partially opaque to red light, which is important because the colour of the skin depends upon the relative amount of each spectral tint which is reflected back to the eye. Further, he considers that when more pigment is deposited the skin becomes yellow-brown.

The 'Arneth count' (see p. 1898) in healthy native children has been investigated by Breinl and Priestley; taking the figure for normal Europeans as 40, native children varied from 71·0 to 83·80, while in adult natives it stood at 74·04. They are of the opinion that the alteration of the blood picture is the outcome of climatic influences, and not, as suggested by Scott-Macfie, as the outcome of abortive inoculation with malarial parasites, though they think that the higher figure—viz., 83-86—may be accounted for by infection.

Sweet agrees that high 'Arneth index' is very regularly present in healthy children over the whole coastal area of Eastern Australia; he maintains that no factor apart from disease is found definitely to influence this index, but he says that external temperatures do apparently influence the index in animals, and that further research is required with reference to this in man.

We are disinclined to believe in a marked anæmia purely and solely due to climatic influences without any other causal factor, but diminished resistance against disease is certainly produced by long residence in the tropics, and is probably largely climatic in its cause, though food may also be a causal factor therein; but the chemical factors of resistance to disease still require investigation.

With regard to the sugar content in the blood, McCay finds that for Europeans it is 0·08 per cent., while for Bengalis it is 0·13 per cent., and the increase appears to be entirely due to the excessive amount of the carbohydrate in their diet. In the fat indolent classes it is 0·150 per cent., while in the poorest classes it is only 0·125 per cent., and he points out that there is a very close relationship, other things being equal, between the sugar content in the blood and the amount of fat deposited in the tissues, which again is a dietetic and not a climatic effect.

Effect on Digestion. With regard to the alimentary canal there is often less appetite and less desire for animal food, and greater demand for spiced articles of diet, all of which show a tendency to lower power of digestion; but we are convinced that the tropical hyperæmia, other than alcoholic, is a myth, and we base this statement on a large number of clinical and pathological observations spread over a period of some twenty-one years.

There is, however, one point to which special attention should be drawn, and this is to the danger of constipation in tropical climates with low humidity, and to the necessity of imbibing daily a sufficiency of water to combat the loss of moisture from the skin. This tendency to constipation in healthy people in very hot dry climates is usually aggravated by the difficulty in obtaining fresh vegetables and fruits in those regions during the driest times of the year. Constipation, if allowed to become chronic, may cause passive hyperæmia, but this is pathological, and due to the lack of free evacuation of the bowels and not due directly to the climate.

Effect on the Nervous System. It appears that the cells of the nervous system obey the general law that vital activity is increased with a higher temperature, but only up to a certain point, after which their functional activity becomes markedly depressed. This is the case in most Europeans, though a great deal of mental and physical work can be done in the tropics if the bodily health is maintained. Natives naturally are less prone to feel the depressing effects of continuous high temperature.

It is possible that this condition, together with the effect of the actinic rays of the sun, may result in weakening the control of the higher centres over the lower, and thus inducing outbursts of what Plehn calls 'tropical fury' (*Tropenkohler*), by which he means fits of passion caused by trivial incidents. This is seen not only in Europeans, but in natives, who are apt to do violent deeds under the impulse of unreasoning anger. It appears to be one of the causes of assaults and violent crime in certain parts of the Tropics.

Effect upon the Urinary System.—Urine is diminished in quantity in the tropics, and this is said to be due not merely to diminution of water, but also of solids, among which urea and chlorides may be noticeably mentioned. Lawson says that the pigments are increased.

The diminution of the urine is very markedly noticed in hot dry climates and should be carefully combated by drinking a sufficiency of watery fluids because of the danger of lithiasis.

Effect on the Generative Organs.—The generative organs act more vigorously in the tropics, but venereal excess is distinctly more deleterious than in the Temperate Zone.

Menstruation begins about one year earlier in European girls living in the tropics than in those living in the Temperate Zone. For instance, it begins in 48·4 per cent. at thirteen to fourteen years of age, and in 50·07 per cent. at fifteen to sixteen years of age. Eurasian and East Indian girls, according to Das, mostly begin to menstruate at thirteen years (54·8 per cent.), though a considerable number do so at twelve years (18·6 per cent.). Natives of India mostly begin about eleven to twelve years of age (63·51 per cent.), and high-caste Indian girls begin in their eleventh year (50 per cent.) or twelfth year (48 per cent.); but this early menstruation may be associated with child-marriage rather than climate. Puberty in boys appears at an earlier age than in temperate climates.

There appears no reason to doubt that the climacteric is a more trying time for the European woman in the tropics, and tends to produce neurasthenia. If possible, therefore, such a woman should be sent to the Temperate Zone during this period.

It is possible that fertility is not affected in Europeans, though there is some doubt on this subject, and evidence is increasing that it greatly decreases after the second or third generation. Abortions are said to be more common in the European in the tropics than in the Temperate Zone, and post-partum hæmorrhage is also said to be more common, but these statements require careful investigation before being accepted.

Effect on Growth.—Rattray made observations on the weight and growth of forty-eight naval cadets, aged from fourteen and a half to seventeen years, during four successive changes of climate during a voyage. He considered that they grew too rapidly and lost weight considerably in the tropics, and that their strength and health was impaired by the heat.

These conclusions of Rattray's are of the greatest importance, showing clearly the necessity (well known) of sending European children as soon as possible to live in the Temperate Zone, not merely, as some writers assert, for education, but, much more importantly, for their health.

Effect on the Skin.—The cutaneous system in all tropical regions is flushed with blood, and in the damper parts is more or less covered with visible sweat, which is apparently suitable for the growth of fungi.

In the dry hot climates the skin is dry, and in persons who possess few layers of horny cells it is liable to become inflamed and cracked. The hair, particularly on ladies who have resided some time in the dry tropics without a change, is apt to fall out.

PRESSURE.

The atmospheric pressure at different localities scattered all over the world may be measured by the barometer, due care being taken to correct the reading for index error, capacity, capillarity, temperature, and altitude; and the data so obtained may be entered on a map of Mercator's projection of the world, and finally points of similar pressure, as indicated in this map, may be joined together by curves, thus producing an isobaric chart.

The result of this investigation shows that, generally speaking, at sea-level there is high pressure at about 30 degrees north or south of the Equator, and that from this the pressure decreases towards the Equator.

The reason why the pressure is low at the Equator is partially due to the heating of the air by the sun's rays, but more especially to the considerable addition of aqueous vapour to the air in these regions, with the result that it ascends with considerable force, and goes on ascending to very high altitudes, owing to repeated warming from the condensation of aqueous vapour and the liberation of latent heat.

Though the pressure at 30 degrees is higher than that at the Equator at sea-level, it is considerably less than at higher altitudes. Consequently air passing upwards from sea-level at the Equator into higher strata will then flow either north or south towards 30 degrees; but as it flows it is compressed as the latitude increases, and hence the current of air flowing polewards becomes narrower and narrower, and finally, owing to this, is forced down by the increasing pressure, until it reaches sea-level at 30 degrees north or south, causing the high pressure about this latitude. This compression is helped by the cooling of the air as it proceeds polewards, and by the centrifugal force of the earth's rotation.

Apart from this general distribution, there are diurnal and annual variations in the pressure. The diurnal variation of pressure is best marked in the tropics, diminishing as the Poles are approached —*e.g.*, at Calcutta it is 0·12 inch, whereas at Greenwich it is only 0·02 inch. The cause of this diurnal variation is the heating of the air by the sun, but there is also another cause, producing, according to Blandford, a variation of 0·1 inch in India, and acting twice daily, the nature of which is not known.

The cause of these seasonal variations in the pressure is the heating or cooling of the land, which, in the case of Colombo, is associated with the monsoons. Thus, the low pressures occur in the season of the south-west monsoon, May, June, and July, when air is travelling from high pressure at the Equator to low pressure in the warm plains of Asia; and the high pressures are associated with the north-east monsoon, when air is travelling from the cold plains of Asia, where it is at considerable pressure, towards the Equator, where the pressure is less.

Effects.

The effects on mankind of the slighter variations of atmospheric pressure are quite unknown and unstudied, scientifically, as far as we know, though the subject merits careful research. It is possible that they are without effect, because they decrease with altitude in the same ratio in which the pressure diminishes, but without producing any obvious effect from a climatic point of view. When atmospheric pressure is increased considerably, as in the use of special apparatus for deep diving and in the caissons filled with compressed air which engineers use to lay the underwater foundations of bridges, then a series of symptoms are produced which are called caisson disease, and to this we shall refer in a later chapter, as the conditions are pathological and not physiological.

There is also the condition of diminished atmospheric pressure which is found in mountain climates. Thus, if the pressure at sea-level is 762 millimetres of mercury at 25° C., then at an altitude of 500 metres, and at the same temperature, this becomes 720; at 1,000 metres 679; at 2,000 metres 604; at 3,000 metres 530; at 4,000 metres 475; at 5,000 metres 420; and at 6,000 metres 370. But if the temperature at 5,000 metres were 0° C., instead of 25° C., then the pressure would be 394 millimetres, and at 6,000 metres 343 millimetres; while at 3,000 metres it is 517 at 0° C., and 536 at 25° C.

It must therefore be noted that the mean pressure is *not* the same at similar altitudes in the tropics and in temperate climates, but somewhat higher.

Mankind can live and has formed permanent habitations in Tibet at places over 4,900 metres above sea-level, and Hahn states that in the Bolivian province of Chichas people live at an altitude of 5,000 metres.

Hahn, quoting Pöppig and Reck, states that natives living on the high Andean plateaus suffer from certain disagreeable effects, but we have been unable to find what they mean exactly by this expression.

Mountain sickness belongs to the pathological portion, and will therefore be considered later; and all we can write with regard to the physiological effects of pressure is to invite the attention of observers, who live at or visit high altitudes, to the great lack of accurate information with regard to these matters.

WINDS.

The motion of the air in passing from regions of high to those of low pressure constitute the winds, which may be classified into permanent, periodical, variable, and local.

Permanent winds are caused by the expansion of the hot equatorial air which rises to high altitudes and passes polewards.

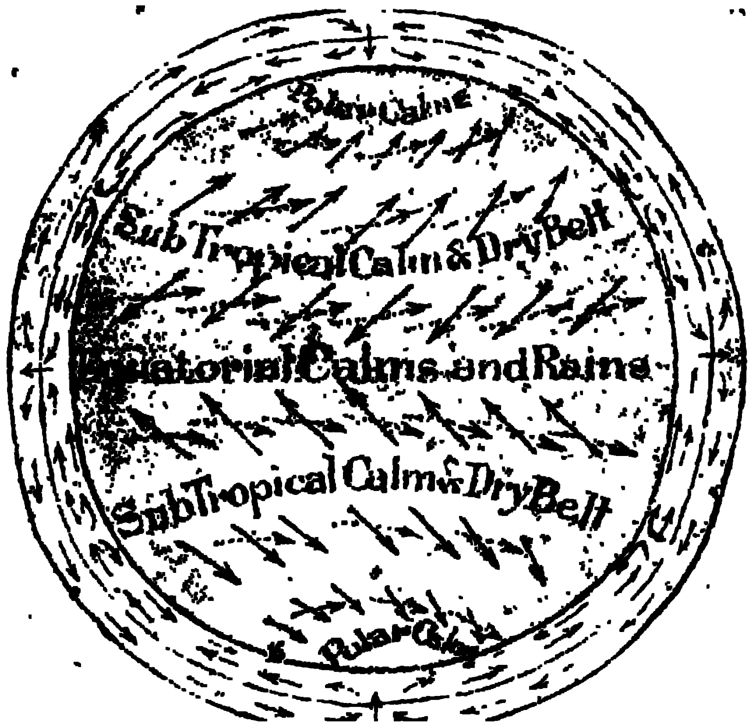
If Fig. 7, which demonstrated Ferrell's latest ideas as to the circulation of the air, be studied, in general it will be noticed that the zones of equatorial calms and rains are indicated, as well as the zones of subtropical calms and drought.

The unbroken arrows indicate the surface winds, and the broken arrows the upper currents. The margin of the circle shows a vertical section of the atmosphere in which the arrows indicate the movements. The equatorial area is marked in the centre.

If this figure be carefully examined, it will be seen from the section of the atmosphere on the sides of the figure that the heated air rises over the Equator to high altitudes, and flows to the poles;

but at lesser altitudes it descends in the region of subtropical calms, and either passes polewards or to the Equator. Within the area from 0 to 30 degrees there are winds called the 'trades,' which blow from 30 degrees towards the Equator, and which on reference to Fig. 6, can be noted as north-east trades and south-east trades, and it will also be observed that the only portion of the ocean free from them is the North Indian Ocean, where the south-west monsoons occur. The north-east monsoon is really a trade-wind.

Further, it will be noted that as the air moves in opposite directions along the surface in the region of latitude 35 degrees, there is an absence of prevailing winds. These belts of calms are called 'the subtropical belts,' or the calms of Cancer and Capricorn. Again, at the Equator there are calms for the same reason, and these are often called 'the doldrums.'



Polar Calms

Polar Calms

FIG. 7.—DIAGRAM OF THE CIRCULATION OF THE ATMOSPHERE.
(After Ferrel.)

The trade-winds are only to be seen typically in oceanic regions, where the temperature is equable, and there are no local conditions to cause them to deviate from their course. But they, together with their intermediate zones of calms, shift their positions according to the temperature, having, therefore, different areas in such months as March and September. On an average the north-east trades extend from 7 degrees to 29 degrees north in the Atlantic, and the south-east to 20 degrees south. During the summer they advance a few degrees north, and in the winter recede to the south. In spring the centre of the doldrums is only 1 to 2 degrees north of the Equator, while in summer it is about 9 or 10 degrees north latitude, and, as will be explained later, the tropical rains of certain regions depend upon this movement. Their easterly direction is due to the rotation of the world.

Periodical winds are the movements of the air produced by the alternate heating (by the sun) and cooling of large tracts of lands, and the most important of these are the monsoons; to which reference has already been made.

Variable winds are found in the regions of calms interposed between the trades in the Atlantic and Pacific Oceans.

Local winds are of great importance in the tropics, constituting the so-called land wind, sea breeze, mountain wind, etc., and several others to be referred to later, to which special local names have been given.

The wind about which a great deal is spoken in every tropical country is 'the land wind.' During the day the land becomes heated by the sun, and causes the air to rise, thus lessening the pressure, and drawing the air from the sea, causing a sea breeze, which is, of course, very humid. During the night, however, by terrestrial radiation, the land becomes cooler than the sea, and the air travels from the land to the sea, and constitutes the land wind. This wind, as a rule, is dry, and has a very deleterious effect on men and animals by extracting moisture and abruptly cooling the body, and thereby lowering the resisting-power to disease. Hence the complaints made by old residents about the land breezes. On the other hand, new-comers delight in them, because they are so cool.

This land wind is more marked at certain seasons of the year than at others, being particularly felt in Colombo in those months when there is less cloud, because the terrestrial radiation is then more marked. There is, however, nothing like a definite season for a pronounced land wind, for it can take place at any time, only depending upon terrestrial radiation.

A few remarks may be useful with regard to some local winds:—

The Sirocco (Italian, *scirocco*).—The sirocco is a south-east wind with a high temperature, which, coming from the high land of North Africa, descends to the Mediterranean, and may reach Malta and some parts of Italy. It is considered to be very enervating.

The Solano.—The solano is a south-easterly wind, blowing from the Sahara into Spain.

The Harmattan.—The harmattan is a hot easterly wind, coming from the Sahara Desert, and carrying dust far out into the Atlantic.

In the months of November to March this wind meets with the north-east trade in its most southerly position, with the result that it is deflected southwards down the west coast of Africa. It is a very dry wind, and therefore extracts moisture from everything it comes across. Hence human beings feel their skin dry and hard, and may suffer from bleeding from the nose and lips while furniture creaks and groans in a most supernatural manner.

The Khamsin.—The khamsin, or khamseen, is the dust-laden wind which blows from the Sahara into Egypt at intervals during fifty days about Easter-time, and is very disagreeable, especially when associated, as it often is, with high air temperatures, when it may produce pathological changes in persons in poor health situate in places unsuitable for bearing heat, such as railway trains.

Pamperos.—These are the south-westerly winds of Brazil. Europeans have altered the significance of the name to squally cyclonic winds in the same vicinity.

Ghibli.—The ghibli is a violent south or south-east wind blowing into Tripoli from the desert, and carrying with it a quantity of sand, which causes irritation to the conjunctivæ and which may induce nervous symptoms.

The Foehn.—Though essentially a temperate or cool climate wind, still the foehn exists in the tropics. The foehn is to be seen in its home, Switzerland, as a warm dry wind which blows with great violence downwards from the crest of the Alps, and has marked effects upon man and animals, as it has a depressing effect upon the mind and the nervous system. It was thought at one time that this wind came from the Sahara, but all evidence is against this, and the present idea is that it is a local wind which is produced by a high south-east and a low north-west pressure, and attains its high temperature as well as its dryness in its descent from the summits of the Alps on their northern side, and less typical on the southern aspect when the pressure is high in the north-west and is low in the south-east.

Foehn-like winds occur in Trebizond, and on Lake Urmia, in Persia, where it is called *samum*, and blows down the eastern side of the New Zealand Alps on to the Canterbury Plains.

It also occurs at Resht, on the southern shores of the Caspian Sea; also in South Georgia, as well as in the Andes and at Kanazawa in Japan.

We have, above, given the usual explanation of the sirocco, but it must be noted that it is probably a 'foehn' wind, for Brydone, many years ago, noted that in Sicily it could not possibly come from the Sahara, because it would have been most violent on the south coast, whereas it is actually at its greatest violence on the north coast, especially at Palermo.

The 'sirocco di Levante,' between Pylos and Kyparissia, is also a 'foehn' wind, as is the sirocco of Algiers, and probably the solano of Spain and the vent d'Espagne on the northern aspect of the Pyrenees.

Cyclonic Storms.—Besides ordinary winds, cyclonic disturbances called storms occur. Cyclonic storms receive different names in various parts of the world, being called cyclones in India, Ceylon, and Mauritius, hurricanes in the West Indies, typhoons in the China Seas. Mild cyclonic storms met with on the West Coast of Africa and elsewhere are called tornadoes.

Electrical Conditions.

Silent electrical discharges are frequent in the tropics, and the acidity which they produce is supposed to be the cause of devitrification, which is so trying to persons working with all except the best microscopical and other lenses.

Thunderstorms of astonishing violence are frequent in many parts of the tropics, and generally cool the atmosphere for the time.

It is a popular belief that the electrical condition of the atmosphere has some influence upon life, but if this is so then it is an untrodden field, as far as we know, for we have been unable to find any definite scientific observations which can confirm or refute the popular belief. Hahn considers that there is no indication that atmospheric electricity plays a notable part in climatology.

Sun's Rays.

Sunlight contains heat rays (red), light rays (yellow), and chemical rays (blue, violet, and ultra-violet); that is to say, rays extending from the infra-red to as far as 291 $\mu\mu$ in the ultra-violet (Gibbs), but is much influenced by latitude, longitude, altitude, and the daily and hourly varying local meteorological conditions.

These rays reach the earth, according to Langley, in the following percentages:—

	Per Cent.
Ultra-violet	39
Violet	42
Blue	48
Greenish-blue	54
Yellow	63
Red	70
Infra-red	76

Freer, Gibbs, and Bacon have shown that, though the tropical light of Manila contains few, if any, more ultra-violet rays than the Temperate Zone, still the chemical rays have more effect there than in a temperate climate, and these effects vary on different days. Freer distinguishes 'actinic' and 'non-actinic' days, on both of which the sky may be equally clear. The cause of the difference between an actinic and non-actinic day is not understood. Gibbs does not believe that the normal intensities of the light in the tropics is different from that of any other region, the influence of local meteorological conditions being excluded, the most important of these being the humidity. Aron suspects that the deleterious influence of tropical sunlight is due to the long heat waves rather than to the short chemical waves, which we will now consider.

The chemical rays appear to have, first, a stimulative and beneficial influence, and, secondly, a harmful influence.

Stimulative Influence. Finsen, by experiments upon tadpoles, earthworms, beetles, flies, etc., came to the conclusion that the action of the chemical or blue-violet rays was very considerable as compared with light (yellow) or heat (red) rays, and that, though their action was probably very complex, still, it could be best considered as an excitation of the nervous system.

This excitation was so powerful as to produce reflex actions in tadpoles and movements in other animals, while in man he considers them to be the cause of the feeling of *bien-être* experienced on a bright, sunny day, which he compares with the depression felt on a dark, cloudy day.

Bactericidal Properties.—Downes and Blunt in 1877 showed that the chemical rays could kill bacteria, while D'Arsonval and Charrain showed that they could kill the *Bacillus pyocyaneus*. In 1903 Bernard and Morgan demonstrated that it was the middle third of the ultra-violet portion of the spectrum which caused these bactericidal effects.

Harmful Influences ACUTE SKIN IRRITATION.—Charcot in 1859 first expressed the opinion that it was the chemical and not the heat rays which produced sunburn, and showed that the dermatitis caused by strong electric light was identical with that caused by the sun.

In 1889 Widmark proved this definitely by using an electric arc of 1,200 candle-power, the light of which was first passed through water to absorb the heat rays, and then allowed to fall upon the shaven skin of a white rabbit, when the characteristic inflammation resulted. He then interposed a plate of ordinary glass to exclude the ultra-violet rays, when the skin remained unaffected.

In 1901 Finsen placed on the flexor surface of his forearm a plate of rock-crystal and pieces of different-coloured glass, and also wrote his initials in Indian ink. He then exposed the arm to the rays from an 80-ampère arc for twenty minutes, ten minutes at a distance of 50 metres and ten minutes at 75 metres. The result was that first all parts were slightly influenced by the heat, and then those parts which were unprotected or covered with rock-crystal became red and inflamed, and later desquamated and became pigmented, while the parts covered by glass and Indian ink, after the slight initial inflammation due to the heat, did not further react. This experiment is interesting as showing that the effects due to heat appear at once and pass off quickly, while those due to the chemical rays do not begin until after a lapse of three hours, which agrees with the well-known fact that a sunburn takes some time to develop.

Freund, as the result of his experiments, concluded that the chemical rays penetrated into the skin. Bernard and Morgan found that the ultra-violet rays were the active agent in producing sunburn.

The histology of solar erythema is not well known. Leredde and Pantrie made a biopsy on the skin of the shoulder of one of their friends who was suffering from sunburn of three days' duration. The skin was in a condition of acute erythema, without œdema or effusion. Under a low power of the microscope the epidermis appeared normal in thickness and disposition, but the horny layer was exfoliated in places. The dermis was richer than normal in cellular elements, and the connective-tissue bundles were swollen. Under a higher power the intercellular spaces appeared larger than normal. The vessels of the dermis were dilated, and there was a slight leucocytic infiltration, while the connective-tissue cells were swollen. These appearances are exactly like those produced by the rays of an electric light.

If the sun's action stops at this, the only change will be the deposit of the yellowish-brown pigment in the skin so well known in the tropics. If, however, the action is more intense, an exudation appears, which may be sero-fibrinous, cellular, or bloody, while the depth to which these changes may extend depends upon the intensity of the light. The epithelium becomes swollen, and bullæ may form, and the connective tissue of the dermis be swollen.

The pigmentation of the epidermis is important, and will be referred to at greater length in the next section.

Chronic Skin Irritation.—The chronic effects produced on the skin by the chemical energy of light are:—

(1) Pigmentation.
(2) Vascular modification.
(3) Disease.

(1) *Pigmentation.*—It is well known that pigmentation follows sunburn, but until recently it was not evident that it was of a protective nature.

In 1888 Wedding, confirmed by Charcot, first made this point clear, though Unna in 1885 was the first to say that it was to be regarded as useful, inasmuch as it prevented the rays penetrating too deeply, thus preventing inflammation.

In 1896 Finsen painted a black ring 2 inches wide round his arm with Indian ink to imitate the colour of a negro's skin, and then exposed it for three hours to a very hot sun. For a time the skin remained normal, showing only a little redness at the edge of the black paint, but in due course it became red and inflamed, except where it had been painted black. After several days the erythema disappeared, and the area which had been red was noticed to have become distinctly pigmented, or, in plain language, was sunburnt.

He then exposed it again to the sun, but this time the area which had originally been covered with Indian ink was unprotected. The result was that this part became red and inflamed, while the pigmented area was unaffected, except that it became a little more pigmented.

This experiment of Finsen's shows that the colour of native races living in the tropics is protective, and was possibly originally induced by the sun. Sambon and Baly found that the ultra-violet rays were entirely absorbed by a pigmented piece of skin, and therefore support the theory that pigmentation affords an efficient natural protection against ultra-violet rays.

Dyson studied cutaneous pigmentation in 1911, and concluded that the formation of melanotic pigment was a normal function of the nuclei of the epidermal cell, metabolism being due to a lipochrome, in which melanin is the chromatic protein portion. This pigment passes to the cutis by way of the lymph stream. The formation of the pigment can be increased by agents such as light, heat, and toxins, but the increase is usually transitory and tends to disappear; but if there is deficient drainage of the lymph from the cutis the pigment accumulates, and unless the drainage is improved tends to become progressively worse. Decreased vitality of the cells may possibly cause the overproduction of pigment due to diminution in nutrition, but if the cells become functionally inactive then pigment production ceases, and the existing pigment being carried away by the blood-stream, the part becomes depigmented, which is probably the case in vitiligo, in which, after hyperpigmentation, the skin becomes depigmented.

That the dark pigmentation is useful is shown also by the observation made by us on various occasions that natives suffering from leucoderma avoid going into the sun, as they state that the unpigmented portions of the skin become inflamed and painful. In this connection, an interesting case showing the importance of these rays came under our notice. A native, who had developed large leucodermic patches involving the whole of the face, noticed that he could no longer work in the sun, as each time he tried to do so the patches became painful and he felt sick, very weak, and giddy, and therefore asked to be relieved of his outdoor duties; but it was held that he was still fit to discharge his ordinary duties, with the result that the unfortunate man was compelled to resign his appointment a few months later. It is therefore well that the importance of skin pigmentation should be more widely known.

Generally speaking, in regions where the sunlight is very intense the race is densely pigmented. As a rule, the people who live nearer the Equator are more pigmented than those farther away—*e.g.*, the black colour of the West African can be compared with the red of the American Indian or the yellow of the Chinese. But this rule is not without exceptions, for the

Sinhalese, living nearer the Equator, are distinctly less pigmented than the Tamils of the warmer regions of Jaffna and South India.

There is also not the slightest doubt that the European living in tropical countries becomes darker, a fact which specially applies to the descendants of the settlers. On the other hand, according to Finsen, the dark colour of the negro diminishes to a sensible degree in Europe.

It must be noted, however, that a certain number of Europeans do not become sunburnt in the tropics. On the contrary, their skin, especially in localities where the climate is damp and hot, may take a peculiar whitish colour, even in cases in which the blood examination does not reveal any sensible decrease in the amount of hæmoglobin. As a result of an extended series of observations made by medical officers in the Philippine Islands, Chamberlain reports that the red cell counts averaged 5,200,000 per cubic millimetre in healthy American soldiers, averaging twenty-six years of age, after twenty months' service near sea-level, which count does not differ from the normal as at present recognized for healthy young men in the Temperate Zone. The hæmoglobin averaged 80·6 per cent., and the colour index 0·80 to 0·87, both of which were a little low, but not sufficiently so to indicate a definite anæmia. He believes that the pallor mentioned above is as a rule due to a superficial ischæmia.

The effect of tropical light on man has been made the subject of a special memoir by Woodruff, who points out that all over the globe the people who live nearer the poles are blonder than those residing near the Equator. He thinks that insufficient pigmentation, by permitting the penetration of the chemical rays, conduces to the increased activity of the mind and vigour in the muscles which is found in new-comers in the tropics. This condition of excitation causes them to overdo themselves sooner or later, and so to produce a feeling of exhaustion which he describes as tropical exhaustion.

He further considers that white men cannot become acclimatized in the tropics, and also that they should be protected by clothing opaque to the blue and ultra-violet rays. For this purpose he says that the outer clothing should be white, grey, or yellow, because heat will be least absorbed by these colours, while the underclothing should be black or yellow, to stop the ultra-violet rays. For office-workers and others not exposed to the direct sun-rays he advises black or dark blue, but he states that it is not known whether blue or black excludes the ultra-violet rays.

He also strongly advises opaque head-gear, as he says it is surprising how transparent the scalp and skull are to light rays, and that it is certain that the ultra-violet rays pass through them.

He points out the nuisance of the glare from houses painted white in the tropics, and mentions the better colours of green, dark yellow, and brown. The gradual disappearance of the white buildings in the business part of Colombo, and the appearance of new buildings coloured brown, indicates the correctness of his views.

While it is not possible to agree with all or even with many of Woodruff's statements, there is no doubt whatever that there is a great general truth in what he says, though many of the matters upon which he touches are purely speculative.

On the other hand, there is most urgent need for protection from sunlight both as regards the eyes and the whole body. With regard to the effect of the tropical sun on man and animals, some most interesting experiments have been performed in the Philippine Islands by Aron and Gibbs separately. Rabbits and monkeys—*i.e.*, animals with limited power of physical heat regulation—die if exposed to the sun's rays. The body temperature of these animals rises to febrile heights, while the post-mortem reveals hæmorrhages into the meninges, and in the case of monkeys into the heart. If, however, the increase of heat absorbed from the sun's radiation is compensated by increased loss from the animal by such means as a strong wind, the animal suffers no discomfort. Insolation of the skull alone is without effect if the body temperature is kept within normal limits. Our own experiments showed that rabbits died in about an hour if exposed to the sun with their head shaven, and lived if protected from these rays by means of red glass Aron and Gibbs have also shown that if the human skin is exposed to the sun's rays the temperature of the area so exposed rises as a rule more rapidly and reaches a higher maximum in a dark skin than in a light, until the nerve endings of the latter are irritated by the prolonged exposure. The black skin is protective because it guards the nerve endings from irritation, and because of the more rapid radiation by means of which heat is quickly lost, especially from the area in the shade, which is usually greater in extent than the part in the sunlight Further, it is probable that the relatively greater number of sweat glands in the dark skin is also protective. The air in the human hair, especially in black hair, under the influence of the tropical sun acquires exceedingly high temperatures. There is not the slightest doubt that the pigmentation of native races is protective, and that the older theories of Waltz that carbon was deposited in the tissues owing to imperfect oxidation due to heat, and that of Darwin that it was due to a survival of those best fitted to withstand tropical disease -for he believed that pigmentation prevented the native from being attacked by the fatal miasmata of the country -cannot now be seriously considered.

As to the origin of the pigment, this question must be considered as far from settled. There are two possible sources for the melanin, viz.: --

(a) The hæmoglobin of the blood.
(b) The cells of the epidermis.

(a) *The Hæmoglobin.* -This theory suggests that hæmoglobin is altered into melanin either in the blood-stream, in the connective-tissue cells, or in special melanoblasts, which by amœboid movement take the pigment to the epidermis.

(b) *The Cells of the Epidermis.*--This theory states that melanin is manufactured *in situ* by the epithelial cells, and is not derived from hæmoglobin, and in view of the histology given above this appears to be probably the correct solution of the problem.

Melanosis, which varies from mere freckles through the diffuse yellow and brown pigmentation to the jet-black of the African negro's skin, is caused by melanin granules lying in and between the cells of the epidermis.

With regard to the pigmentation of different races, it must be remembered that it is only absent in albinos, and that it occurs in the epidermis of the areolæ and mammillæ of the breast, the scrotum, labia majora, and around the anus in white races, being contained chiefly in the large basal cells of the Malpighian layer, and to much less extent in the more superficial layers, and the connective-tissue cells of the papillary layer of the corium. In negroes the pigmentation is deeper and more diffusely spread in the epidermis.

(2) *Vascular Modification.*—Associated with pigmentation there is said to be a persistent dilatation of the vessels and capillaries of the skin, and it is stated that hair and nails grow more rapidly in the tropics than in the Temperate Zone.

Light in general is believed to have an effect upon the blood, which absorbs the violet and ultra-violet rays, and the red corpuscles under these influences probably absorb more oxygen.

(3) *Disease.*—With regard to disease, there appears to be no reason to doubt that the irritating effect of light has at least a part in the ætiology of Kaposi's disease (*Xeroderma pigmentosum*), which we have met with in the tropics, where it would naturally develop rapidly in children prone to the disease.

There is also no doubt that these rays play a part in the production of the erythema of pellagra, as will be described later on, and they may have some effect in producing sunstroke.

Woodruff draws attention to the almost universal neurasthenia of white men in the tropics, among whom he says insanity is more common than in Temperate Zones. In support of the latter statement, he asserts that the insanity rate in the Philippine Army in 1901 was 2·02 per mille, while in the United States from 1889-1898 it was 1·13; but he remarks that the diagnosis was not confirmed on the arrival of several of the Philippine soldiers in the United States, as they recovered *en route*. He draws attention to the loss of memory in the tropics (*tropical amnesia*), a condition which is very prevalent on the West Coast of Africa, being often called 'coast memory.' He also mentions the midday siesta as useful in preventing this neurasthenia, and in this he is also probably correct, especially for ladies. Ordinary officials and business men, however, cannot afford to rest in the middle of the day.

Moon's Rays.—The extravagant stories by old writers, and especially the tales given by sailors with regard to the influence of the rays from the full moon, have thrown such discredit upon this subject that we have been unable to find any literature seriously considering the effects of its rays upon man.

Nevertheless, in our own experience, the rays of the full moon do produce headache and a certain amount of nervous irritability in persons who sleep in the open. The subject requires and deserves scientific study.

ACCLIMATIZATION.

Plehn seems to have been the first careful observer clearly to prove that the changes induced in the new-comer as he enters the tropics in due course disappear, and his organs becoming accustomed to the new work demanded from them, he virtually returns to the same condition of temperature, respiration, etc., as in the Temperate Zone—in other words, becomes acclimatized. Further, if constantly exposed to the sun's rays, his skin is apt to become more pigmented than normal, and to afford a certain degree of protection against its rays.

Sambon pointed out long ago that if proper sanitary and other measures against disease were introduced into the tropics, and if care were taken with regard to food, drink, excessive heat, and the rays of the sun, there is no reason why the European should not live healthily in these regions; and this is true to a certain extent, but in our experience the length of residence must be considered, as even with every care he may become debilitated by the direct climatic influences and require a change to a temperate climate, otherwise after a time, the length of which varies much in individuals, his health will be undermined and break down in some way.

The extraordinary success of the American sanitarians in the canal zone of Central America, once one of the most unhealthy regions of the world, but where now the sickness-rate has been diminished to less than half that of the death-rate of many a tropical town is often quoted. We feel that the basis of the largest proportion of illness and death in the tropics is bad sanitation and not climatic influences. Notwithstanding these facts, a permanent colonization of the low lying regions of the tropics by a white race is, in our opinion, not possible, as a uniformly damp, hot climate endured for years diminishes the resistance against disease, and has a markedly deleterious effect on the nervous system. Fertility probably also decreases after the second or third generation. The climate greatly deteriorates the physique of the children, as can easily be observed in any district of the tropics at sea-level. In the highlands, such as some parts of British East Africa, colonization by a white race may be possible, though Van Standel has pointed out that prolonged residence in tropical highlands produces changes in the nervous systems of the second and subsequent generations, even if it does not do so in the first.

These remarks in general agree with Caddy's work, as he considers that the European is unable to rear strong healthy children in India, and that even those which are sent home, when four or five years old, owing to the debilitating influences of the tropical climate at an important growing period, are not so fine physically as their parents.

If, however, the new-comer into the tropics desires to become acclimatized he must use some protection for his head, and in many cases for his spine and eyes; he must wear suitable clothing, live in suitable houses, work in suitable offices, dwell in sanitary surroundings, avoid alcohol and exposure to the midday sun, while roads in common use should be suitably constructed and well shaded.

It is not within the province of this work to go into detail with regard to these matters, but a few brief remarks may be made.

Suitable Head-gear.—All Europeans should wear a light helmet or topee covered with white or khaki-coloured cloth externally and ventilated. This helmet should have a broad brim lined with green and prolonged down the back of the neck, should be lined internally with red, or red and yellow, or black, and should possess an internal band attached in such a manner that the head does not touch the frame of the hat, while it allows free circulation of the air.

When persons are compelled to work under the tropical sun and to expose their backs to its rays, a thin strip of yellow and red coloured silk should be sewn into the shirt along the spine, or attached to the inner aspect of the coat by means of hooks and eyelets. Eyes should be protected with dark glasses, or with Sir William Crookes' non-actinic glass with side-pieces.

Ladies who are particular about the skin of the face should wear veils, though these are very warm.

The reasons of these requirements are, while white reflects heat very well, and absorbs very little, and is therefore excellent externally, yet it transmits the chemical rays, while red and yellow absorb them.

Clothing.—Clothing should be loose and as light as possible in weight, and of a white or khaki colour externally. Sambon some years ago devised a cloth, called 'Solaro,' khaki-coloured externally and red internally, with the object of preventing the action of the sun's rays on the body. It is made by using threads of yellow and blue twisted separately and together for the warp, while red threads are used for the weft, but these latter are brought back in the proportion of three to one, so that the front has three yellow and three blue threads to one red thread, thus producing the khaki colour. It should only be used as a coat, and should be obtained as thin as possible, and made up as lightly as possible without linings or doublings. The general opinion at the present is, however, that white is by far the best colour.

As regards underclothing, we are of the opinion that thin woollen materials are the best, but we are not in favour of openwork underclothes. At the present time the use of abdominal woollen or flannel belts (so-called 'cholera belts') is much abused; they are useful, however, to people with a tendency to intestinal disorders.

It should be remembered that when clothing is wet it is a good conductor of heat, and hence the risk of sitting down in damp clothes. Clothing should not be too heavy, nor too tight-fitting. Ladies should not wear too heavy skirts, which congest the pelvic viscera.

A silk hat and frock-coat have still to be worn by men at official functions at midday, but the custom is unfortunate, and may perhaps in time disappear.

Houses, Offices, etc.—Buildings should never be painted white or blue, but should be of a dark red colour. The amount of light admitted to a room should be restricted, and care should be taken that reflection from the ground into the room does not take place. Deep verandas, without which no building in the tropics is comfortable, are of the greatest value in controlling the light, as are tatties or tats made of grasses and wood, and jalousies.

Rooms should be capable of being cooled by punkahs or fans, and should be lit with electric light whenever possible. Ice-blocks are very useful in very warm weather or at meetings, or in sick-rooms. The walls of rooms should be painted rose-colour, not white.

Damp courses are required in the tropics, as walls are apt to absorb moisture and become very damp. Round roof-tiles and ventilated double ceilings are necessary to keep off the sun's rays.

Roads.—Roads should be protected from the glare of the sun by shade-trees—that is to say, trees with spreading branches—while plots of green grass are most valuable in towns. There is not the slightest doubt that red roads are the most comfortable for the eye and soothing to the nervous system, and that white roads are exceedingly trying to both.

Avoidance of the Midday Heat.—If possible, travelling and muscular exertion should be done in the early morning or late afternoon, and avoided in the middle of the day, when a siesta is most beneficial. The absurd custom of making social calls at 12 noon in certain parts of the tropics should be discouraged, and a more reasonable hour substituted.

Avoidance of Alcohol.—Alcohol should never be taken before the sun goes down, for it unfits the individual for work, and is the most important predisposing cause of sunstroke.

REFERENCES.

The most suitable work for the tropical practitioner is Hahn's 'Handbuch der Klimatologie,' of which there exists an English translation of Part I. 'General Climatology,' by Ward, but unfortunately there is no such translation of Band II., 'Klimatographie,' Teil I., 'Klima der Tropenzone,' of which the third edition appeared in Stuttgart in 1910, which is the only work, with which we are acquainted, which deals with the climatology of the various tropical countries in at all a full manner.

A much smaller but very excellent work is Ward's 'Climate,' in the Progressive Science Series, published in 1908, and also Giles' work mentioned below. Chamberlain (1913), Annual Meeting of the American Society of Tropical Medicine, May 6, 7, and 8, Washington, is an excellent paper with full references.

CHAPTER IV

TROPICAL FOODS

Preliminary Remarks—Evolution—Chemical composition—Quantity—Quality—Tropical food materials—Calculation of diets—Low protein dietaries—Vitamines—Lipoids—Less known matters—References.

PRELIMINARY REMARKS.

It is not our purpose to attempt to give an account of the foods found in various tropical regions, but merely to give a brief summary of some of the more important facts known to us with regard to tropical foods and their effects upon man.

The subject owes much to the labours of McCay in India, while Wilson in Egypt has shown how this work can be extended to other parts of the tropics.

We will begin by tracing briefly the origins of foods as far as we know them.

EVOLUTION.

At the present time human food is everywhere more or less cooked, and it is rare for mankind anywhere to eat, even for a limited period, absolutely raw materials. Dr. Campbell, in a most interesting manner, has traced the evolution of man's diet. He distinguishes first of all the pre-cookery epoch, during which evolving and primeval man lived upon raw materials, unaltered by any of the chemical and physical processes involved in cooking; secondly, the cookery epoch, which may be subdivided into the pre-cibicultural and the cibicultural eras. In the former, although he cooked his food, man did not cultivate vegetal foods, nor did he rear animals for purposes of food. During this period vegetal foods would probably be used in greater quantities than before, as they are easier to obtain than hunted animals; and, also, because the processes of cookery by breaking up the cellulose, rendered them more easily digestible and absorbable, and therefore more nutritious, as well as more palatable. Just as we have already pointed out that certain tribes have remained in the status of the Stone Age almost to the present day, so certain tribes—*e.g.*, the Bushmen of Africa, the true Veddahs of Ceylon, the Andamanese of the Bay of Bengal, and the aborigines of Australia—have remained in this pre-cibicultural era. These peoples obtain their foods from all sorts of animals—*e.g.*, worms, centipedes, flies, caterpillars ants, etc.—as well as from game, while their vegetal foods are collected and stored, but they have never learned to extract any chemical substance—*e.g.*, sugar—from their vegetal foods. Probably this is one of the reasons why they prize honey so highly. In the cibicultural era man cultivated his vegetal foods, and reared domestic animals for the purposes of animal food, and here again his vegetal feeding increased in amount, as this food was the cheapest and easiest to produce. Here again rose the urgent need for salt, to which we have already drawn attention in the account of the migrations of negro tribes.

The arts of cultivation and domestication became gradually dispersed over the world, but to-day it is exceedingly difficult to trace the means by which this diffusion took place, though it is probable that much of it was due to Aryan invasions.

Primitive wheats can be found growing wild in Palestine to-day, and it is probable that the home of this cultivation was Mesopotamia. It also seems likely that the art of bread-making was known to the Chaldeans and to the Egyptians some three thousand and more years before the commencement of the present era.

According to Tibbles, rice cultivation was in existence in China some three thousand years before Christ, and was introduced into India by the Aryan invasion. From India it passed into Europe with Alexander the Great's army in 334 B.C., and from Europe it was introduced into America in the fifteenth and sixteenth centuries.

Maize, on the other hand, was first cultivated in America by the ancient inhabitants of Mexico and Peru, and was brought by the Spaniards to Europe and has gradually found its way all over the world.

Millet appears to have been cultivated from very ancient days in Africa and Asia, and even in [illegible] Stone Age it had extended into Middle and Southern Europe.

Beans were first cultivated by the Aryans, but the haricot bean comes from South America, while lentils are of prehistoric origin, and spinach was apparently cultivated by the Medes and Persians. Onions possibly originated in India, while the potato came from Chile.

Fruit-growing is not as ancient as cereal cultivation.

The domestication of animals enabled man to obtain meat without being compelled to roam over large areas in search of wild game. Man is omnivorous and desires greatly to eat meat, but when this is unobtainable or in too small a quantity to supply the needs of the population, as in the present war, he eats the foods which are available, and is thankful even though they are not those after which his stomach hankers.

The reason why man in Eastern countries eats so much rice must be sought for in the overpopulation of the Eastern Asia of long ago, when the great food difficulties began those large movements of peoples which we have noted in Chapter II.

To-day Governments place peoples on meatless days and give them food tickets, and the peoples obey willingly because they understand the reason, but it might have been extremely dangerous for a despotic monarch of Eastern Asia to have issued orders of this nature long ago. The ruling powers of those days must have invoked the aid of the religious sects, who, being feared and respected by the people, were obeyed; and to-day these religious maxims are still in force, and the people avoid animal food, although the over-population on account of which the rulers probably originated this custom has ceased to exist.

During historic days man has attempted to improve the appearance, the smell, and the taste of his food by all sorts of devices, which vary in different countries. These refinements include condiments and colouring matters, and form part of the basis of the science and art of modern cookery.

But man desires not food alone, but something to cheer and exhilarate him when he feels ill or depressed, and when he wishes to celebrate some occasion; and hence in all countries some form of stimulating liquid is to be found, be it in the form of tea, coffee, or cocoa, of malt liquors, wines or distilled spirits, and all these are of great antiquity.

Early dealers in food materials soon learned that it was profitable to adulterate their merchandise, as this could be done with impunity. Of late, legislation, aided by chemical, physical, and physiological research, is endeavouring to insure that foodstuffs shall be pure, though with regard to some foods, such as milk, the standard is far from perfection, and certainly in the tropics mixed milk can rival sewage in the numbers of its organisms.

With regard to quantity and composition of primitive foods, naturally but little is known, and this little is entirely due to McCay, who has investigated the dietary of the primitive peoples of Chota Nagpur in Bengal. Among those there are peoples who have begun to cultivate the ground, while others still live upon the food which they can gather. Thus the Dravidian Mundas and Uraons eat insects, lizards, snakes, rats, jackals, and pigs—or, in other words, anything which they can catch. Their daily dietary is composed of protein 80 grammes, carbohydrates 500 grammes, and fats 50 grammes, which provides calories 2 800.

The Todas of the Nilghiri Hills live upon milk, the meat of buffaloes and of such animals as they can kill or capture. They take no vegetal food, and hence, like the carnivora, require no salt, which is an essential to vegetal feeders in order to prevent acidosis.

The Bushmen of South Africa and the Bedouin of Arabia are meat eaters.

The necessity for food is to provide heat and energy, and to form new bodily tissues, as well as to make good the wear and tear of existing tissues; and to do this a community requires pure water and plenty of it, and good and varied foodstuffs in quantity proportional to the numbers of the population, a fact which the present war has made clear to nearly every family in the civilized regions of the earth

Dietetics are based upon chemical and physiological considerations, into which we will now inquire very briefly.

CHEMICAL COMPOSITION.

In order to meet the requirements of the body, foods must be composed of the same essential chemical substances as that body. They are therefore made up of proteins, carbohydrates, fats, mineral substances, and water, but these alone are insufficient to keep the body in health, and they must be associated with vitamines and lipoids or nitrogenous fats.

Proteins may be obtained from the muscles, bones, and organs of animals used as food, also from animal products such as milk and eggs, while the many vegetal substances, but particularly legumes, nuts, and cereals, also provide this valuable food constituent. Their primary value is as tissue formers, and their secondary value as heat-energy producers, but all proteins are not of equal value, as we shall see later.

Carbohydrates are chiefly of vegetal origin, and are principally of value as heat-energy producers.

Fats are widely distributed both in the animal and in the vegetal kingdoms, and are essentially heat-energy producers, while the **Lipoids** or nitrogenous fats are indispensable to man, though their exact use is not known.

Mineral Substances are compounds of sodium, potassium, calcium, magnesium, manganese, and iron, either with carbonic, sulphuric, phosphoric, and silicic acids, or with acetic, citric, malic, oxalic, and tartaric acids, or with chlorine or fluorine. They produce no heat or energy, but are essentials for building up the fluids and tissues of the body, in which they represent some 5 or 6 per cent. of the total weight.

Water, forming some 58·5 per cent. by weight of the human body, is an indispensable.

Vitamines are nitrogenous complexes, which are essential for the growth or the well-being of the organism.

The food materials may therefore be classified into the great tissue-forming protein, aided by salts and water, and the great heat-energy producing carbohydrate and fats, aided by protein, and essentials, the work of which is not understood—viz., vitamines and lipoids.

As the heat and energy can be expressed in terms of the calorie (or large calorie written with a capital C), which is the amount of heat necessary to raise the temperature of 1 kilogramme of water one degree centigrade, and as protein is the essential tissue-former, it follows that in calculations as to a diet two matters stand out—viz., the quantity of protein in that diet, and the number of calories which can be obtained therefrom.

Water has a food value of 1 in 1,000, and should be freely available, and salt is usually easily procurable, though we have lived in parts of the tropics in which neither were easily obtained.

Vitamines and lipoids we cannot measure, and at present we are merely concerned with their presence.

Therefore, from a practical point of view, the quantities which require calculation are the amount of protein in a diet and the number of Calories, and this brings us to the subject of quantity.

QUANTITY.

The only accurate method of determining the quantity of the various food factors of any given diet is by means of the *respiration calorimeter*, in which the work done, the heat generated, and the waste products eliminated, are expressed in terms of the Calorie, which, in energy, is the equivalent of 1·54 foot tons, or, in other words, represents that amount of mechanical energy which is required to raise 1 ton in weight 1·54 feet in height.

When the respiration calorimeter is not available, the quantity of the total food consumed by the person or persons under observation should be carefully weighed and records made. Then samples of the various constituents of this diet should be analyzed, with the view of determining the quantity of protein, carbohydrate, and fat contained therein.

With regard to the Calories produced by these various factors, Rubner's experiments upon animals enabled him to enunciate the so-called *isodynamic law*, which states that 227 grammes of protein, or of carbohydrate, yield 930 Calories on consumption in the body, and that this is the same as the heat so produced by 100 grammes of fat, and therefore 227 grammes of protein, or of carbohydrate, are *isodynamic* with 100 grammes of fat. In other words, 1 gramme of protein produces the same amount of heat as 1 gramme of carbohydrate—viz., 4·1 Calories, while 1 gramme of fat gives 9·3 Calories.

It may, perhaps, be incidentally noted that 1 gramme of alcohol produces 7·0 Calories.

Standard diets expressed in grammes have been determined for an average strong healthy man weighing some 11 stone (68-70 kilogrammes) and living under average conditions of work in the Temperate Zone. The following table gives some examples of these standards:—

Observer	*Protein.*	*Carbohydrate*	*Fat.*	*Calories.*
Ranke	100	240	100	2,324
Voit .. .	118	500	56	3,055
Rubner .	127	500	52	3,092
Moleschott	130	550	40	3,160
Atwater .	125	400	125	3,315

As these diets are on the *man value*, it is necessary to have a table showing the values of children and women in terms of this man value. Such a table as made by Greenwood and Thompson is given below:—

Atwater's Coefficients.		*Inter-Allied Food Commission.*	
Ages.	*Man Value.*	*Ages.*	*Man Value.*
0 to 5 ..	0·4	0 to 5 .	0·5
6 to 9 ..	0·5	6 to 10	0·7
10 to 13 .	0·6	11 and over:	
14 to 15:		Males ..	1·0
Males	0·8	Females	0·83
Females	0·7		
16 and over:			
Males .	1·0		
Females	0·8		
All children, combined ages	0·51	All children, combined ages.	0·68

These figures may be compared with some Indian dietaries given by McCay:—

Class of Person	*Protein.*	*Carbohydrates.*	*Fats.*	*Calories.*
Cultivators ..	52	475	25	2,390
Poor middle .	50	400	50	2,310
Middle .	70	300	90	2,350
Better	85-100	300-400	150	2,050-3,450
Bengali prison diet ..	93	693	30	3,500

In Égypt, Wilson has inquired into the food of a Bedouin, and found that large quantities of rice and milk were used, while meat was eaten once a week in the winter and only once a fortnight in the summer, and lentils eaten in the winter were rarely used in the hot weather, being replaced by extra rice. About ½ pound of butter was taken in the winter, but less in the summer. Bread consisted of a mixture of two parts of dura and one part of wheaten flour, but on desert journeys was made entirely from wheat. Onions and cheese were also used.

He investigated the diets of two Egyptian men, with the following results, which, however, are complicated by the fact that they are calculated from the amount used by the family:—

Egyptian Men	*Protein*	*Carbohydrate.*	*Fat.*	*Calories.*
Strong and healthy	89·1	628·0	47·5	3,328
Not very robust	82·0	520·0	49·0	2,870

Perhaps the best practical test is the British war ration, which, according to Delean, was inadequate in the South African War, producing loss of efficiency from neurasthenia and debility, as was afterwards proved by experimental marches performed upon it, but which, in 1913, was altered to one containing a high amount of protein, which, indeed, is required to meet the needs of tissue repair. It is as follows:—

Protein.	*Carbohydrate.*	*Fat.*	*Calories.*
175	218	515	1,855

We have already invited attention to the possible simplification of these tables, and have shown that the essentials are the protein and the Calories, and now we will see how Atwater applies this method for determining the diet of a man doing various kinds of mechanical work:—

Nature of Work.	*Protein.*	*Calories.*
Rest	100	2,700
Light work	112	3,000
Moderate work	125	3,500
Hard work	150	4,500

In Japan, Oshima found that a jinricksha-man doing hard work consumes different foods during his periods of work and rest. During work he eats large quantities of rice, and during rest quantities of fish, eggs, beef, and pork. He consumes about 20 to 30 ounces of beef or mutton per diem, which works out at 158 grammes of protein and 5,050 Calories.

Light-worked Japanese require 100 grammes of protein and about 3,000 Calories per diem.

In India, McCay determined the amount of nitrogen excreted daily in the urine, and adding to this the other metabolized nitrogen mentioned above, and converting this into terms of protein, obtained the absorbed protein, which, he calculated, was 75 per cent. of the dietary protein.

For example, the urinary nitrogen being 6 grammes, which is the equivalent of 35·5 grammes of absorbed protein, adding to this the other metabolized nitrogen and 25 per cent. for that lacking, he concludes that the average *rice-eating Bengali* of 50 kilogrammes weight only uses 55 grammes of protein per diem—or, in other words, lives on a poorer protein supply than any other race investigated.

Further, this *rice-eating Bengali* exemplifies on a large scale the results of Chittenden's experiments, and as claimed by this experimenter, should exhibit *good bodily health, great working power, and freedom from disease,* whereas he shows none of these traits, and, as a matter of fact, *the reverse is true.*

Our own experiences of Chittenden's dietary in the tropics is that the experiment, if continued sufficiently long, lowers the resistance of the body against disease; and this can scarcely be surprising, as he maintains that 0·12 gramme of nitrogen per diem per kilogramme of body weight is sufficient to keep a man in health. This is certainly not so in the tropics. And we doubt its general application to temperate and cold climates, where one would expect more food to be required

Chittenden's figures of the nitrogen metabolized per kilogramme of body weight may be compared with Voit, McCay's, and Oshima's figures as follows:—

Bengalis and Ooriyas (rice diet largely)	0·110-0·120
Chittenden	0·120-0·130
Beharis and Eastern Bengalis ..	0·140-0·160
Japanese poorer classes .	0·177
Nepalese	0·180-0·250
Sikkim Bhutias	0·250
Average European .. .	0·270
Thibetan and Bholan Bhutias. .	0·350
Nepalese Bhutias	0·420

Indeed, McCay found that Indian dandy carriers, Indian rickshaw-men, and Indian coolies performing exceedingly hard work, did so on a diet containing 175-200 grammes of protein and 6,300-6,500 Calories per diem, whereas the British Army ration mentioned above only allows 175 grammes of protein and 4,855 Calories.

It will be noted that nothing is said in these diets as to the quantity of the food digested and absorbed into the body, as it is from this alone that tissue-formation and heat-energy production can take place—or, in other words, we require to know something as to the quality as well as the quantity of the food supplied in a diet.

QUALITY.

In this section we desire to know the amount of any given food which is absorbed, and is therefore available for use in producing heat, energy, and repair.

The amount which is capable of being digested may be determined by artificial digestion of a sample, but though said to give good results, it is hardly reliable as to absorption.

A better method is to begin by giving the person to be experimented upon a dose of charcoal, and after a few hours to administer a given quantity of the food to be tested of which the protein, carbohydrate, and fat factors are known. The fæces are in due course carefully collected and weighed, and the total amount of nitrogen and of fat determined. From the nitrogen, after deducting 0·5 gramme to allow for the daily amount of excreted metabolized nitrogen, can be calculated the amount of protein in the fæces, and this deducted from the amount of protein in the food gives the quantity absorbed.

The fat is determined in the same way by ether extraction, while the carbohydrate is obtained by calculation.

Nature of Food.	*Protein*	*Carbohydrate*	*Fat*
Mixed diet :			
Total foods	92	97	95
Animal foods .	97	98	95
Vegetal foods .	84	97	90
Meat and fish .	97	98	95
Eggs ..	97	98	95
Milk, cheese, etc. ..	97	98	95
Cereals ..	85	98	90
Starches and sugars ..	[illegible]	98	—
Legumes (dried)	78	97	90
Vegetables	83	95	90
Fruits	85	90	90

Langworthy gives the table above showing the *coefficients of digestibility* or the amounts per cent. of the foods which were digested. It must be remembered that by the word 'digestibility' as used in dietetics is meant not 'apparent digestibility,' or the time a food requires to pass through the stomach, but 'actual digestibility,' which is the quantity of a given food which is absorbed, from which alone tissue formation and heat energy can take place.

Benedict, taking into account this factor, together with the work done, gives the following table:—

Nature of Work	*Total Protein*	*Ingestible Protein.*	*Calories.*
Light	100	92	2,700
Moderate	115	105	3,300
Hard ..	175	160	5,500

It will be noted that the British Army ration is below Benedict's hard-work calories by 745.

So far we have been writing as though all proteins were of equal value, but they are not, as the researches of Rubner and Thomas have shown.

The minimum quantity of protein required daily, so that a man of average weight may live without drawing upon the proteins in his tissues, is 30 *grammes of animal protein*—that is to say, protein derived from meat and eggs.

To reproduce this value, 34 *grammes of rice protein* and 102 *grammes of maize protein* are required.

This factor is called the *biological value of protein*, and so far as we know has only been studied by its authors and by Wilson in Egypt, as set forth below:

100 Grammes of Food Material.	*Available Protein*	*Biological Value of Protein.*	*Absorption Co efficient calculated on Available Protein.*
Meat ..	19·00	19·00	95
Wheaten bread	5·00	2·00	75
Millet bread .	3·40	1·36	55
Rice .	6·50	6·00	80
Lentils ..	19·39	10·70	70
Beans	18·60	10·30	70
Fresh vegetables ..	1·00	0·50	—
Dura	7·80	2·30	75
Millet	4·15	1·78	55
Milk (buffalo) . .	5·90	5·90	—
Dried dates .	1·90	0·90	—
Fûl Sudâni (shell ..	19·00	10·50	70

Wilson gives the following table of the diets in use at Egyptian prisons, with suggested modifications:—

Details.	*Available Protein*	*Biological Value of Protein.*	*Protein from Animal Sources*	*Fat*	*Available Carbohydrate Gross, less Five per Cent.*	*Energy Value in Kilo-Calories*
Hard labour diet:						
Before 1898 .	72·0	37·0	8·28	20·7	524·0	2,786·0
1898-1899	77·0	39·5	6·89	80·0	569·0	3,136·0
1900-1905 .. .	71·0	37·5	0·0	50·0	516·0	3,056·0
1905 (wheat bread)	96·0	57·8	22·5	46·0	547·0	3,058·0
1911 (millet bread)	83·0	53·34	22·5	40·0	521·0	2,987·0
Suggested	89·2	45·28	7·0	48·0	588·3	3,218·0
Ordinary labour diet						
1898-1899 .. .	68·5	31·5	0·0	56·5	520·5	2,978·5
1900-1905 .. .	57·1	25·4	2·5	48·0	460·0	2,561·0
1905 (wheat bread)	82·7	44·2	0·0	43·0	553·0	3,010·0
1911 (millet bread)	60·7	38·7	6·0	43·0	520·0	2,844·0
Suggested ..	78·175	40·05	3·0	47·8	522·7	2,861·0
Non-labour diet						
1898-1899	49·0	21·5		38·5	404·0	2,216·5
1899-1905	42·8	20·0		28·5	345·0	1,890·0
1905 (wheat bread)	70·2	35·1		37·0	499·0	2,680·0
1911 (millet bread)	59·2	31·2		37·0	480·0	2,556·0
Suggested	65·20	32·0		36·0	450·5	2,442·0
Bread diet, 1898-1911	38·0	16·0	-	12·0	375·0	1,803·0
Millet bread diet, 1911	28·0	11·0	-	12·0	354·0	1,679·0

Starling has recently drawn attention to the *fat factor* in the diet, and concludes that if the Calorie value of the total diet is sufficient there is no evidence of a physiological minimum, but the human alimentary canal has become so accustomed to fat that it requires this factor in the following ratio:—

Age in Years.	*Total Calories per Day.*		*Fat in Grammes*	*Fat Calories per Cent. of Total.*
	Gross.	*Net.*		
0 to 6	1,650	1,500	62	35
6 to 10	2,310	2,100	62	25
10 to 13 .. .	2,750	2,500	74	25
13 to 20:				
Males	3,300	3,000	88	25
Females	2,750	2,500	74	25
Adult average bodily workers:				
Males	3,300	3,000	70-88	20-25
Females	2,750	2,500	60-74	20-25
Adult sedentary workers:				
Males	2,750	2,500	60-74	20-25
Females	2,200	2,000	47-60	20-25
Adult very heavy bodily workers	3,900 to 5,000		12-100	30

Chalmers Watson found by actual analysis that the daily dietaries of eight healthy English children between four and six years of age contained protein 71 grammes, fat 67 grammes, carbohydrates 198 grammes, and yielded a total of 1,725 Calories.

A most important matter is that food must be made tasty, and should be well cooked and look nice—matters of great importance in armies.

As emphasized by Rho, in making a dietary the racial food peculiarities, which are, after all, adaptations to climate, should always be taken into consideration—*e.g.*, the beef-eating British soldier requires a different dietary from that of the soldiers of Southern countries.

TROPICAL FOOD MATERIALS.

Excluding the work of McCay and of Wilson, there is very little information available as to the chemical composition, the biological value, or the absorptions of tropical food materials.

Wheat.—This is a very important cereal in many tropical places. The grain is ground between small hand moved stones and the bran removed by sifting, while the meal contains the germ and the endosperm. Wheat and barley are often mixed, while poor samples may contain gram, maize, linseed, etc. McCay finds that the absorption of wheat in India amounts to about 80·5 per cent. of the protein contained in all the elements of the wheat grain, including the germs—everything, in fact, except the coarser parts of the bran.

In the modern steel-roller milling both bran and germ are removed and the flour is composed solely of endosperm, of which the central portion, poor in protein and rich in starch, forms the *patents*, and the remaining part *household or bakers' flo* while the flour from the whole wheat is called *Graham*, and from the entire grain—*i.e.*, with germ and semolina—is *standard*.

Rice.—Turning now to the consideration of certain articles of food in common use in the tropics, one of the most important is rice, because it is widely used throughout the East, where it is believed to be consumed by over 400,000,000 Indians, Chinese, Japanese, and Malays, and because it is very deficient in protein material, and for this reason has to be consumed in large quantities in order that a sufficiency of this important factor may be obtained. Unfortunately dry rice absorbs water very greedily, and is increased by boiling in water to five times its original bulk. Further, its progress through the stomach is slow, and therefore it not merely distends, but keeps this organ distended for some hours.

Rice is, however, well digested in the intestines, nearly all the starch being absorbed, while the protein absorbed varies from 45·76 to 84 per cent. This lack of absorption of protein leads, therefore, to a loss in the nitrogenous value of the rice, and, indeed, is the chief method of loss of its nitrogenous value, as but little disappears during cooking. The percentage of nitrogen, absorbed from a rice diet has been shown by McCay to vary directly with the quantity of the rice. Thus, in a mixed diet containing 32 ounces of rice 6·55 grammes of nitrogen, or 45·76 per cent., were absorbed; while the same diet, with only 20 ounces of rice, showed 8·40 grammes of nitrogen, or 68·33 per cent., to be absorbed. From this it will be evident that mixed diets containing large quantities of rice tend to a low standard of protein absorption.

There are two kinds of rice commonly met with, viz.:—

(*a*) The Indian, country rice, or paddy, variously described in medical papers as 'cured,' 'stale,' 'unpolished,' or 'parboiled' rice, which is prepared by soaking in water for twenty-four to forty-eight hours, and then steaming in cylinders, and finally drying by exposure to the sun. This rice is yellowish-brown in colour, and carries attached to it the outer layers of the grain, while it has not lost much of its protein in the process of preparation.

(*b*) The Burma, Rangoon, or white rice, also variously described as 'uncured,' 'milled,' or 'polished' rice, which is prepared by milling the unhusked paddy until the husk, the pericarp, and the surface layers of the seed are removed, which results in the production of a nice clean white grain, partially denuded of its outer layers and to some extent of its protein.

At the present time many authorities believe that the differences between these two methods of preparation of rice are the explanation of the etiology of beri-beri, as they believe that the latter method, by separating the subpericarpal layers from the rice, deprives it of a substance which is absolutely necessary for the health of the human body.

Maize.—With reference to this much-abused and excellent food, which has, in our opinion, been wrongfully accused of causing pellagra, we may briefly state that it is prepared for food by crushing between millstones or milling by machinery to produce maize meal, which can be made into unleavened bread (porous bread cannot be made, because of the absence of the gluten found in wheat-meal), into porridge or polenta. Often, however, it is roasted, and eaten with butter and salt.

In general, about 74 to 88 per cent. of its protein is absorbed, and, as regards India, McCay says that it is decidedly superior to all the cereals experimented upon, with the exception of wheat. Woods says that it is wholesome, cheap, and well suited to its numerous uses as a food material, and provides a greater return in protein, carbohydrates, and energy for the same outlay than any other cereal.

Millet.—The sorghums, or millets, according to McCay, show a very defective protein absorption—*e.g.*, *Sorghum vulgare* 53 per cent., and *Pennisetum typhoideum* only 49·4 per cent.

Legumes.—The legumes are extensively used in the tropics, and among them come the dals, or dhals, of India (*Cajanus indicus*, *Ervum lens* Linn., *Cicer arietinum* Linn., *Pisum sativum* Linn., *Phaseolus radiatus*, *Ph. mungo*, all belonging to the Leguminosæ), which are allied to the European pea, and all contain a high percentage of protein, whereby they occupy an important position in the food of tropical peoples. They are utilized by being ground into meal, from which unleavened bread, porridge, or sauce is prepared, or they are simply dried (parched) and eaten in this condition.

They resemble rice in absorbing a large quantity of water when cooked, and so becoming bulky, but they differ from this and other food materials in that they are less thoroughly digested. Moreover, their addition to diet lowers the percentage absorption of all the food factors, but especially that of the protein factor.

McCay considers that these dhals produce a great waste of nutriment, in that 25·42 per cent. of the nitrogen of the food appears in the fæces of Bengalis, while only 15 per cent. appears in that of Europeans on a vegetable diet. Moreover, he considers that they are a factor in the production of the bowel disorders so common among the Bengalis.

Wilson has recently performed much excellent work in investigating diets in Egypt. He gives a table of food values, of which the following is an extract:—

100 *Grammes of*—	*Available Protein.*	*Available Carbohydrate.*	*Fat*	*Calories.*	*Cost in Milliemes*
Millet bread ..	3·4	15·0	1·5	212·5	0·0577
Dura	7·8	65·5	54·0	344·3	0·82
Soya bean meal ..	32·0	28·5	2·1	269·0	0·80
Dried dates ..	1·9	47·0	0·6	253·0	2·44
Fûl Sudâni (shelled) ..	19·0	16·8	45·0	562·0	1·787

CALCULATION OF DIETS.

In the calculation of diets it appears to us that two important matters must be considered—viz., the quantity of protein and the number of Calories.

With regard to protein, having obtained from the tables of analysis the *available protein* in the food, it is necessary to determine its *biological value* and the quantity of the *absorbed protein*, and from this the Calories can be calculated. The fat and carbohydrate present no difficulties, except that it is necessary to know the quantity of the available matter which is absorbed. Having obtained the quantities absorbed, the matter is simple arithmetic.

Protein : fat : carbohydrate :: 5 : 3 : 1.

Having done this, certain facts must be considered. It is necessary to remember that the figures given for Europe will not apply to the tropics, and that as a rule they do not represent a minimum, and that no diet should be based upon a minimum.

Wilson has invited especial attention to the quantity of protein, which is not a producer of energy until the carbohydrate and fats are used up, but repairs wear and tear or is stored up as fat or carbohydrate.

The nearer the quantity of protein is to the minimum, the longer will the organism require to rebuild damaged tissue and the less will its powers of resistance be against disease. He states that excess of protein will mean increased heat production, and therefore in the tropics, where there is a cold season, two diets should be in existence—viz., one with less protein for the hot weather, and one with more protein for the cool weather or cool regions.

If this is not done, then the increased heat must be got rid of by radiation and conduction, and this can be obtained by natural or artificial breezes or by exercise, when the extra heat of muscular exertion will be dissipated by sweating.

He also draws attention to the low biological values of the vegetal proteins, which are less well absorbed than are the animal proteins, a fact which he thinks is due to the structure of the food materials rather than to the nature of the proteins.

His conclusion with regard to protein appears to us to be worth quoting.

'A minimum amount of protein is required daily, over and above which a certain excess is desirable; this minimum is different for different proteins, and is measured by the biological value of the protein. In determining, therefore, the requisite amount of protein it is essential to take into consideration the biological value of the protein components of the diet, and fix the daily quantities on this basis rather than on the nitrogen content. In determining the amount of protein the defective absorption of vegetable proteins must be allowed for.'

We would add that care should be taken that vitamines and lipoids are present in the dietary, and that the former are not destroyed entirely by cooking.

Water should be freely supplied in tropical towns—*e.g.*, Calcutta and Peshawar allow 4·15 gallons per head per diem of filtered water, but many tropical towns are not so well provided, and the minimum in the tropics for drinking purposes should be 3 to 4 pints per head per diem.

Salts are also of great importance, and usually present in the food, but with much vegetal food addition of ordinary table salt is necessary.

LOW PROTEIN DIETARIES.

In tropical lands there are many peoples who live mainly upon cooked cultivated vegetal foods, with but little admixture of animal foods, and this is due to force of circumstances rather than to any desire of the peoples, who would be glad enough to eat animal food if it could be obtained. Among these peoples the protein in the food sinks to a very low amount, with, as we shall presently see, a markedly deteriorating influence on the race.

The effects produced by this low protein standard may be illustrated by the following table, which is given by McCay to exemplify the differences in the diets of Bengalis as compared with those of Anglo-Indians and Eurasians:—

Food.	*Bengalis I*	*Bengalis II.*	*Anglo Indian. and Eurasians*
Proteids in grammes ..	67·11	43·61	80·56
Carbohydrates in grammes	518·73	200·31	376·53
Fats in grammes ..	71·55	33·02	51·75

McCay, in his excellent works quoted at the end of this chapter, has shown that when the protein standard of a tropical dietary is very low, then the physique, the capacity for work, the health, and the resistance against disease are also lowered, and he has illustrated these facts by reference to the rice-eating Bengali. Moreover, he has answered his critics in a most able manner, and has demonstrated by comparing closely-allied tribes living under identical conditions of climate, solar irradiation, sexual excesses, early marriage, etc., that it is the influence exerted by the food, and particularly by the proteins of the food, that is all-important in determining the degree of muscular power, the general physical endowment, the powers of endurance, the resistance to disease, and, most important of all, the place which a tribe or race has won for itself in manliness, courage, and soldierly instincts. It is impossible to discuss at length in this place the facts which he has adduced, but certain important results may be briefly mentioned.

Thus, he has drawn attention to the great difference in the analysis of the blood of male Bengalis in India, as compared with that of the blood of Europeans in Europe, as set forth in the following table:—

Nature of Observation.	*Male Bengalis in India.*	*Europeans in Europe.*
Erythrocytes	5,300,000	5,193,000
Leucocytes	9,000	7,500
Hæmoglobin (Haldane's method)	81	100
Colour index ..	0·71 to 0·85	0·95 to 1·1
Water	78·88	78·87
Total solids	21·12	21·13
Proteids	18·20	19·17
Salts	1·06	0·78
Blood-pressure in brachial by Riva-Rocci's sphygmomanometer	100 millimetres Hyg	110 to 130 millimetres Hyg.
Ratio of salts in the urine to those in the blood	1·2	2·0

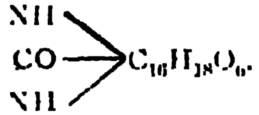
His observations show that too little protein in the food affects the growth of the Bengali boy, who grows up slender, and is defective in vigour and vitality, and in conjunction with Bannarji, Dutton, and Ghosal, he has demonstrated the differences in the constituents of the urine in male Bengalis in India, as compared with male Europeans in Europe as is shown in this table:

Constituent in the Urine.	*Male Bengalis in India*	*Male Europeans in Europe.*
Quantity	1,177 c.c.	1,200 to 1,500 c.c.
Specific gravity	1,006 to 1,024	1,015 to 1,025
Urea	5·50 to 10·68 grammes per diem	30 to 35 grammes per diem
Total nitrogen	5·0 grammes per diem	14 to 18 grammes
Chlorides ..	0·43 grammes per diem	15 grammes per diem
Phosphates .. .	0·05 to 1·4 grammes per diem	2 to 3·5 grammes per diem
N : P_2O_5 ratio .. .	5 or 6 : 1	Practically the same
Uric acid	0·18 gramme per diem	0·3 to 7 grammes per diem
Total sulphates	1·75 to 2·2 grammes	2·5 to 3 grammes
Ethereal sulphates .. .	0·15 to 0·22 gramme	—

These are most important conclusions, and we must state that our own observations in tropical practice support McCay, and are directly in opposition to Chittenden's observations. We have observed that when persons in good health have for some time carried out Chittenden's dietary, the result has often been sharp attacks of illness, indicating a lowered resistance to disease.

VITAMINES.

Eijkmánn, Gryns, Takaki, Fraser, and Stanton, have shown that the uncured, milled, polished, or white rice is deprived of its subpericarpal layers by the processes of milling or polishing, and that these layers contain some substance of importance in the prevention of beri-beri. This substance is present in the proportion of 0·1 gramme to the kilogramme of rice. Funk has isolated this substance, called ***beri-beri vitamine***, from the polishings of the rice mentioned above, and has determined its chemical composition—*i.e.*, 55·63 per cent. C, 5·29 per cent. H, and 7·68 per cent. N, which correspond best to the formula $C_{17}H_{18}O_4N(HNO_3)$—and has demonstrated its power of curing the polyneuritis induced in fowls by a rice diet, 4 milligrammes being sufficient to cure pigeons. In further researches he came to the conclusion that the beri-beri vitamine was a base belonging to the pyramidine group, and that its formula was:—



$$\left.\begin{matrix} NH \\ CO \\ NH \end{matrix}\right> C_{16}H_{18}O_6.$$

It was described as being soluble in water, alcohol, and acidulated alcohol, as being dialyzable and capable of being destroyed by heat at 130° C., while the amount present in 1 kilogramme of rice is 0·01 gramme.

According to Funk, this substance is essential for the metabolism of the nervous system, and if it is lacking in a diet it must be supplied from the body, and when this fails then symptoms of beri-beri appear.

Beri-beri is, therefore, according to general opinion, a *deficiency disease*, and is grouped with epidemic dropsy, scurvy, experimental scurvy, infantile scurvy, ship beri-beri, pellagra, and polyneuritis of birds.

All vitamines are not the same, and the *scurvy vitamine* appears to be different from that of beri-beri, being a crystalline substance destroyable at 120° C. or less, and constant in fresh potatoes, onions, cabbages, apples, lemons, limes, and lime-juice; and being less stable than that of beri-beri, is only found in the fresh condition of vegetables and fruits.

There appears also to be a *specific growth vitamine*, the composition of which is unknown. It is contained in milk, and is necessary for the growth and development of the child. If the mother suffers from beri-beri, as Andrews has shown, there will be great risk of the child dying either of beri-beri or some other complaint, owing to defective growth and development.

There is also a suggestion that pellagra may be a deficiency disease.

With regard to the distribution of vitamines, they are present in yeast, milk, cereals, and probably in muscle juice, brain, fish, legumes, and fresh vegetables. With regard to cereals, they are present in the germ and subpericarpal layers of the bran of wheat, in rice bran, and in the pericarp and outer layers of maize.

Their action upon metabolism is unknown, and it is still doubtful whether they assist anabolism as hormones.

The processes associated with the sterilization and canning of foods destroy vitamines.

Lipoids.—The best known of the lipoids is lecithin, and it is suggested that they are required to enable amino-acids, fats, and salts to enter the cells of the body, and so to form the colloidal substances thereof. It is further suggested that mice cannot live on lipoid-free food, and that perhaps vitamines are unable to enter the cells except as lipoidal compounds, but the whole subject is very nebulous.

LITTLE-KNOWN MATTERS.

All proteins contain amino-acids, but these are not combined in the same proportions, and it appears possible that a minimum thereof is necessary for the growth, if not for the maintenance in health, of the organism; but the whole subject is in its infancy, and the same holds good with regard to the salts, some of which may be necessary for proteins and others for the lipoids.

REFERENCES.

CHAPTER V

TROPICAL DISEASES

Preliminary remarks—Evolution—Geographical discovery—Endemicity—Epidemicity—Eugenics—Incidence—Distribution—Prevention—References.

PRELIMINARY REMARKS.

BEFORE entering upon the systematic study of tropical diseases a few remarks may be made upon their evolution, the influences of geographical discovery upon their dissemination, their endemicity and epidemicity, tropical eugenics, the geography of tropical disease; with special reference to countries and not to given diseases, and finally the prevention of these diseases.

It will be obvious that, if these subjects were to be treated at all fully, they would require several volumes, each of which would be larger than the present little book; but this is not our object, which is to bring subjects to the notice of the tropical practitioner with the view that he may apply them to the diseases and peoples by whom he is surrounded, and references are given whereby he may extend his reading and knowledge far beyond the confined limits of our manual.

All tropical countries are inhabited by three different sets of inhabitants. Firstly, there are the true *indigenous natives*; secondly, there are *immigrants* from other countries; and, thirdly, there are the *descendants of an admixture* of the first two, and generally of a European with a native. Such are the Mulattoes of Central and Southern America, the Eurasians or Anglo-Indians of India, and the Burghers of Ceylon, and it is our duty to try to trace out the cause of disease and death among these peoples.

EVOLUTION.

Auckland Geddes and Adami consider that the Piltdown skull is pathological, and that its remarkable thickness and the bold outline of the temporal ridges are to be explained by the assumption that its original owner suffered from *acromegaly*.

The researches of the late highly talented Sir Armand Ruffer into *palæo-pathology* have demonstrated the existence of bilharziosis, tuberculosis, rheumatoid arthritis, and pyorrhœa alveolaris in Egyptian mummies dating some 4,000-6,000 B.C., while certainly some of the organisms of disease were present then, as he was able to demonstrate the tubercle bacillus in mummies of the Twelfth Dynasty.

But disease is much older than man, for Moodie has noted the presence of arthritis and osteomyelitis in cave bears, of pyorrhœa in early tertiary three-toed horses, and caries in Permian fish.

There can be no doubt as to the great antiquity of bacteria, and it seems possible that they performed great geological works in the early history of the world, and may be largely responsible for the formation of some of the oldest sedimentary rocks, in much the same way as Drew's *Bacillus calcis* does its work to-day in the lagoons of Florida and on the Great Bahama Reef.

When higher plants and animals evolved, the struggle for existence must have compelled minute animal and vegetal organisms to seek protection for themselves therein, and at first this protection would be used temporarily to tide over some difficulty.

This being admitted, the parasite would desire an easy method of entrance into and escape from the body of the temporary host, and hence the common infection of the alimentary canal with organisms.

So long as the chemical substances produced by the metabolism of the parasite were innocuous or helpful to the host, there would be no reaction on its part against the intruder, and the two would live together in peace, as many bacteria do at the present day in the human alimentary canal, and a condition of commensalism may be arrived at.

Other intruders, on the other hand, might give rise to irritating chemical substances which would provoke a reaction on the part of the host. And thus begins the long struggle between the invading organism and cells of the host which has produced all those complicated mechanisms which are gathered together under the term 'immunity.' The reader will notice that the whole of this struggle is *adaptation to environment*—viz., to that portion of the host's environment in which is centred the invading organism.

The parasite would naturally attempt to escape from the defensive chemical substances poured on to it by the host, and in so doing pierced more deeply into the tissues of that host; but now its escape would not be so easy as when living in some cavity freely communicating with the exterior, and hence it would be to its advantage to either kill that host, or, if it failed to do that, to enter some cavity communicating with the exterior and suitable for the parasite's existence,—*e.g.*, the enteric bacilli in the gall-bladder and the pelvis of the kidney.

All these changes of environment would cause variation in the protists (protozoan and bacterial), and, if the same environmental conditions acted long enough, then these changes would become inherited (*vide* Adami); hence the origin of the numerous parasitic protists, animal and vegetal, and hence also the preservation of characters, including those complicated phenomena associated with the reaction of the host which we call the signs and symptoms of disease and the natural recovery therefrom It appears to us that just as disease arose *de novo* in the long ago, so it has probably been arising century after century, and we see no reason why new diseases should not appear in the twentieth century of the present era in man and animals, as they did when hosts were first evolved, only the matter is more complicated owing to the evolution of methods of defence upon the part of the host.

In his most interesting and masterly book Adami has shown that a non-pathogenic organism can be made pathogenic by injecting into an animal killed non-pathogenic bacilli, and then ten or fifteen days later the live bacilli. These, when recovered from the tissues of the experimental animals, were found to have undergone considerable variation due to their altered environment, and had so changed their characters as to be very virulent to guinea-pigs. In other words, by means of a preliminary anaphylactic phenomenon a non-pathogenic microbe may become pathogenic and a new disease be evolved.

Similarly, according to some of our observations, when man is immunized artificially against typhoid and the paratyphoids, he becomes more susceptible to infections by chance intestinal organisms, which in this way give rise to new diseases.

Finally a germ accustomed to a human race which has developed a certain amount of immunity may meet with another race which lacks this immunity, and immediately a disease which is mild may develop rapidly fatal attacks and spread widely—*e.g.*, measles in the Sandwich Islanders in London long ago.

Enough has been said to show the line of thought—viz., the importance of environment, the difficulty of impressing characters, but the hereditary transmission of these characters when once evolved producing variation in the parasites, while the reaction on the part of the host tending to produce an immunity against older forms, and yet leaving, in the phenomenon of anaphylaxis, a gate open for further variation on the part of non-pathogenic organisms and the possibility of the origin of new diseases.

GEOGRAPHICAL DISCOVERY.

Just above we have mentioned the introduction of pathogenic organisms to races to which they were previously unknown, and as this is primarily due to geographical discovery, we desire to invite the reader's attention to this factor in the dissemination of tropical disease, as the discovery of new lands has eventually led to the betterment of means of communication, and hence to the easier and quicker transference of the microbes of disease.

Diseases which may have been endemic in one region for centuries may, by means of geographical discovery and by means of the present and past wars, spread to other regions where they were previously unknown; and this brings us to the consideration of endemicity and epidemicity.

ENDEMICITY.

As so much epidemiological investigation of disease has of late been undertaken, mainly due to the initiative of Manson and Sambon, we feel that a few general remarks on endemicity and epidemicity as applied to disease in general may not be amiss.

The presence of a given disease in a locality depends primarily upon the presence of conditions favourable for the action of the causal agent, and upon the presence of suitable vehicles for its conveyance into the human body, which must be non-immune to its attack. The causal agents of disease may be physical, chemical, or parasitic.

Physical causes of disease are often cosmopolitan in their distribution—as, for example, the action of gravity in producing the traumatisms brought about by falls; but though some causes, such as the rays from the sun, are also cosmopolitan, still they are unable to produce deleterious effects upon human beings unless assisted by secondary influences, such as latitude, altitude, the rotation and inclination of the world, etc., while some are restricted—as, for example, the traumatisms due to ferocious animals, which, though occasionally taking place in other parts, whither the animals have been artificially conveyed, generally only occur in the natural habitats of these creatures.

Chemical causes of disease have become largely cosmopolitan in distribution owing to improved methods of intercommunication and the manufacture of chemical principles: still, certain chemical causes have very restricted localities even to-day, because they are little known, and only affect primitive peoples living in these regions —*e.g., Gloriosa superba*, etc.

The parasitic causes of disease may be animal or vegetal. The endemicity of a given parasite depends upon (*a*) the presence of non-immune human beings, in which part of the life-cycle can be gone through, and which for convenience we will term the *human hosts*; (*b*) easy modes of escape from the human host into the exterior; (*c*) suitable means of continuing the life-cycle in the exterior—*i.e.*, in earth, water, air, on or in other animals or plants, *intermediary hosts* we will call them; (*d*) ready means of re-entry into the human host or into some other animal host in which the life-cycle is completed; (*e*) partially immune animal hosts or partially immune human hosts to act as reservoirs or carriers, to enable the parasite to complete its life-cycle without producing marked pathological changes in the host. Examples of these may be found in the malarial parasite attacking (*a*) the white man and the native child in West Africa and elsewhere, and passing by the agency of (*b*) blood-sucking into (*c*) *Anopheles costalis*, which, by the act of biting, (*d*) conveys the parasite to another non-immune host or to the partially immune adult native, who acts as a reservoir or carrier.

Another example is the passage of the plague bacillus from the rat via the flea back to the rat or man.

Other examples are the amœbæ of dysentery, which pass from man by the evacuations on to vegetal substances or into water, by which they may be reintroduced into man direct or by the agency of flies.

By a suitable non-immune host is meant a host which, while providing abundant suitable food material for the parasite, does not produce such a quantity of chemical substances antagonistic to the parasite as to seriously hamper or prevent its growth and development.

Given such conditions as those just described, a parasite should be capable of developing enormously in a given district; but there are still other factors to be considered, and the first of these is the fact that the intermediary host, if an animal, depends for its existence upon the presence of a suitable food-supply, as well as suitable means for propagating its species.

If anything untoward happens to these, the intermediary host may die out, but the problem is not quite so simple as this, because the intermediary host itself may be preyed upon by some other animal, or may be affected by disease, and so reduced in numbers.

If the intermediary host is reduced in numbers, even without being exterminated, the parasite will have difficulty in completing its life-cycle, and is therefore faced with the problem of seeking another intermediary host, or another entirely different method of leaving the human host, or of being exterminated.

The reduction in numbers of the intermediary host in a given area is one of the bases of prophylaxis in malarial fever, yellow fever, dengue fever, and sleeping sickness. Faced with these difficulties, it would appear possible that the parasite can change its intermediary, probably undergoing certain changes itself in so doing, and this would appear to be a possible explanation of the slight modifications of the various forms of spirochætes causing the relapsing fevers.

On the other hand, the malarial parasite would seem to be less capable of accommodating itself to a change of hosts, for it would appear to be only capable of completing its life-cycle in the less common anophelinæ, and not in the more common culicinæ—a most important fact in malarial prophylaxis.

Another factor to be considered is the effect of atmospheric temperature upon the parasite, for the study of the life-cycle of the malarial parasite has clearly shown that this has a marked effect upon the development of the oöcyst in the anopheles. It is also quite possible that other physical and chemical factors, concerning which we are at present ignorant, may play important parts in controlling the life of parasites.

Finally, the parasite itself may suffer from the attacks of another parasite, a condition of affairs called 'hyperparasitism,' and, thus becoming diseased, may be unable to complete its life-cycle, and so become extinct.

It will thus be seen that the problems connected with the appearance and the disappearance of a disease in a locality are extremely complex; and that next to the parasite itself the most important factor is the intermediary host, its food, its life-cycle, and its habits—in one word, its œcology.

Hence, in studying an endemic parasitic disease, or a disease thought to be possibly parasitic, it is not advisable to restrict one's researches solely to work in the hospital or the laboratory—for it must be remembered that the parasitic causes of some diseases are most probably ultramicroscopical—but to associate with the clinical and experimental methods of research epidemiological researches conducted by visiting several widely separated and, if possible, completely detached endemic areas, in order by carefully studying therein all the conditions of life and the habits of the human hosts to endeavour to find factors common to the different localities. A further study of these common factors from the point of view of possible modes of infection may indicate one or more possibilities, and then these must be put to the crucial test of experiment with a view of ascertaining definitely the accuracy of the epidemiological observations.

EPIDEMICITY.

From an endemic area diseases due to physical causes may spread by the alteration, naturally or artificially, of the physical conditions in the surrounding regions, and would draw back to the original region upon the return to normal of these conditions. Similarly, chemical causes of disease may be spread from their original restricted area by modern methods of intercommunication—*e.g.*, poisonous plants or their products may be brought from the tropics to the Temperate Zone, and *vice versa*.

In order that a parasitic disease may spread from its endemic focus several factors are necessary:-

(*a*) Carriers to convey it from one place to another. These may be either the human host, an animal host, or the intermediary host —*e.g.* fleas infected with plague.

(*b*) In order that the disease may spread in the new area there must be the suitable conditions already mentioned.

(*c*) There must also be suitable climatic conditions.

If these, and perhaps other still unknown factors, are present, the disease will be able to spread with perhaps increased virulence, first within the new area and then from one area to another, until an epidemic or pandemic is produced. With the appearance of partial immunity in the human and animal hosts, altered climatic and other conditions, as well as the æstivation or hibernation of one of the hosts, the epidemic will die down, perhaps only to reawaken after the hibernation of the host is over or with a change of climatic conditions; and this may be repeated for years, until conditions become too adverse for the life of the parasite or its host, when the epidemic dies away, and the disease again becomes restricted to its endemic areas.

The possibilities of epidemics and the presence of endemic diseases raises the question of the possibility of giving man such a start in life that he may be advantageously placed in the combat before him. The questions involved in such a possibility constitute the large and ever-increasing subject of *Eugenics*, to which we will now turn our attention.

EUGENICS.

Any attempt to improve the racial qualities, mental and physical, of the future generations will, without doubt, equip them better for the struggle for existence, including therein the fight against disease. In order to bring about an improvement two factors are open for consideration– viz., the parents and the child.

With regard to the parents, eugenics attempts to combat such racial poisons as are represented by alcohol and such social diseases as are indicated by syphilis, gonorrhœa, and tuberculosis.

In regard to *alcohol*, when taken in large quantities and for long periods it is said to act upon the germ cells, leading to the production of children possessing a lower resistance against disease. Unfortunately, as we shall see later, alcoholism is common among the natives of many tropical regions, and has already produced marked racial effects.

Alcoholism in the mother is a more serious matter than alcoholism in the father, because in the former the embryo is produced by alcohol-poisoned germ cells, while during intra-uterine life its growing cells are being constantly alcoholized, and finally the child, after birth, is either fed upon an alcoholic mother's milk or, as is more frequently the case, is reared by such hand-feeding as an alcoholic mother may give it.

As hand-feeding in the tropics requires the greatest care, it is not surprising that when reared by an alcoholic mother the child usually acquires disease at an early stage of its life-history, and often helps to swell the infant mortality rate.

Alcoholism is a great social question, and can only be combated by a sociological movement such as to-day is taking place in England and other Temperate Zone countries.

With regard to the so-called social diseases, every medical practitioner is conversant with *syphilis* and *gonorrhœa*, and all that is necessary is to invite attention to Sir Malcolm Morris's summary of the Recommendations of the Royal Commission on Venereal Disease, which include facilities for diagnosis and treatment, diffusion of knowledge with regard to the diseases, and the collection of statistics. It is particularly to be noted that they conclude that at the present time any system of compulsory personal notification would fail to secure the advantages claimed. The Commission considered that undeclared venereal disease should be a ground for the annulment of a marriage. They further considered that advertisements of patent medicines should be prohibited, and apparently they were in favour of making it penal for unqualified persons to treat venereal diseases. Venereal disease is at the present time exceedingly common in all parts of the tropics, and undoubtedly is leading to racial degeneration, and we strongly advocate that some preventive scheme should be inaugurated in all tropical countries. At the same time, we desire to record our disapproval of attempts to combat these evils by the registration and general police supervision of prostitutes as we believe such a system is bound to increase rather than diminish the disease, as it leads to secrecy; and, indeed, it has so far been a failure wherever it has been put to the test seriously.

With regard to venereal disease, there is no doubt that, although the war has increased the numbers of infections, it has nevertheless acted beneficially in bringing the seriousness of the subject home to the authorities; and, even in England, preventive measures, for male and female alike, are being widely distributed free of charge, and institutes are in existence for the diagnosis and treatment of these diseases. It is impossible to close the section without acknowledging, with honour, the great work which New Zealand has done in Europe with regard to this matter. When a country with traditions like England has awakened from its sleep of ages, a sleep largely due to its religious tendencies, it is possible for tropical countries, unhampered by these religious bands, to do even more than what we see going on around us as we write these lines in London.

Turning now to *tuberculosis*, it seems probable that the tubercle bacillus has had an opportunity of infecting every child living in the slums of the large European cities before it has attained the age of twelve years. It would further appear as though tuberculosis was either being better diagnosed or was increasing in many tropical lands.

There ought to be no slums in tropical countries, and where they exist it is the duty of the Government, forthwith, to formulate a scheme of betterment whereby in the course of years they shall be removed, and State-built State-owned, and State-regulated buildings should be provided, where the poor may live in a reasonable condition of sanitation. Further, it should be the duty of the State to take over and to bring up such illegitimate children as cannot be properly provided for, thereby not merely helping in the population and work questions, but also in the diminution of tuberculosis.

In the tropics there are two other eugenic problems to which we may invite attention, and these are *food* and *half-castes*.

With regard to food, the low protein dietary of the poorer native population of such regions as India is a great sociological problem, being connected with religious sentiment. It leads to racial degeneration, as we have already seen, but its remedy is very difficult, and must be done by a social movement on the part of the natives themselves.

In regard to *half-castes*, the number of poor Eurasians or Anglo-Indians in India is increasing, and as their children live in the slums of great cities they tend to degenerate.

After fourteen years of strenuous work Graham has shown that if these children are taken to sanatoria in the Himalaya Mountains, and placed in a new physical, mental, and moral environment, they do not show this degeneration.

This is a great discovery, and if confirmed and acted upon may produce lasting results, because, as we have already hinted, there is a belief that the third generation of children, with European parents, born and living entirely in the tropics, tend to degeneration in every way, and yet it is desirable that portions of the tropics should be permanently colonized from temperate climates if possible.

Lastly, the *infantile mortality* of most tropical countries is appallingly high, and this passes unheeded, even in places where a local dearth of labour indicates to those in authority the necessity for a steady and rapid increase in the population. This is not a book on hygiene, but perhaps as practitioners for many years in various tropical countries we may be permitted to recommend anyone anxious to reduce the death-rate of a district to study the factors which contribute to the local infantile mortality, and to combat those of greatest importance, which will often be found to be tetanus and diarrhœa, the latter being associated with the question of a pure milk supply.

Enough, perhaps too much, has now been written as regards lines of thought associated with the word eugenics as applied to the tropics, and we will now pass on to consider the incidence of disease in tropical countries.

INCIDENCE OF DISEASE.

In previous editions we gave in considerable detail the analysis of the causes of death in Ceylon, and their incidence in the various peoples inhabiting that island. Several years have passed since these figures were compiled, and as they are old we omit them, and take a general view of the distribution of disease in tropical countries.

DISTRIBUTION OF DISEASE.

Asia.

Asia Minor is not a tropical country, as it possesses cold and prolonged winters, but it also has very hot summers, during which it resembles the tropics, and becomes the home of many diseases, such as malaria, enteric fevers, dysentery, and often cholera, while diphtheria is usually present, and cerebro-spinal meningitis is by no means unknown. Goitre and cretinism exist in the Valley of the Upper Euphrates.

In *Mesopotamia* the winters are temperate, but the summers are very hot, and heat-stroke is well known, while malaria, the enteric fevers, dysentery, and cholera are present. Plague is said to have been endemic in this region for years. Typhus, smallpox, measles, whooping-cough, and, it is said, scarlet fever, occur there. Bagdad sore is almost too well known to be mentioned, while beri-beri occurred in the siege of Kut, and also among other troops.

In *Arabia*, in addition to the fevers mentioned above, ophthalmia is to be noted.

Very little is accurately known as to the diseases of *Persia*, though we possess a large manuscript written thereon many years ago. Cutaneous Leishmaniasis, leprosy, and some form of relapsing fever may be noted.

As regards *India*, in the Bombay Presidency the infantile mortality in native races is 220·08 in males and 219·07 in females per 1,000 births. In Bombay City the ratios were 557·24 and 569·66, but it is stated that these ratios are very fallacious.

The racial death-rates are:—

	1905.	1906.
Europeans	14·36	14·41
Eurasians	20·89	26·99
Natives	31·84	41·39

The year 1905 seems to have been unusually healthy; only 588,394 natives died, as compared with 1,318,783 in 1900.

The principal cause of death was plague, which accounted for 71,363, or 12·13 per cent., in 1905, as compared with 223,957, or 29·28 per cent., in 1904.

The plague deaths in Bombay for the ten years 1896-1905 are as follows:—

1896	2,086
1897	46,944
1898	86,191
1899	96,596
1900	33,196
1901	128,259
1902	184,752
1903	281,269
1904	223,957
1905	71,363
Total	1,154,613

The population in 1901 was:—

European (exclusive of cantonments)	18,804
Eurasian	6,557
Native	18,481,362

The above figures will thus give the reader some idea of the mortality caused by the plague in India.

The next important cause of death is cholera:—

1896	35,404
1897	57,109
1898	4,368
1899	8,579
1900	163,889
1901	13,600
1902	3,229
1903	1,825
1904	13,156
1905	5,396

The general term 'fever' causes a mean of 310,420 deaths in the six years 1900-1905; most of this is supposed to be malaria.

The simplest way to show the Bombay death-rate is in the ratio per 1,000 inhabtiants:—

Cholera	2·11
Smallpox	0·26
Plague	9·18
Fevers	17·43
Dysentery and diarrhœa	4·90
Injuries	0·39
Other causes	12·12
Total	46·39

Respiratory disease in 1904 caused 3·22, and in 1905 2·95, deaths per 1,000 of the populatoin.

The Bombay death-rate indicates clearly the incidence of cholera, plague, and fevers. In many parts of India—*e.g.*, Madras—kala-azar is an important death-producing factor. In Calcutta, phthisis is causing some apprehension by its increase. The importance of snake-bite as a cause of death is marked in India. Relapsing fever is also known.

Ceylon possesses a high infantile mortality, of which the principal factors are infantile diarrhœa and convulsions, and often the bad condition of the mother *before* the birth of the child, associated with improper and bad food, and lack of proper care of the child. Eugenics requires more study in that island than, so far as we know, it has received.

The deaths of women in child-birth are high, and the principal cause is puerperal fever.

Among adults diarrhœa, dysentery, and the various forms of enteric fever are important factors of the death-rate. Plague has recently visited the island, but has been well controlled; cholera is present from time to time; while systematic steps have been taken to deal with the prevalent malaria and ankylostomiasis. Cancer exists in all races, and diabetes is a prevalent disease among better-class natives, such as lawyers, doctors, and merchants. Syphilis is common, though the parasyphilitic diseases are very rare, while insanity is also relatively less than in Europe. Leprosy is endemic, and eye diseases frequent; though, thanks to the Victoria Eye Memorial Hospital, where they are skilfully treated, blindness is less frequently met with.

With reference to the Straits Settlements, the infantile mortality, after deducting immigrant deaths, is 250·29 per 1,000 births in 1905, and is racially classified as follows:

Europeans	57·32
Other nationalities	224·07
Malays	229·78
Indians	278·72
Chinese	302·03
Eurasians	307·69

The general death rate was 40·51 per 1,000 inhabitants, and its factors, phthisis, beri-beri, unclassed fevers, dysentery, cholera, malaria, cancer, anæmia, sprue, dropsy, and parasites.

In Indo-China the enteric fevers, the diarrhœas and dysenteries, liver abscesses, intestinal parasites, cholera, diphtheria, spreading ulcer, which used to be called Cochin China ulcer, scurvy, purpura hæmorrhagica, beri-beri, dengue fever, and parasites, are to be mentioned.

Much has been written on the diseases of China, where Manson and Cantlie did their work, and its diseases are beginning to be known; but of special interest are its trematode infections, its beri-beri, its plague, and its skin diseases.

Japan is now the centre of much scientific work, and no passing reference would do justice to the valuable work being performed therein; but it may be noted that it is interesting in its parasitic diseases, its tsutsu-gamushi disease, its trematode infections, its fuguismus, its rat-bite and cat-bite diseases, and its beri-beri.

The Philippine Islands are monuments of American carefulness, forethought, and hard work, and their diseases are well set forth in the valuable *Philippine Journal of Tropical Medicine*. Especially to be noted are their parasitic affections, their beri-beri, and though much remains to be done, yet much has been done with regard to malaria and smallpox, which has been reduced to insignificant proportions, while tuberculosis, cholera and plague, and the enteric fevers, are present, and the whole problem of eugenics is still in its infancy.

Australasia.

The diseases of tropical Australia, which includes Queensland, Papua, Torres Straits, Thursday Island, etc., are:—Sprue, amœbic dysentery, filariasis, malaria, beri-beri, ulcerative granuloma, frambœsia tropica, dengue fever, leprosy. The intestinal parasites are:—*Ancylostoma duodenale, Trichuris trichiura, Oxyuris vermicularis, Strongyloides stercoralis*, and *Tænia saginata*.

Under the term 'sandworm disease,' Breinl describes an inflammation of

the inner side of the sole of the foot in the Innisfail and Cairns districts, which, beginning as a small erythematous area, spreads in the form of spirals, and after a time disappears. No animal parasite could be found. It appears to us that this is a form of 'creeping eruption.' He also describes 'barcoo rot.'

Seligmann, during the eighteen months which he spent in British New Guinea and the islands of the Torres Straits in the years 1898 and 1904, gathered much information as to the incidence of disease among the Papuo-Melanesians of Papua, who are really only just emerging from the Stone Age.

He found talipes equino-varus to be common, while hare-lip, meningocele, dwarfism, albinism, and erythrism (*i.e.*, aborigines with auburn or reddish-brown hair, pinkish-brown skin, and brown eyes) occur. Albinism and erythrism showed a family distribution.

Malaria was common, and children with greatly enlarged malarial spleens were easily found. Adults with large spleens could also be seen, but this enlargement might not be malarial. Leprosy was endemic in the valley of the St. Joseph River—*i.e.*, in the Roro-Mekeo district—and could not be attributed to foreign influences. Yaws was common, but syphilis was considered to have been introduced in comparatively recent times; in fact, he is of the opinion that in Oceania the introduction of syphilis is possibly not antecedent to Captain Cook's voyages. Respiratory diseases and dysentery are very common, as are skin diseases—*e.g.*, eczema, tinea imbricata, tinea flava, keratosis pilaris, and leucoderma. With regard to new growths, he records cutaneous papillomata, fibromata, lipomata, osteomata (?), and angiomata. Malignant tumours were rare, but sarcomata were found. He describes and illustrates subcutaneous nodules freely movable over the deep fascia, over or near bony prominences, and especially about the elbow, which are probably juxta-articular nodules. He describes and illustrates a nasal ulceration somewhat similar to gangosa, variously referred to as lupus by Sir William MacGregor and cancer by the white residents of British New Guinea. He also describes a peculiar ulcerative process of the legs and other parts of the body. He draws attention to the impulsive character of the people as a crime-producing factor. Paralysis and psychoses are not common. The presence of cretinism was noted. He did not meet with tuberculosis except in natives in intimate contact with Europeans, nor with arterio sclerosis, valvular heart disease, rickets, or gout, locomotor ataxy, or general paralysis, while anæmia was rare.

Oceania.

This is interesting for its diarrhœas, dysenteries, and elephantiasis, which have been studied in detail by Baker; for its yaws, leprosy, and skin diseases, which latter are common, and of which tokelau and ringworm may be especially noted.

Syphilis is believed to have been unknown in the Sandwich Islands before the visit of Cook in 1779, while leprosy is believed to have been introduced therein in 1830 by Chinese emigrants.

Epidemic gangrenous rectitis and a similar form of stomatitis occurs according to Corny in Fiji. Cerebro spinal meningitis was introduced probably about 1876.

Tropical America.

The tropical medical schools situate in Harvard University and in other parts of the United States, the work of the American Society of Tropical Medicine and of the Canal Zone Medical Association, added to the researches of the Institute Oswaldo Cruz of Brazil, are steadily increasing our knowledge of the diseases of tropical America, among which malaria, yellow fever, the enteric fevers, the dysenteries, elephantiasis, Chagas' disease, Leishmaniasis, verruga peruviana, parasites, yaws, and certain skin diseases, stand out as pathological features, among which must be given prominence to those caused by the jigger.

Moreover, it is in tropical America that the most brilliant prophylaxis with regard to malaria and yellow fever has been conducted.

With regard to *Northern Mexico*, Aleš Hrdlička made six expeditions in the years 1898-1905 to study the physiological and medical conditions of the Amerinds residing in Northern Mexico and in the south-western portions of the United States.

He concludes that on the whole the health of these people is superior to that of whites living in larger communities, as they do not suffer so much from inherited morbid conditions, or from those connected with teething, puberty, menstruation, gestation, puerperium, menopause, and senility, nor do they suffer so much from malignant growths, but they have a weak resistance to a few contagions—*e.g.*, smallpox.

Their most common ailments are diseases of the gastro-intestinal tract, especially dysentery; of the respiratory organs, especially pneumonia, while consumption is very rare; of the eyes, especially ophthalmia due to dust, which, being neglected, leads to blindness, as does smallpox; of muscular rheumatism and arthritis. Malaria, smallpox, and pemphigus contagiosus in children are very common. Typhoid fever appears to be rare; leprosy and elephantiasis are known, as is goitre.

He very much doubts the presence of syphilis prior to Columbus, and points out that the bones in the ancient graves in California, on the north-west coast, in Peru, and other localities in South America, do not show any signs of the disease, even when thorough examinations of extensive osteological collections have been made.

In children the common cause of death is diarrhœa. He makes most interesting observations on the mites which burrow under the skin of the toes in the Huastec, who live to the east of the Otomi (Hidalgo region), and which may cause suppuration and even loss of a toe. Injuries due to spiders, centipedes, scorpions, rattlesnakes, and the gila monster are mentioned, as well as poisoning from aconite, datura, and fungi. The narcotic effects of Peyote are noted, while two plants, cul-ick-um-ek (*Donedia suffrutescens*) and hā-van tātat (*Phacelia infundibuliformis*), cause dangerous wounds when journeying through forests, leading to some form of poisoning, and in the case of the former even to death. He met with albinism and leucoderma, but pinta was unknown, though stated to occur farther south. The diseases which were rare were: anæmia, diseases of breast, circulatory organs, liver, female generative organs, and skin; while asthma, dental caries, cancer, rickets, hernia, idiocy, insanity, nervous diseases except epilepsy, scarlet fever, and fracture of bones were also rare.

With regard to the *Virgin Islands*, Butler and Hakansson have pointed out that malignant tertian and quartan malarias are present, but that the carrier anopheline has not been identified, while pellagra is quite common and ankylostomiasis is present. The lack of sanitation causes considerable morbidity and mortality, and there is a high illegitimacy rate, venereal disease rate, and infantile mortality, while the poor food conditions are held to be the cause of pellagra, and the poor sewage disposal and defective water-supplies to encourage diarrhœa, dysentery, enteric fevers, and the encouragement of mosquitoes to breed in houses causes the high filarial infection and its associate morbidity.

Ecuador has been studied by Espinosa-Tamayo, who finds *Ancylostoma duodenale* and *Necator americanus* present, as well as *Oxyuris*, *Tænia solium*, and *Hymenolepis nana*. The jigger is noted and so is *Xenopsylla cheopis* and *Clinocoris rotundatus*. Yellow fever has almost disappeared, but malaria, amœbic dysentery, enteric fevers, and tuberculosis, are rife. Chichismos caused by drinking 'chicha made from fermenting maize is said to be like pellagra.

Tropical Africa.

The outstanding features of tropical Africa are its trypanosomiases, its malarias, and its relapsing fevers, while enteric fevers and typhus are more prevalent in the north, where the schistosomiasis and pellagra also abound. Porocephalosis is likewise a feature of this country, which is the home of numerous local diseases, such as guondou, while skin complaints are extremely common.

Whether or no cerebro-spinal meningitis originated in Central Africa is an interesting speculation.

The primitive forms of medicine, the venomous animals, and the poisons are all of great interest and require much further research.

PREVENTION.

It is not our intention to write upon prophylaxis in this portion of the book, but merely to indicate that many diseases exist in the tropics which medical research has shown to be due to definite parasitic organisms spread in a very definite manner, and therefore more or less preventable.

We would venture respectfully to quote His Most Gracious Majesty King George V., who long ago said:—"*If preventable, why not prevented?*" We would further venture to ask that more regard should be paid to this memorable utterance, which we believe will echo down the rolling centuries and will be more and more appreciated as they pass.

We would, however, ask the reader to remember that to prevent disease entails hard unappreciated work, usually in the face of much opposition and in direct contrast to the comfortable life of letting things drift; but in the light of His Majesty's words this work should be taken up by his subjects.

Moreover, the present war has shown what can be done when military authorities work hand in hand with medical research, and we are of the opinion that civilian Governments should learn this lesson also.

It is, indeed, a satisfactory sign that the Secretary of State for India is reported as stating, in a remarkable speech made to a British Medical Association deputation, that a modern Government required and should take all suitable means to obtain the best and most accessible advice on various medical and sanitary problems with which every such Government is called upon to deal. If this dictum is acted upon—*i.e.*, if it passes the realm of advice—a new era will dawn in the tropics.

REFERENCES.

If the reader desires further literature with regard to evolution, we invite his attention to Adami (1918), 'Medical Contributions to the Study of Evolution.' If he wishes to dive into geographical discoveries, he may well begin with Keltie and Howarth (1913), 'History of Geography.'

CHAPTER VI

FITNESS FOR TROPICAL LIFE

Preliminary—Examination—Women—Invaliding—Natives—Life assurance —Expectation of life in tropical natives—References.

PRELIMINARY.

THE selection of European and American men for service in the tropics, the fitness of European and American women for tropical life, the question as to how long white children should remain in warm climates (Chapter LXXXVI.), the invaliding of sick persons of all races, the selection of natives for employment under Governments or in mercantile houses, and the problems of tropical life assurance, are all matters of great importance to the tropical practitioner.

He may have nothing to say in regard to the selection of persons for tropical service, but he has very considerable knowledge of their after medical history.

We are unable to allow much space in the present book for the consideration of these questions, but we will endeavour to touch upon such points as appear to us to be of importance, and to leave the elaboration of the same to the reader, and for this purpose we give references at the end of the chapter.

EXAMINATION.

We presume that every medical practitioner appointed for the purpose of selecting men for service in the tropics will go faithfully through a routine examination more or less based upon that adopted by the best type of assurance companies, and therefore we need not lay stress upon such an examination; but there are certain points to which we desire to invite especial attention.

First-Class Lives.—Every selected candidate be a first-class life and *free from any trace of albumen* in the urine.

Venereal Disease.—The examining physician should make it his duty to exclude *gonorrhœa*, not by mere question, but by actual examination, and the same is true for *syphilis*. No one should be allowed to proceed for the first time to the tropics with an uncured gonorrhœa or with an imperfectly treated syphilitic infection.

Further, we are of the opinion that it is the duty of the examiner to warn all selected candidates as to the dangers of infection with venereal disease in the tropics, and at the same time to give and to read to him *printed instructions*, similar to those provided to-day for soldiers, detailing methods for prevention of infection.

Every tropical practitioner knows how much sickness and loss of work is due, directly or indirectly, to venereal disease; and we feel that it is not too much, in the interests of the employer and the employee alike, to ask that the above should form part of the duties of every medical examiner of candidates destined for the tropics. We further submit that each health report should state clearly that these duties have been carefully carried out by the examiner.

Vaccination.—It is necessary that every selected candidate, before final appointment, should produce a certificate that he has received two injections of a vaccine prophylactic against typhoid and the paratyphoid fevers, or of a so-called tetra- or penta-vaccine containing in addition to the already mentioned three diseases, cholera or cholera and plague. Evidence of Jennerian vaccination forms part of the routine medical examination, and must not be older than seven years.

Quinine.—Every selected candidate, before final appointment, should produce a medical certificate that he is able to take a dose of 10 grains of quinine without developing serious symptoms.

Teeth. No candidate should be finally selected for the tropics until his teeth are in such a condition as to satisfy the examiner, or until he produces a dentist's certificate to the effect that they are in good order.

Alcohol.—The objections to alcoholic candidates are so well understood that the mere mention of this point is sufficient (see Chapters III., V., and LVI.).

Age.—We are convinced that no one under twenty-one years of age or over fifty years should be allowed to proceed for service for the first time in the tropics. We are also of the opinion that the nearer the minimal age is to twenty-five years the better for employer and employee alike.

Heat and Sun.—Whatever personal views the examiner may have as to the effects of heat and sun, he should nevertheless, as part of his duties, warn the selected candidate as to the possible dangers of careless exposure to the tropical sun and as to the effects of tropical heat, and should acquaint him with methods of prophylaxis. He should also give advice on clothing, as we have seen distinguished visitors arrive in the tropics in clothing suitable for an English winter. There are, of course, cold regions and cool seasons in the tropics, but the cold is not generally felt by the new arrival from the Temperate Zone.

Energy.—The selected candidate should be warned that, on first arrival, he may not feel the heat of the tropics to be excessive. On the other hand, he may feel that the climate suits him admirably, and that he is full of energy for work and play, and should be told that this state of affairs will not last for ever, and that, if he allows his energy to outrun his common sense, there will be trouble.

Moderation in all things should be indicated as the motto for a tropical life.

Duties of the Examiner.—We have insisted upon the medical examiner giving advice upon various points to the selected candidate. Our reasons for so doing are because he may be the only medical practitioner to examine the candidate before the tropics are reached.

We feel that it is in the interests of employer and employee that every opportunity should be given for the selected candidate to keep fit until he reaches the local medical officers.

Check Examination.—We are of the opinion that a check medical examination by the local medical officers immediately upon the arrival of the new official is advisable, in order to see whether entry into the tropics has induced any changes in his health, and also for the purpose of giving him local medical advice.

This check examination is very necessary, as we know that persons have arrived slightly indisposed, and have allowed these slight symptoms to become serious owing to lack of knowledge.

WOMEN.

European and American women proceeding to the tropics are usually either married or about to be married, or, because of the scarcity of white women therein, are very likely to be married fairly soon, although they may start as nurses, missionaries, etc.

We therefore consider that all women proposing to live in the tropics should be medically examined in the same way as men, and should be specially tested as to their ability to stand quinine therapy; and if this is found wanting, should be educated up to a necessary quinine standard, by regulated small doses, before being allowed to begin their new life.

Our experience makes us agree with Mrs. Scharlieb that the medical examination of women should include the bony pelvis and the organs contained therein when practical.

Often women have to live in out-stations far from medical aid, and it is little short of criminality not to take the external measurements of the pelvis, and if necessary to investigate the condition of the internal pelvic organs by means of a rectal examination. If abnormalities are discovered the woman or her husband, or both, should be warned as to the possibilities of such abnormalities.

At such an examination care should be taken to see that there is no obvious cause for dyspareunia, as it may cause trouble to the examinee and her husband. This has been brought home to us in our long experience of tropical practice.

Moreover, the woman should be warned as to the possibility of menorrhagia (or the much less common amenorrhœa), which may begin after arrival in warm climates, and should be given advice as to clothing.

The necessity of having the urine examined on the occurrence of pregnancy should be impressed upon the wife and her husband, as well as the requirements of diet, exercise, rest in the warmer hours of the day, etc.

White men, as a rule, require at regular intervals visits to temperate climates if their health, strength, and mental vigour are to be maintained unimpaired; and the same holds good, but perhaps with more force, for women, who should be allowed leave to cooler tropical regions and to the Temperate Zone as often as circumstances permit. When a woman returns to a temperate climate she should be advised as to the necessity of an immediate medical examination, as well as of the dangers of the change into cooler weather.

INVALIDING.

Two classes of cases require to be considered under this heading – viz., the *tropical resident* about to be invalided to cooler climates, and the *cool-climate resident* about to be sent to the tropics for the benefit of his health.

With regard to the first, there are two quite different aspects of the case, viz.. –

(*a*) **Invaliding for the Good of the Employer and Employee Alike.** —This is a matter of common sense, and is the kindest method of dealing with many cases.

(*b*) **Invaliding because of Health.**– Temporary invaliding or sick leave should always be advised if the patient's health requires it, but his financial status should also be taken into consideration before too drastic recommendations are made.

More difficult by far is the question of permanent invaliding from service, and in coming to a decision the medical practitioner has many points for consideration with reference to the present condition of the patient and his future prospects.

The nature of the illness, the physical and mental condition of the patient, his age, his pension or gratuity, his possibilities of future employment in cooler regions, his family, etc., have all to be considered.

Among the many difficulties which present themselves under this heading we venture to express the opinion that one attack of *blackwater fever* should not constitute *per se* a reason for permanent invaliding.

On the other hand, we are of the opinion that *mental symptoms* should constitute a reason for permanent invaliding, as the tropics are climatologically unsuited for an unstable nervous system.

As a general rule, if an endemic infection– *e.g.*, bilharziosis– is playing havoc with a patient, he should be permanently invalided from that particular area or areas, which may not mean that he should be invalided from the tropics or from the service.

NATIVES.

Natives should never be accepted for employment unless they are first-class lives. The eyes require careful attention, and colour-blindness should be looked for, especially in certain employments such as railways, steamers, ports, etc.

Particular attention should be paid to the urine, and natives know many tricks with regard to this part of a medical examination.

Schistosomiasis of any part of the body should cause rejection, and diffuse leucoderma if the candidate is to work in the sun, but it is not possible to give further details, which must be left to the common sense of the examining officer.

The invaliding, temporary or permanent, of natives from a service, particularly if a pension or a gratuity is available, requires great care, and the possibilities of malingering must be remembered. On the other hand, the effects of such apparently harmless diseases as diffuse leucoderma should be borne in mind, and injustice should, if possible, be avoided.

LIFE ASSURANCE.

Tropical life assurance is in its infancy, and so far has been mostly studied in regard to India.

Insurance offices usually regard 33° north to 30° south latitude as including the dangerous climates of the world. They usually consider those lands which lie nearest to the Equator as the most dangerous, because of the heat, the endemic diseases, the lack of sanitation, and the imperfect food-supplies.

But the advance of knowledge with regard to the prevention and treatment of tropical diseases, and the dawn of tropical sanitation, has reduced, and is reducing, the baneful effects of many of these factors. For example, the West Coast of Africa used to have an official mortality rate of 80 per thousand, and an official invaliding rate of 95 per thousand, but these had been reduced to 21·7 and 76·3 per thousand as long ago as 1903, and to-day are probably much less.

It is true that the older type of official, medical and non-medical alike, disliked spending money upon improved sanitation and upon the prevention of disease; but this type of official is slowly but surely disappearing, and the danger to-day is that official inertia may undo years of official toil.

It is therefore necessary that a high standard of sanitation and disease prevention should be set for the tropics, and that this should be maintained; and if this is done, then many of the serious objections to tropical life assurance may be removed or abated in the future, and as this is done better assurance terms should be forthcoming.

Very many tropical practitioners have had experience in the selection and rejection of tropical candidates for life insurance, but, unfortunately, there are but few records to be found based upon this work.

In 1897 and later, Cantlie, writing with regard to this matter, stated that although the person in the tropics was exposed to many deadly diseases, he was not very liable to scarlet fever, rheumatism, and pneumonia, and that, excluding malaria, his chief dangers were diseases affecting his alimentary canal and abdominal organs, and that alcohol was an even greater curse in the tropics than in temperate climates.

He states that the insurance companies deal with each case individually, and he suggests that during the first seven years of residence in a proscribed area an extra premium should be paid, but that after that period it should be reduced to one-half upon a certificate from the company's medical officer that no permanent injury to health has been incurred, and that the cost of this examination should be paid by the insurer. Further, after ten years' residence the extra premium should be reduced to one-third of the original sum, and after thirteen years no extra premium should be charged, provided always that the necessary certificate was forthcoming.

He points out that a period of danger is the first year or two after the old tropical resident takes up his permanent abode in the Temperate Zone, and he recommends that an extra premium be charged for these two years.

The next paper, published by Winter in 1909, we have been unable to peruse in the original, but he apparently lays stress on the first few years of residence in India, on the ground that Europeans are very likely to become victims to enteric and similar fevers.

Caddy in 1912 came to the conclusion that the European does not acclimatize well in the tropics, meaning by this statement that he is unable to rear healthy strong children in India, and that he becomes debilitated by residence there, requiring a change to a temperate climate every four or five years, and that after years of residence he is even more liable to sunstroke than on arrival.

Out of 1,799 cases he rejected 6 per cent. and loaded 8 per cent., making together 14 per cent., which was caused by inferior physique, obesity, glycosuria, albuminuria, consumption, consumptive family history, bad family history, syphilis, heart disease, sundry diseases (3·39 per cent.), alcoholism.

With regard to natives desiring insurance, it is true that years ago it was only the Europeanized native who sought after this; but to-day it is different, and even native women of due social standing are allowed assurance, provided that careful inquiries have been made, though years ago such an assurance was never considered.

Caddy adds to the list of causes of rejection 'elephantiasis,' and he is of the opinion that opium and hemp are very harmful, but that they are not commonly consumed by the insuring classes of India.

He considers that Rajahs, wealthy landowner Marwaris, or bankers and money-lenders, and petty merchants, are bad lives, while the best native risks are Government servants and native clerks in European offices.

As a rule the native does not consume alcohol, but if he does he should be regarded an indifferent risk.

He also states that the native of India is a shorter man than the European, and that height for height he is about the same weight, but he is very subject to glycosuria and to hydrocele.

The discussion on this paper was interesting, and in our opinion some of his views are open to criticism.

With regard to life assurance in Egypt, the only publication with which we are acquainted is by Day, who distinguishes four groups of proposers—viz., the Western European, the Southern European, the Eastern, and the Egyptian.

In general, he considers the first class to be a good risk on the same terms as in Europe, but with regard to the second he considers that they should be examined in their own homes, and each case should be judged on its own merits, and the third class is intermediate in risk between the second and fourth.

The native Egyptian appears to be a great difficulty, owing to the paucity and unreliability of the family history, while sexual excess and cigarette-smoking are considered to balance the lack of alcoholic excess. Rheumatic fever, tuberculosis, and syphilis are rife, and he is liable to many tropical diseases, including ankylostomiasis, pellagra, splenomegaly, relapsing fever, typhus fever, and the schistosomiases, so that he is not a good risk until education and sanitation improve matters; but Day says a proposer then in good health, and whose children are successfully reared and whose education has been sound, may be accepted for a whole life on European terms, but this was contested during the discussion on his paper.

The common sense of the whole matter is that there is an increased risk on the life of the European living in the tropics, and that it is most marked during the earlier years of his residence; there is a considerable risk in insuring native men, and that this is greatly increased when considering native women.

EXPECTATION OF LIFE IN TROPICAL NATIVES.

The expectation of life in India compared with the same for England may be gathered from the following table obtained from Hardy via McCay's book:—

Age.	*India.*		*England.*	
	Males.	*Females.*	*Males.*	*Females.*
0	24·6	25·5	43·7	47·2
5	37·1	30·1	52·7	54·9
10	35·5	34·4	49·0	51·1
15	32·3	31·7	44·5	46·5
20	29·2	29·3	40·3	42·4
25	26·3	27·0	36·3	38·5
35	21·1	22·4	28·9	31·2
45	16·5	17·9	22·1	24·0
55	12·2	13·2	15·7	17·2
65	8·2	8·7	10·3	11·3

The figures speak for themselves, but they were compiled years ago, and it is possible that more modern tables might show a better expectation of life.

CHAPTER VII

TEMPERATURE AND HUMIDITY

Preliminary—High atmospheric temperatures—Conclusions—References.

PRELIMINARY.

HAVING finished with the introductory portion of our task, we enter upon the second part of this book, which is devoted to the *causation of disease,* and is therefore essentially pathological. This subject is divided into three sections, embracing the physical, chemical, and parasitic causes of tropical diseases.

HIGH ATMOSPHERIC TEMPERATURES.

The present short chapter is confined to a brief consideration of the pathological effects of high atmospheric temperatures, which are the most important physical causes of disease in the tropics, and are only markedly evident when there is a definite amount of atmospheric humidity; and therefore we have entitled this chapter Temperature and Humidity.

To exemplify what we mean we will quote a concrete example. In a certain tropical locality there were the usual high air temperatures with relatively low humidity and cool nights until about the middle of a month, when the temperature rose to 116° F., the humidity increased, the sky became cloudy, and for twenty-four hours there was little breeze. During this period about fifty laboratory animals died, though well protected from the sun by living in large brick houses. They showed post-mortem the typical signs of heat-stroke—viz., the congestion of the meninges and brain, and the marked congestion of the lungs, which were almost black with stagnated blood. During this period there were a few deaths in the population of the place from the same cause.

Clinical experience has shown that there are two different pictures associated with the pathological effects of high air temperatures. The first picture is that of extremely high fever, and is called *heat-stroke;* while the second is depicted by collapse and low bodily temperatures, and is named *heat-syncope.*

We have investigated these two conditions experimentally. It was our practice in our journeys from Ceylon to Europe to test the effects of high air temperatures upon ourselves, and such of our fellow-passengers as took an interest therein, when passing through the Red Sea in the hot months thereof.

The air of the engine-room in steamers is laden with aqueous vapour, and certain corners can be found near the condensers with high air temperatures and practically no draught—or, in other words, with conditions analogous to those under which Haldane performed his experiments which we have mentioned in Chapter III.

When the steamer is in the hottest part of the Red Sea in a warm month, if a person, lightly clad and in good health, places himself in such a corner, with a clinical thermometer in his mouth, it will be found that at first he begins to sweat violently, and for a time remains at a normal temperature. But in due course his temperature will gradually rise and his pulse-rate increase, until temperatures of over 102° F. are reached, and the person breaks off the experiment because he feels uncomfortable, after which his temperature slowly returns to normal.

We have performed this simple experiment several times, but on one occasion, in a person who was not in very good health, the temperature, after reaching 101° F., ceased to rise; the skin became cooler, the tension of the pulse altered remarkably, and he began to look ill. The experiment was quickly stopped and stimulants administered, so that he did not suffer any serious effects, though it was some hours before he felt quite right.

These two experiments show that a high atmospheric temperature can act in two ways. In the first there was a gradual rise of the body temperature, which, if continued long enough, would probably have resulted in hyperpyrexia. In the second, after an initial rise, the heart became embarrassed, and if the heat had been continued, there appears no reason to doubt that this person would have passed into a condition of syncope.

There are, therefore, two distinct clinical entities to be considered—viz., heat-stroke, characterized by high bodily temperature; and heat-syncope, in which there are symptoms due to cardiac failure but no fever, both of which are brought about by the same cause—viz., high atmospheric temperatures associated with moderate or high humidity.

Such are our views; but it is as well for the reader to be acquainted with those of other authors, which may be briefly stated in an historical account as follows:—

High air temperatures, whether in the day time or at night, have been known since ancient times to have an effect upon human beings. The case of the child of the Shunamite woman described in the English Bible in 2 Kings iv., from verse 18 onwards, is probably the earliest on record. The child complained to his father of his head when out with the reapers, and was carried to his mother, and is reported to have died at twelve noon—became insensible—but recovered under Elisha's treatment, which appears to have been of the nature of massage. This treatment reminds one strongly of the active friction by which the miners of the Comstock Silver Mines of Nevada are said to treat successfully those of their fellows who faint when coming out of the warm mine in which the hot, steamy air has a temperature of 128° F.

It has been said that though old writers such as Dio Cassius described these conditions, the medical writers of ancient times were silent about them. This does not seem to be quite just, for Paulus Ægineta, Oribasius, and the Arabians certainly understood that there were head symptoms which they called 'siriasis' (after Sirius, the dog-star), due to excessive heat. Certainly this knowledge was lost, and Cardanus, in the sixteenth century, describes symptoms due to morbus attonitus (apoplexy) brought about by the heat and drought of the summer of 1543 in Florence. After this for a long time the disease was considered to be an apoplexy till Boerhaave, early in the eighteenth century, introduced the name 'insolatio,' and considered it to be a phrenitis—*i.e.*, meningitis.

Steinkühl (1819) thought that the congestion of the lungs caused death by asphyxia; Swift (1854) that it was due to exhaustion produced by fatigue; Hill (1857) evidently confounded pernicious malaria and heat stroke. Levick (1859) suggested that it was an acute specific fever; H. C. Wood (1863) considered that it was due to a poison developed in the blood, and called it thermic fever; while Stiles (1864) performed experiments on animals, and concluded that the disease was due to the direct effect of heat on the muscular system.

In 1869 Eulenberg and Vohl stated that the disease was due to sudden liberation of the gases in the blood; and Weikard and Richardson attributed it to clotting of blood in the vessels.

In 1870 Vallin performed several experiments by locally heating parts of the body, and concluded that there were two conditions: (1) sthenic insolation, due to coagulation of the muscle fibres of the left ventricle; (2) asthenic insolation, due to the action of heat on the nerve centres of the brain, thus disturbing the innervation of the heart.

In 1871 and 1872 Claude Bernard performed some experiments which tended to show that when a warm-blooded animal died as the result of heat, it was due to rigor in the musculature of the heart.

In 1872 H. C. Wood performed experiments which showed that sunstroke could be produced in animals as readily as in man by artificial or natural heat.

He came to the conclusion that death took place from asphyxia, and that after death the rigidity of heart and muscles was due to the coagulation of the myosin, and he further pointed out that this will take place at once in the heart if the temperature of the body reaches 115° F., and said that he considered it to be the cause of sudden deaths in soldiers in battle. Further, he pointed out that the heating of the brain of a mammal to 108° F. produces insensibility, with or without convulsions, and that when 113° F. was reached the animal died, and that, though the general symptoms of sunstroke were absent, the nervous symptoms were present. He came to the conclusion that no capillary thrombi were formed, that no poisons were generated in the blood, and that the real condition was the heat acting upon the nervous system, as a result of which there was rapid metabolism, which used up oxygen and at the same time induced brain changes, causing asphyxia. But he distinguished from the true heat-stroke:—

1. Acute meningitis or phrenitis, due to exposure to the sun, in which he disbelieved.

2. Heat exhaustion, due to working in a heated atmosphere, which he said did not differ from acute exhaustion due to other causes, and therefore was not true sunstroke.

In 1879 Jacubash classified heat accidents into: (1) sunstroke due to the action of the sun on the body, when the temperature may reach 113° to 115° F. (45° to 46° C.); (2) heat-stroke, due to exertion, and often seen in marching troops in the Temperate Zone; (3) thermic fever, which he considered to be the true heat-stroke of the tropics, due to accumulation of heat in the human body in consequence of high atmospheric temperatures without exposure to the sun or muscular exercise.

Dony (1884) considered that there were two main conditions: (1) sunstroke, due to the sun's rays acting upon the cranium and brain, only without very great rise of temperature; and (2) heat-stroke, due to intense heat acting on the whole body and after certain prodromes, resulting in a rapid rise of temperature to a great height.

In 1893 Saquel classified the diseases into (1) sunstroke, meaning the erythema due to the sun's rays; and (2) insolation, meaning the action of the sun on the nervous system, producing either congestion (mild form in the Temperate Zone) or meningitis and encephalitis (severe form in the tropics); (3) heat-stroke; and (4) thermopeliosis, a combination of insolation and heat-stroke.

In 1898 Sambon defined heat exhaustion as an ordinary syncope, while he considers that under the term 'sunstroke' there is confounded an infectious fever which he calls 'siriasis,' due to some micro-organism as yet not defined.

In the period 1898-1907 Sir Patrick Manson, in his book on tropical diseases, recognized three conditions: (1) heat exhaustion—sudden cardiac failure or fainting, brought about by exposure to high atmospheric temperature; (2) siriasis, an acute disease developing in the presence of high atmospheric temperature, and characterized by sudden incidence of hyperpyrexia, coma; and (3) sun traumatism, or direct action of the sun's rays on the tissue, causing either sudden death or a febrile condition.

In 1905 Van Brero, in Mense's 'Handbuch der Tropenkrankheiten,' recognizes (1) heat exhaustion, due to excessive heat from the sun or other source; and (2) sun traumatism, caused by the direct action of the sun's rays.

In 1907 Sir Joseph Fayrer, in Allbutt and Rolleston's 'System,' recognizes (1) a state of exhaustion leading to syncope, and (2) an overheating of the nervous centres, blood, and tissues, leading to thermic fever.

In 1908 Brook defines diathermasia as the effect of heat on the thermotaxic mechanism, and phœbism, a kind of shock due to the actinic rays from the sun.

(For the continuation of this history see Chapter LVI.)

It will thus be seen that authorities in general recognize the action of heat and the action of sun's rays as being separate, and, further, that heat may produce a syncopal condition of fever, while the sun's rays may also cause syncope and fever. Some few, including especially Sambon, suspect the presence of an acute specific fever as being concealed in the diseases above mentioned. Others, again, consider the symptoms to be toxic in origin, so that there are four theories: (1) caloric; (2) actinic; (3) microbic; (4) toxic.

CONCLUSIONS.

Personally, we believe that high atmospheric temperatures with a sufficiently high atmospheric humidity and more or less stagnation of the air can produce the clinical pictures called *heat-stroke* and *heat-syncope*, especially in people working hard at manual labour and clad in unsuitable clothing.

As to the reason why some persons should develop these symptoms, while others living under exactly similar conditions escape, we believe it to be a matter of general health and personal habits, which in the one case disturb the metabolism of the body, causing a derangement of physical or chemical heat regulation, while in the other case this mechanism is working normally.

The regulation of bodily heat can be disturbed by anything which tends to derange metabolism or heat regulation, such as overwork, lack of care in protecting the body as much as possible from heat by the means indicated in Chapter III., p. 89, alcoholism, and the effects of bodily disease.

Muscular work is especially dangerous, as under certain conditions even a couple of sets of tennis may produce a temporary increase of the bodily temperature, which may rise as high as 101°-102° F.

If in addition to the deranged heat regulation there is added cardiac weakness or lack of vaso-motor control, then ***heat-syncope*** and not heat-stroke appears.

The essential pathological change producing death from heat-stroke is the partial coagulation of the globulin found in the cells of the body. It is possible that this coagulation takes place first in voluntary and cardiac muscles, thus leading to respiratory and cardiac failure, while later marked changes are to be found in the nerve cells, especially in the medulla, leading to chromatolysis.

The clinical description of these diseases will be found in the third part of this book, in Chapter LVI.

CHAPTER VIII

PRESSURE AND RADIATION

Preliminary—Increased pressure—Diminished pressure—Radiation—Electricity—References.

PRELIMINARY.

THE present chapter is devoted to the study of the *pathological effects* of atmospheric pressure when considerably increased or diminished, and of the rays from the sun under conditions which produce disease.

If there are pathological effects, other than those already mentioned (p. 88), as the result of rays from the moon, they are unknown. Probably they do not exist, and possibly the effects already described may be due to the fact that the moon's rays when reflected become polarized.

A passing reference will be made to the effects of lightning, as death from this cause is not infrequent in the tropics.

INCREASED PRESSURE.

The work of facilitating trade by means of roads and railways throughout the tropics necessitates the construction of bridges across deep rivers, and therefore for many years to come the effects of artificially increased atmospheric pressure will be more obvious in these regions than elsewhere.

Moreover, for centuries tropical natives have been exposed to increased pressure when diving for commercial purposes, and though generally they do not remain down long enough to suffer any bad effects, still at times these are noted.

The effects of greatly increased atmospheric pressure are usually termed 'caisson disease,' because it was observed first in connection with the special compressed air apparatus used by engineers for work under water.

In 1878 Paul Bert, as the results of his experiments upon animals, showed that the extraordinary symptoms of this disease could all be explained by increased atmospheric pressure, but it is mainly by the labours of Leonard Hill that Paul Bert's work has been confirmed and made known.

Symptoms of the disease are rarely observed until a pressure of one atmosphere (15 pounds to the square inch) has been reached, but above that point the danger rapidly increases, and at two atmospheres the risk is very considerable.

The causation is due to the fact that the blood absorbs nitrogen from the compressed air, and this gas is retained in simple solution in the blood-plasma solely by the increased pressure. If, now, this pressure be rapidly diminished, the nitrogen is liberated in the form of bubbles in the plasma, and these in their turn block the capillaries and also tend to accumulate in the heart. The other gases, oxygen and carbon dioxide, have nothing to do with the causation, for obvious reasons, because oxygen would be rapidly absorbed by the tissues, and the other gas cannot be increased in the blood affected by compressed air.

Nitrogen is also held in solution in the tissues, especially in fat, and hence fat people are more susceptible to the disease.

Time is required to saturate the blood and tissues with nitrogen, and therefore the danger increases with the length of exposure.

The actual liberation of the bubbles of nitrogen will not take place until decompression is begun. If this is rapid, then the symptoms will be severe; if slow, they may be few or absent; but it has been found that danger depends upon relative and not absolute reduction. Thus, two atmospheres may safely be reduced to one, four to two, six to three, but three atmospheres cannot be reduced to one without danger.

Decompression should therefore be based upon reduction to one-half of that at which work has been done, and after that there is a considerable pause, during which muscular exercises are performed to rid the body of the nitrogen; and, again, a half-decompression, and so on, but each interval must be considerable.

As the symptoms are due to bubbles of gas, they are extremely varied, but pain and paralysis are the most marked, and should be treated by immediate recompression, followed by slow decompression.

The medical examination of persons about to work on these lines is most necessary, and all fat persons and those with any organic lesion should be rejected.

DIMINISHED PRESSURE.

The attention of tropical workers has been drawn of late to the effects of diminished atmospheric pressure as exemplified by able accounts of the mountain sickness of the Andes.

Normal atmospheric pressure in alveolar air, which is saturated with aqueous vapour, is 760 millimetres of mercury, of which 47 are due to the pressure of the aqueous vapour, and therefore the rest is due to air gases, of which oxygen, which is present in a proportion of 14·2 per cent., is responsible for 101 and carbon dioxide for 40 millimetres.

If the oxygen percentage in inspired air falls from 20·9 to 12 per cent., hyperpnœa takes place; if to 10 per cent., cyanosis appears and increased frequency of the heart; and at 5 per cent. there is loss of consciousness.

If the atmospheric pressure is reduced to 580 millimetres, the want of oxygen begins to tell upon the breathing, and the carbon dioxide pressure in alveolar air is also diminished.

Mosso and Aggazotti, noting the favourable effects of adding CO_2 to inspired air and reduced oxygen pressure, came to the conclusion that mountain sickness was 'acapnia'—*i.e.*, primarily due to deficiency in carbon dioxide—but the real facts are that Paul Bert was right in tracing it primarily to lack of oxygen, produced gradually. Mountain sickness usually begins about 6,000 to 7,000 feet, and is more marked at heights of over 10,000, but after a sojourn of one or two weeks the effects pass away. The physiological effects of high altitudes have been studied by Haldane, Douglas, and others, at a height of 14,000 feet and a barometric pressure of 457, when it was found that though persons became ill within half an hour of arrival, their symptoms were relieved immediately by inhalation of oxygen, and acclimatization took place within eight to ten days.

The partial pressure of CO_2 in alveolar air had fallen to 27 millimetres, and the carbon dioxide ventilation had increased considerably, and therefore the alveolar oxygen pressure was raised above what it otherwise would have been—*i.e.*, 52 millimetres.

The arterial oxygen pressure was 35 millimetres above oxygen pressure in alveolar air, and accounted for the disappearance of mountain sickness and for the bright red colour of the lips. On arrival it is little above that of alveolar air, therefore acclimatization depends upon the development of the powers of the epithelium of the lung alveoli to actively secrete oxygen inwards, a power which does not exist during rest at sea-level.

The hæmoglobin is increased in a few weeks' residence to 115 to 154 per cent., as indicated by the Gowers Haldane scale; and this slow increase is associated with a slow increase in the total hæmoglobin of the body and a slight increase in the blood volume.

The red bone marrow is increased in amount (as shown by experiments on dogs by Zantz), and there is new formation of red corpuscles and a diminished alkalinity of the plasma for unknown reasons.

RADIATION.

Radiation from the sun, of heat and chemical rays, is potentially an important factor in producing pathological conditions in man residing in all climates, but more particularly in the tropics.

In temperate climates its heat effects have been especially studied by Rubner, Cramer, and Wolpert, who state that, adding half the number of degress of difference between the register of the black bulb thermometer and that of the shade thermometer to the shade temperature, one obtains a figure which corresponds to the thermic effects of the sun. This calculation in the tropics gives a temperature considerably above that of the body, but the only exact method of measuring the caloric value of radiation from the sun is the *pyrheliometer* of *Angstrom*, as used in Manila by Aron. Schmidt estimates the heat effect of the tropical sun as being equal to 2 small calories per square centimetre per minute.

Now, the animal body having a much higher coefficient of absorption of heat than has the air, is capable of absorbing these rays, and hence of becoming hotter; therefore in this way exposure to the sun tends to make the body hotter and helps in the production of the heat-stroke already considered in the last chapter.

It is, however, with the chemical rays that we are more concerned in the present section, and as yet there are but few observations on this subject in the tropics.

The earliest experiments, with a view to ascertaining definitely whether there is such a condition, were those by Scaghosi on rabbits exposed to the Sicilian sun. Their temperature rose considerably, and if the experiment was continued long enough they died, but if it was stopped they recovered. The post-mortem changes were hyperæmia of the meninges, heart, lungs, liver, and spleen. The nerve cells of the brain and spinal cord showed coagulative necrosis and chromatolysis.

The next experiments of importance on the ætiology of this condition are those of Möller on rabbits, who showed that thermal rays, with or without chemical rays, if directed on to the skin covering the skull, produced more or less intense cerebral disturbance, and sometimes even sudden death. The autopsy after intense irradiation showed the skin of the head much swollen and bloody, with gelatinous exudation in the subcutaneous tissue. The periosteum, cranial bones, and dura were discoloured, and covered with ecchymoses. The vessels of the brain surface were much dilated, and showed numerous, and in part confluent, ecchymoses.

Our own experiments on rabbits, performed yearly for several years, during the particularly hot weather in Colombo, show that if such animals are exposed to the sun at about twelve noon they die with all the symptoms, post-mortem appearances, macroscopical and microscopical, of sunstroke, in about sixty-seven minutes, whereas other rabbits similarly treated and exposed at the same time and in the same place, but protected by red glass, live. Although it is true that the red glass did absorb a proportion of the heat rays, still the rabbit was intensely hot to the touch at the end of the experiment, being kept in position under the red glass by being placed in a box painted black externally and so narrow that the sun's rays fell directly upon its shaven head and unshaven back. Nevertheless, the protected rabbits, though kept under observation for months, never seemed to be any the worse for their treatment.

We came to the conclusion that the ultra-violet rays were not the pathogenic agent in these experiments, but that the active rays were in the visible blue and violet; and in this we were much aided by Professor Browning, who supplied us with glasses spectroscopically adjusted.

Aron studied the action of the tropical sun in the Philippino Islands, and concluded—

1. Under climatic conditions rabbits and monkeys, having by nature only a limited power of physical heat regulation, die if exposed to sun, the body temperature rising to febrile heights.

2. The post-mortem findings are hæmorrhagic lesions of the meninges and (in monkeys) of the heart.

3. In animals with a poorly developed sweat-gland system the subcutaneous tissues are heated by radiation from the sun to temperatures above that compatible with life.

4. The human skin is warmed to about 3° to 4° above normal skin temperature, but an increase in bodily temperature is prevented by evaporation of sweat, which causes a fall of skin temperature.

5. Brown skin shows a smaller rise in temperature than white skin, due possibly to an earlier and better water evaporation by sweat secretion. Hence a coloured skin is a better heat regulator than a white skin.

6. The air in human hair, especially black hair, under the influence of the tropical sun, acquires temperatures far above those compatible with life.

He also states that increased body temperature probably accounts for many of the accidents called sunstroke or heat-stroke, and he thinks that an excessive and continued watery evaporation from the skin, while avoiding a rise of body temperature, may lead to collapse, unless the lost water is replaced.

We believe that it is possible that direct radiation from the sun can bring about sudden death and congestion of the meninges of the brain. The connection between sunstroke and the chemical rays requires more investigation; but, whatever this may produce, there is no doubt that if the improperly protected head is exposed to radiation from the sun, headache and a feeling of illness is often produced, and that therefore adequate protection is required.

As is well known, monkeys prefer the shade to the sun's rays, and seem to understand the danger therefrom; and yet no one is afraid of monkeys dying from the heat in laboratory outhouses, though its effect on other kinds of tropical animals, such as gerbils, is a matter of bitter experience, leading to the loss of strains of trypanosomes.

We hold, however, that there is no clinical difference between heat-stroke and sunstroke, and therefore these will be considered as one and the same disease in the clinical section of this work (see Chapter LVI., p. 1449).

ELECTRICITY.

Thunderstorms are often of extreme violence in the tropics, and death from lightning-stroke is much commoner than in the Temperate Zone; but the signs of lightning-stroke are exactly the same as those usually recorded in books on general surgery, and need not be repeated here.

CHAPTER IX

SOME TROPICAL TRAUMATISMS

Remarks—Traumatisms brought about by animal agencies: the larger Carnivora; the smaller Carnivora; the Ungulata; the Proboscidæ; the Reptilia; the Selachii; Man—Traumatisms due to physical agencies: Foot-binding—Heavy fruits—Electric fans—Powdered glass—Bamboo hairs—References.

REMARKS.

In the tropics many accidents and injuries occur which are but rarely met with in temperate climates. These accidents and injuries may be divided into two categories—traumatisms brought about by animal agencies, and those due to physical agencies. Under the first heading come those caused by the bites or maulings of wild and domestic animals, as well as the injuries caused by man's bite. In the second division are grouped various accidents caused by electric fans, by the fall of heavy fruits from trees, and, lastly, the peculiar deformity of the foot in high-class Chinese women brought about by bandaging the feet of young female children.

There are, of course, many other traumatisms which might be worthy of note, as, for example, penetrating wounds of the abdomen by sword fish, as described by Renner, or bites by Congo fish, as privately mentioned to us by Christy; but they are either too rarely met with, or else they are too well known in the Temperate Zone to require notice here.

It will be observed that we make a distinction between the physical injury caused by the bite of one of the larger animals and the chemical injury caused by a venomous animal, and we do this advisedly, while fully recognizing that the former may introduce septic toxins, sometimes in large amount, as well as germs into the wounds so produced.

TRAUMATISMS BROUGHT ABOUT BY ANIMAL AGENCIES.

Traumatisms caused by the Larger Carnivora.—The word 'traumatism' is peculiarly suitable for this nomenclature, as it is derived from the Greek words *τραῦμα* (a wound) and *θηρίον* (a wild animal). The synonyms are **Morsus** and Rostro et Unguibus dilaceratio (Latin); *δῆγμα, δῆξις, διασπασμός*; *κἄπσις, σπαραγμός* (Greek); **Morsures**, Déchirements musculaires, Dilacérations, Dépiecement des chairs, Myalgies traumathérigènes (French). Under the definition 'Traumatisms caused by the larger Carnivora' we refer especially to the injuries inflicted by the bites, rends, and scratches produced by the teeth and claws of species belonging to the families Felidæ and Ursidæ.

In the Felidæ are *Felis leo* Linnæus, whose habitat is Africa and Asia; *F. tigris* Linnæus, habitat Asia; *F. pardus* Linnæus, habitat India; *F. leopardus*, habitat Africa; *F. onca* Linnæus, habitat South America; *F. pardalis* Linnæus, habitat South America. These cats have a general dental formula, $\frac{3.\ 1.\ 3,\ 1,}{3.\ 1.\ 2,\ 1}$ giving thirty teeth for the whole mouth, which include the most perfect types of carnassial teeth capable of producing exceedingly severe lacerations. These animals feed not merely on the fresh prey which they have recently slain, but also on its body for a day or so after its death. Their maws and claws, therefore, become exceedingly foul, being infected with micro-organisms and their toxins, and hence the great danger of septic intoxication and infection, which markedly increases the gravity of the injuries inflicted.

The other family, Ursidæ, includes the bears which are found in India and Ceylon—*e.g.*, *Ursus torquatus*, of the Himalayas, and *U. malayanus*. Their dental formula is $\frac{3.\ 1.\ 4,\ 2}{3.\ 1.\ 4,\ 3}$ = forty-two teeth in the mouth, but these do not include carnassial teeth, which, added to the facts that they are not as a rule such foul feeders and often eat vegetal foods, causes their bites to be not quite so serious from a septic point of view as those of the Felidæ. Their claws, however, may produce most serious effects of both a traumatic and of a septic nature.

The importance of the septicity of these wounds has been well appreciated from the earliest times, for in the fifth book of his 'De Medicina' Celsus remarks with regard to the bites of men, apes, dogs, and ferocious animals, 'Omnis autem fere morsus habet quoddam virus,' and on this he based his treatment. This statement has been quoted again and again in the centuries which have passed since the days of Celsus: for example, by Morgagni, when investigating the serious illness produced in a young lady by the peck of a sparrow inflicted on a finger, and by Heister, of Helmstadt, in the section on bites in his 'System of Surgery,' published in 1739.

It is of course possible for any person of any age and either sex to be the victim of wounds inflicted by these animals, but the persons most frequently injured are hunters (shikaris) and sportsmen, while the district postmen in jungle regions run great risk, as do shepherds and, to a less extent, herdsmen, and to a still less extent cultivators and villagers living in lonely places in the bush or jungle. The present writers have also encountered wild animals under unexpected circumstances during their journeys into the interior of Africa; but the risk which an ordinary traveller with his gang of porters runs is relatively small, particularly if he has some slight knowledge of the habits of these animals. The most dangerous region to travel through is tall grass, as the hunter or traveller and the wild beast may meet suddenly, and it is here that an accident is more likely to occur than in more open scrub country. Another prevalent cause of accidents is the beating by means of men on foot of jungle or bush into which a wounded animal has retreated. The especially dangerous animal under such circumstances is the tiger, and as eminent as authority as Sir Samuel Baker has especially drawn attention to this fact, and has stated that if no elephants are available then a herd of buffaloes should be driven through the jungle, as they will quickly dislodge the tiger. The possible presence in the vicinity of the mate of the attacked animal should always be borne in mind, as the omission to remember this simple fact has often led to unpleasant accidents.

The physical signs and symptoms produced by these bites and mauls may be divided into general and local. With regard to the former, immediately after being bitten or mauled the victim, if able to stand, feels giddy, turns pale, becomes unable to stand, and, if the injury is at all severe, quickly passes into a condition of shock with a weak pulse, cold extremities, pinched and drawn face, and weak voice, and may become insensible, which, indeed, is often his condition when first rescued in the severer cases. As a rule he remains in a more or less torpid condition, sleeping day and night, and suffering severely, when aroused, from thirst and pain. All these symptoms are more accentuated in Europeans than in natives.

Usually reaction sets in fairly quickly, the temperature rising to 101° to 102° F. or even more, while the pulse is generally quick, ranging about 110 to 120 beats per minute. Usually the torpor continues for some time, but delirium may intervene. The mouth and throat continue to be dry, and thirst is still a marked symptom. Locally the injured region may show rends and tears in the skin, lacerations of the muscles, tendons exposed and torn, vessels and nerves injured, and perhaps torn across, with more or less haemorrhage, bones may be exposed, bruised, broken, or dislocated, joints may be exposed, opened, and injured. Around the injured regions the parts are bluish or red in colour, and swollen, and quickly become œdematous, firm, and hot to the touch.

If the wounds are but slight, the inflammation may remain superficial, but usually the great danger is a cellulitis associated with pus formation and intermittent fever. A more serious complication is spreading or acute traumatic gangrene. Later, as the patient recovers, there is the liability of sinus formation and of stiffness in joints.

It is very important to remember that malaria can occur as a complication, and that therefore some of the intermittent temperature may at times be due to this cause. There is no difficulty with regard to the diagnosis as a rule, as there is generally a history to be obtained, while the local signs are sufficiently indicative of the condition, but the prognosis with regard to even slight wounds must at first be guarded, especially in Europeans, as it is impossible to foretell how serious the intercurrent septic infection may prove to be.

The treatment resolves itself into two distinct categories: first, the first aid when the rescue is effected; and, secondly, the usual surgical treatment.

With regard to the first aid, the usual methods for arresting hæmorrhage, combating shock, and carrying the victim are too well known to require repetition, but the thorough washing of the wound with water, even jungle water, would appear preferable to leaving the poisons from the animal's teeth and claws in the wound. We consider that a small first-aid surgical case containing antiseptics, bandages, etc., should form part of the outfit of every sportsman, and that antiseptics should be added to the water used to wash the wound.

As a rule the hæmorrhage has more or less abated by the time the man reaches a hospital, but any possible source of bleeding must be at once attended to, and the wound thoroughly washed and syringed with warm iodine lotion. Pieces of dead or sloughing tissue may be removed, but it is better to defer any serious operative treatment for twenty-four hours if possible, as it is very dangerous to perform anything of this nature in the condition of shock usually exhibited by the patient. The parts may be drawn together by a suture if necessary, but very few of these should be inserted, and as free drainage as possible allowed. Repeated and carefully applied antiseptic dressings must be carried out. Antitetanic serum should always be administered with the view of preventing possible tetanus.

As soon as there is any suspicion that cellulitis has supervened, free incisions must be made, and hot antiseptic baths, hot fomentations, or Bier's treatment must be applied.

Amputation is necessary if spreading traumatic gangrene supervenes, when it must be performed as high up the limb as reasonable, as it is useless to do repeated operations first at low and then at higher levels, while all the time the disease is spreading. Sinuses require to be scraped and plugged with antiseptic gauze.

When recovery is proceeding and the septic infections have ceased, plastic operations are necessary to close the large wounds left by the destruction of the tissues, while massage and douches may be required to prevent joints from becoming stiff.

As regards general treatment, the first requirement of the patient is usually plenty of water to drink to relieve the urgent thirst from which he suffers, and to dilute the toxins of the possible intoxication.

At first the food should be of the lightest description—broths, soups, and milk diet—and later the ordinary hospital diets may be gradually introduced.

With regard to prophylaxis, the natives often adopt simple protective remedies, such as a bell and spear, or a stick and a small axe, the latter being in use in districts infested by small bears. For a sportsman it is important to thoroughly understand the habits of the ferocious creatures which he is hunting, and especially to know what they usually do when wounded. In travelling in the African bush, a zareba with a fire is usually a good protection during the night.

Traumatisms caused by the Smaller Carnivora.—Under this heading come the traumatisms caused by members of the family Canidæ, of which *Canis lupus* Linnæus, the wolf, *C. aureus*, the jackal, and *C. familiaris*, the dog, may be quoted. Their general dental formula is $\frac{3.\ 1.\ 4,\ 2}{3.\ 1.\ 4,\ 3}$ = forty-two teeth. A wolf bite resembles that of the larger Carnivora, while jackals generally attack children, inflicting severe wounds, often of a septic nature. The jackal is often infected with hydrophobia, which he spreads to the village dogs, and in this way the disease is kept up in tropical countries. There can be no doubt that, at the present time, hydrophobia is one of the real dangers of a tropical town or village, where a large number of pariah dogs are, as a rule, allowed to run freely about the streets and make themselves as objectionable as they like. The result is that a number of children and adults are bitten every now and again, and are compelled to seek protection against possible infection by treatment at one of the now numerous Pasteur Institutes. In our opinion, some attempt should be made by muzzling dogs for a period of at least two years throughout a country, and the destruction of all dogs not so protected, to diminish this danger. We also consider that the destruction of all ownerless dogs—*i.e.*, dogs without a collar on which a name is engraved—should be conducted by a systematic organization.

The parasite of hydrophobia is described in Chapter XXII., p. 535.

One of the most important forms in which rabies attacks dogs is that called 'dumb rabies,' in which the lower jaw early becomes paralyzed; this is a form often overlooked for some time by non-medical people, and is a source of great danger.

Anyone interested in this subject must, however, consult a book on general medicine, as this is hardly the place for a description of rabies.

Rat and cat bite diseases are described in Chapter LII., p. 1356.

Traumatisms caused by the Ungulata.—Among the Herbivora there are two families which are celebrated for vicious attacks upon man, and these are the Camelidæ and the Bovidæ.

Camelus bractrianus Linnæus may at times have a bad temper, and it is often dangerous for a stranger to approach a camel, for its bite is, as a rule, a serious injury, the deep tissues being crushed and lacerated, while the bones may be crushed, broken, or dislocated, and tendons, bursæ, and joints may be laid bare or opened, and last, and by no means least, because of the possibility of gangrene and severe septic infection. The bites generally occur on the upper or lower limb, but are also well known on the head and face. The shock from such severe injuries is naturally very great, but the symptoms, signs, and treatment resemble those already mentioned under the heading of traumatisms caused by the Carnivora, and need not be repeated.

Among the Bovidæ, the buffalo is very dangerous—*e.g.*, *Buffelus indicus* in India and Ceylon, and *Bubalus brachyceros* in Central Africa—the danger being deep, penetrating wounds of the limbs, chest, or abdomen, as well as severe punctured, lacerated, and contused wounds in any part of the body.

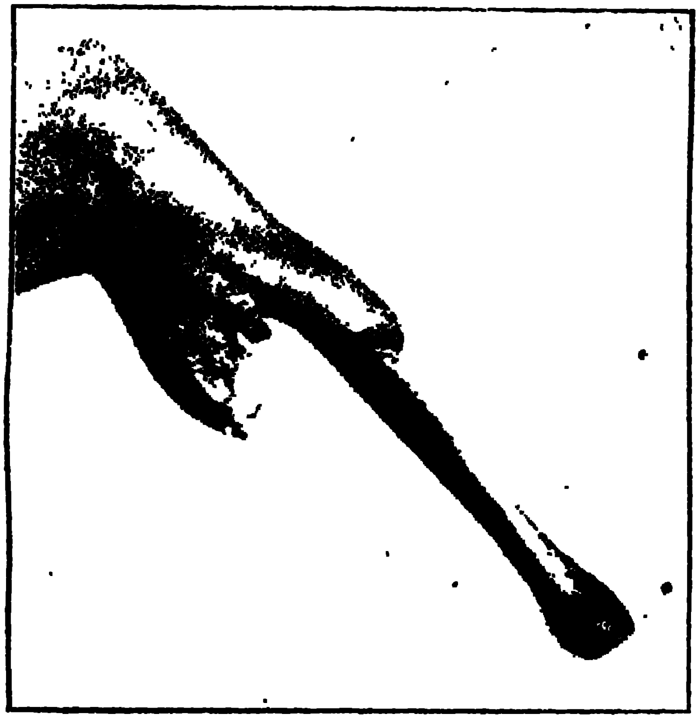

FIG. 8.—CAMEL BITE.

(From a photograph given to us by Christopherson.)

Here attention may be drawn to the fact that horses may become affected with hydrophobia, which, in animals treated as family pets, is a serious danger. The animal appears to be in great pain, and is often thought to have colic; it froths at the mouth and becomes very savage, biting articles in its stable and kicking the wall in a furious manner until weakness sets in.

Kicks may produce serious contusions and wounds, as well as injuries to internal organs.

The Rhinoceri—*Rh. indicus*, *Rh. javanicus*, *Rh. sumatrensis*, *Rh. africanus*—produce most serious punctured and lacerated wounds.

Hippopotami are common in the rivers and lakes of Africa—*e.g.*, *H. amphibius* and *H. liberiensis*. As a rule they are quite peaceful animals when left alone, but, once attacked, they become dangerous, seizing the boat or the persons in their huge jaws and crushing wood or flesh and bones into shapeless masses. They are very courageous, and nothing but death will stop the charge of one of these brutes. They will quickly stamp the life out of any victim they catch on land.

The Suidæ, or pigs, are commonly met with in tropical jungles, and are of importance because of the way in which they eat the remains of persons who have been lost in the jungle. All the soft parts are completely destroyed, while the bones are broken, so that it is impossible to say whether the unfortunate people died or were killed, whether they met with an accident or simply lost their way, whether the pigs ate them while dying or only after death.

Severe lacerated wounds can be inflicted by the tusks of an enraged boar.

Proboscidæ.—The elephants—*E. africanus* and *E. indicus*—usually kill their victim by stamping upon him until the soft parts are terribly crushed, lacerated, and bruised, while bones are broken. They also seize people by means of their trunks and dash them against surrounding objects or the ground.

Traumatism caused by the Larger Reptilia.—The crocodiles, gavials, and alligators are a constant source of danger in the tropics, especially to natives, while bathing in rivers. The names 'crocodile' and 'alligator' are often used as though they were synonyms, but this is by no means so. Some twelve species of crocodile are well known. They possess a most formidable array of teeth, expressed, as a rule, by the formula $\frac{18}{15}$, of which the third and ninth in the upper jaw are longer than the others, and are respectively lodged between the second and third and the eighth and ninth teeth in the lower jaw, in which the first, fourth, and eleventh teeth are the strongest. The muzzle of the crocodile is longer than that of the alligator. The muzzle of the alligator is relatively short and broad.

The muzzle of the gavial is very long. The two species of importance are *Gavialis schlegeli* of Java and Borneo and *G. gangeticus* of the Ganges. The latter has a dental formula $\frac{28\ 29}{25\ 26}$ teeth.

The following list, modified from Ditmar, gives the names and habitats of these formidable reptiles:—

A. Snout extremely long and slender—
  Gavialis gangeticus, India; *Tomistoma schlegeli*, Borneo and Sumatra.
B. Snout very sharp, slender, and triangular—
  Crocodilus cataphractus, West Africa; *C. johnstoni*, Australia; *C. intermedius*, Orinoco.
C. Snout moderately sharp and triangular—
  Crocodilus americanus, Mexico, Central and South America; *C. siamensis*, Siam and Java; *C. niloticus*, Africa; *C. porosus*, India and Malaysia.
D. Snout oval, bluntly triangular—
  Crocodilus robustus, Madagascar; *C. thombifer*, Cuba; *C. morelatti*, Guatemala and Honduras.

E. Snout short and broad—
Crocodilus palustris, India and Malaysia; *Osteolæmus tetraspis*, West Africa.

F. Canine teeth of lower jaw fit into a pit in upper jaw—
I. Snout as in D: *Caiman trigonotus*, Upper Amazon; *C. sclerops*, Central and Southern America; *C. palpelrosus*, Tropical South America. II. Snout very broad and rounded: *C. latcrostris*, Tropical South America; *C. niger*, Tropical South America; *Alligator mississipiensis*, U.S.A.: *A. sinensis*, China.

The celebrated man-eating species are—
Crocodilus niloticus, the Nile crocodile; *C. porosus*, the salt-water crocodile.

The American species are said to be inoffensive, as there are no records of attacks upon man.

Another important anatomical feature of these reptiles is the length and strength of the tail, by means of which they can strike a man standing on the low bank of a river such a powerful blow that he may be knocked into the water.

Accidents are commonly met with while people are crossing streams, or bathing therein, or while women are washing clothes or filling vessels with water at a river or lake. Anyone sitting on a steamer or other craft on a lake or river with his feet hanging over the side, or leaning over with his hand in the water, simply provides bait for any crocodile in the vicinity.

As a rule, if the victim is rescued, it is found that a portion of a limb has been bitten off, but we have met with a case in which only a large portion of the pectoralis major was removed. In this case the victim attributed his escape to driving his thumbs into the crocodile's eyes The wound healed excellently, though of course there was practically no pectoralis major left on the side in question, and in its place an area of scar tissue. Crocodile bites, in our experience, are not nearly so liable to septic infection as the bites of the Carnivora.

Traumatisms caused by the Larger Selachii.—By far the greatest number of sharks live in the seas of warm climates, and are well known because of the great danger of their bite, which is often fatal. The greatest risk is to bathers or fishermen, but it is a curious fact that divers for pearls appear to incur little risk. It is probable that the noise of the large number of people employed in this work frightens the sharks, which keep away.

Carcharias gangeticus was for a number of years a source of great danger to the crowds at the bathing ghats of Calcutta. Sir Joseph Fayrer says that they used to feed upon the partially burned bodies which were formerly thrown into the river, but when this custom was discontinued they began to attack the people at the bathing ghats, especially in the months of April and May, when the river contains much salt water. He says that they would dash into the crowd at the bathing ghat and inflict dangerous and, at times, mortal wounds, though they seldom were able to get away with their victim because of the numerous people at the ghat.

The patient is brought to the hospital suffering from the effects of shock and hæmorrhage, with a limb either snapped off or partially torn off, or with larger or smaller lacerated wounds, in which the bone may or may not be exposed and grooved by the sharks' teeth, and with blood dripping from the ragged surfaces of the wound. Usually the patient is in a state of extreme prostration, covered with a cold sweat, and having a hardly perceptible pulse.

More rarely there are only a few triangular or irregular lacerated wounds, showing that the shark did not obtain a proper hold of the victim.

The great danger is death, either immediately or in a few hours, from shock or hæmorrhage. If this is avoided, the wounds appear to heal readily if the patient is otherwise in fair health, but of course amputation is often necessary.

Man.—The bites inflicted by the Kru men on the West Coast of Africa in quarrels are, or were, of not uncommon occurrence, and it was also fairly common to meet with injuries on the knuckles caused by scratches from their teeth.

These wounds were usually considered to be serious, for, although the teeth of the African appear to be in excellent condition of repair and cleanliness, still the slightest scratch may lead to exceedingly severe inflammations, as the present writers well know. The most careful antiseptic treatment must be applied at once.

TRAUMATISMS DUE TO PHYSICAL AGENCIES.

Foot-binding.—The bandaging of the feet of young female children began in the imperial harem of the T'ang Dynasty in China some 1,400 years after Confucius, the idea probably being to reproduce as nearly as possible a club-foot. As a matter of fact, the result of pressure of the short, heavy bandage commonly used, neatly and tightly applied to the growing feet of young girls aged three to four years, is to produce a very small foot in the condition of a pes cavus, with the outer three toes in a varoid and the inner two toes in a valgoid position.

On examining one of these feet it is noted that it is very short, and that the plantar surface has a deep groove dividing this aspect of the foot into posterior and anterior portions. The posterior portion contains the os calcis, which, when examined radioscopically, presents a very different appearance from and position to that in a normal foot.

Notwithstanding objections to the contrary, we are of the opinion that the person walks upon the posterior aspect of the os calcis, and we further draw attention to the great alteration in the lines of pressure and stress, as compared with those in a normal os calcis. The anterior portion consists of the four small toes bent under the foot, so that the dorsal aspect is placed ventrally, while toes themselves are much atrophied. By radiographs it is seen that the heads of the metatarsals are approximated towards the os calcis. The first toe is only compressed. The weight of the body is then supported by the posterior aspect of the os calcis and by the distal end of the first metatarsal, and the plantar aspect of the great toe, while the dorsal aspect of the other toes may assist a little. The distance from the end of the os calcis to the big toe may be only three inches.

Such a compressed, deformed, stunted foot may easily become the site of disease. In the first instance, there is danger of gangrene, necrosis (especially of the phalanges), and synovitis of the knee-joint during the active bandaging, while the immediate result may be total lameness. As a later complication, tuberculosis of the bones of the deformed foot is liable to occur

Fortunately this horrible proceeding, like many other horrible fashions, is dying a natural death under the influence of increased feminine education and common sense first produced among European women, and by them introduced into China. Naturally no cure can be effected in a foot which has become fully deformed.

Heavy Fruits. The fruits of the coconut (*Cocos nucifera* Linnæus) and of the jak-tree (*Artocarpus integrifolia* Linnæus) are heavy and fairly hard, and injuries may be caused by the fall of one of these fruits from the tree on to the head or other part of the body. When the blow is received by the head, the symptoms produced may be those of concussion or compression, or there may be signs of fracture of the vault or base of the skull.

Electrical Fans.—In the more civilized tropical towns it is common to use small, movable, quickly running electric fans in order to obtain a cooling breeze. These are brought into use specially in the bedroom and dressing-room, but are also frequently seen in the dining-room, and sometimes in the office. Being easily movable, they are apt to have their position slightly altered when running at full speed, and in doing this quite a number of accidents have taken place. Sometimes during the condition between sleeping and waking, people, stretching out their arms while still in bed, catch their fingers in the fans. The most common traumatism is for the fingers to be caught by the blades, and to sustain contused and lacerated wounds, the danger of which is tetanus, as the blades of the fan are generally thickly covered with the dust brought by the current of air.

Another and far less serious but most awkward accident sometimes happens in a lady's dressing-room. The fan is placed on or near the dressing-table, and is so arranged that the back of the fan is towards the person at the dressing-table. The current of air passes from the person towards the back of the fan. If the lady has long hair and is dressing it, the current of air may carry it into the back of the fan and between the blades, which, still revolving, causes the hair to be twisted into a tangle. Usually the lady or her attendant has sufficient nerve to switch off the fan, and no very serious injury is done, but it is difficult to extract the hair from the tangle in the fan.

Powdered Glass.—In certain parts of the tropics, especially in the East, powdered glass is used for suicidal and homicidal purposes. The injury caused is, of course, purely mechanical, and the more finely it is powdered, the less likely it is to cause serious injury, owing to mucus surrounding the particles. The glass is administered in food—*e.g.*, bread, spinach, sweetmeat, etc. The symptoms are those of irritant poisoning—retching, violent vomiting, spasms, convulsions, and racking pain. The most evident post-mortem feature is acute gastritis. The mucosa is covered with a layer of thick mucus, under which it is found to be hyperæmic and lacerated. In this mucus or on the mucosa the minute pieces of glass may be found. No other pathological signs need be present. The treatment is to administer any bulky food at hand, and then, if vomiting has ceased, to give an emetic, and finally a laxative.

Bamboo Hairs.—*Dendrocalamus strictus* Nees. We have met with a case from Malaya in which the fine hairs shaved off the bamboo sheaths were administered in food with the intent to kill. They produced a severe form of enteritis very like chronic dysentery. We are therefore in a position to confirm Ridley's earlier statements that these hairs act as mechanical irritants.

CHAPTER X

POISONS

Preliminary—Definition—Classification—Criminal poisoning—Accidental poisoning—Stimulant and sedative poisoning—Poisons used in trial by ordeal—References.

PRELIMINARY.

THE chemical causes of tropical disease or the tropical intoxications are numerous, and it is impossible in a book of this size to do more than give an account, in condensed form, of the more common, and to provide means, by the references, whereby the reader may extend his information if he so desires.

In the present work we shall divide these chemical causes into Poisons and Venomous Animals; and as we begin the study of these matters in the present chapter, it is as well to state what we mean by a poison.

DEFINITION.

A poison is any chemical substance which, when introduced in sufficient quantity into, or brought in contact with, the living organism, is capable of producing a variation in the structure, the chemical composition, or the functions, of the whole or any part of that organism, which exceeds the limits of physiological variation.

Such a definition includes a large number of substances, and therefore some arrangement is necessary in order that they may be considered systematically.

CLASSIFICATION.

Poisons have been classified into mineral, vegetal, and animal, or according to their action on the human economy; but we have departed from these proposals, and have attempted to arrange them according to the purposes for which they are used, as we consider that this method will be of greater service to the tropical practitioner.

With this end in view, we divide them into the chemical substances which occur in—

I. Criminal Poisoning.
II. Accidental Poisoning.
III. Stimulant and Sedative Poisoning.
IV. Trial by Ordeal.

We leave to future chapters the consideration of poisons used in war, fishing, hunting, and trade, as well as poisonous food and the effects of venomous animals.

I. CRIMINAL POISONING.

Criminal poisoning has been in existence from the earliest and most primitive ages, and as it requires a highly and specially trained chemist with a well-equipped and up-to date laboratory to detect many of the tropical vegetal poisons, the reader will not be surprised to note that criminal poisoning is more frequently met with in the tropics than in the Temperate Zone.

It seems to us that it is more commonly met with in the East than in Africa, and we are inclined to think that the reason for this is that in Africa only the fetish-man knows how to present virulent poisons in acceptable forms to his victims, whereas persons with an elementary knowledge of poisons are common in the East.

The poisons of different tropical countries vary according to custom and tradition, and also according to the plants which happen to grow in the vicinity. It is said that arsenic in the East is the cause of as many criminal poisonings as all the organic poisons put together. This may be so, but we are not certain that anyone is qualified to make this statement, as it came as a great surprise to us to find that in Ceylon a number of the poisonings at one time attributable to arsenic were found by advanced chemical research under an exceedingly able chemist to be due to *Cerbera odollam.*

We are therefore of the opinion that every tropical country requires a well-equipped toxicological laboratory, with well-trained research chemists, whose business, *inter alia*, should be to make themselves acquainted with the poisons of the land in which they are residing, with the view to discovering tests whereby these poisons may be detected and so justice done in criminal cases. This is important, for the native soon learns that methods of bringing the criminal to justice exist, and therefore becomes less inclined to use this method for the removal of his enemy.

The poisons used criminally against man may be divided into (*a*) Inorganic Poisons, (*b*) Organic Poisons.

Inorganic Poisons.

The most common poison is *arsenic* in some form, and the next is *perchloride of mercury*, followed closely by the *mineral acids*. Salts of copper have been used for homicidal purposes, but generally poisoning from this source is accidental, and due to the use of copper cooking utensils, while the preparations of antimony are seldom used.

Organic Poisons.

These may be derived from animal or vegetal sources, but the latter are far more *en evidence*, and are largely derived from plants belonging to the natural orders Apocynaceæ, Loganiaceæ, Euphorbiaceæ, Liliaceæ, and Leguminosæ.

It would doubtless be more scientific to classify these poisons by the natural orders to which the poisonous plants belong, but, following our original proposals, we divide them as follows:—

1. Poisons used for homicidal purposes.
2. Poisons used for suicidal purposes.
3. Poisons used for purposes of infanticide.
4. Poisons used for procuring abortion.
5. Poisons used with the intent to rob.
6. Poisons used with the intent to cure disease.
7. Poisons used with the intent to simulate injuries.
8. Aphrodisiacs.

1. *Homicide*.

Animal and vegetal substances are used for this purpose, but of the former the best known is *viperine venom*, which is said to cause gastritis, gastro-intestinal hæmorrhages, and even death. It is known to Ceylon natives that the venom of *Vipera russellii* Shaw, locally called the *tic polonga*, is supposed to be poisonous when administered by the mouth, and we were informed that this was usually given in toddy, an alcoholic drink prepared from the coconut and from the Palmyra palm. We once met with a case in which we suspected the possibility of this being used, but an experiment in which the recent venom administered orally by means of toddy to a monkey proving a complete failure, we were left in doubt as to the possibility of such poisoning.

The venom of the Colubridæ is harmless when taken by the mouth, provided that there are no cracks or abrasions. Its virulence is destroyed by saliva and by pancreatic juice.

Vegetal substances are sufficiently numerous, but unfortunately, as far as we know, few are on record. The table given on p. 164 is an imperfect list.

With reference to the table, a few notes, arranged in alphabetical order, may with advantage be given:

Aconite.—*Aconite* (Ranunculaceæ) is so poisonous that in India it is known as 'bish' or 'bikh,' which means 'the poison,' which generally refers to *Aconitum ferox* Wall (Himalayas), *A. napellus* L. (Himalayas), *A. luridume* Aorte (Sikkim), *A. lycoctonum* L. (Kashmir); whilst *A. heterophyllum* Wall and *A. palmatum* Don are said to be less poisonous.

The root is the principal source of the poison, which, however, also exists in the leaves and stem.

Aconite is used for homicidal purposes, as a cattle poison, and may at times be taken accidentally. The fatal dose is said to be 30 grains of the root, and the fatal period usually three to six hours.

The symptoms are tingling of the lips, tongue, mouth, and fauces, followed by numbness and anæsthesia, burning pains in the stomach,

Country.	Natural Order.	Genus and Species.
India and Ceylon.	*Ranunculaceæ* De Candolle, 1818	*Aconitum* Tournefort with *A. ferox* Wall and *A. napellus* Linnæus in the Himalayas, *A. luridum* Aorte in Sikkim, and *A. lycoctonum* Linnæus in Kashmir.

and vomiting, muscular and cardiac weakness, and finally death takes place from failure of the heart or respiration.

Barringtonia Forster, 1776 (Myrtaceæ), with the species *B. speciosa* Linnæus and *B. raratonga*, is said to be used for criminal poisoning in Oceania.

Cerbera odollam.—*C. odollam* Gaertner (Apocynaceæ) is a very common plant in Ceylon, and is similar to *C. thevetia*. Its correct name is probably *C. manghas* Linnæus, 1753. Its chemical properties have not yet been properly worked out, and it is said that it *probably* contains the same poisonous principle as *C. thevetia*—viz., thevetin. The symptoms are nearly the same—*i.e.*, gastro-intestinal irritation, followed by cardiac poisoning. These symptoms are easily mistaken for arsenical poisoning. The treatment is the same as for irritant poisoning in general.

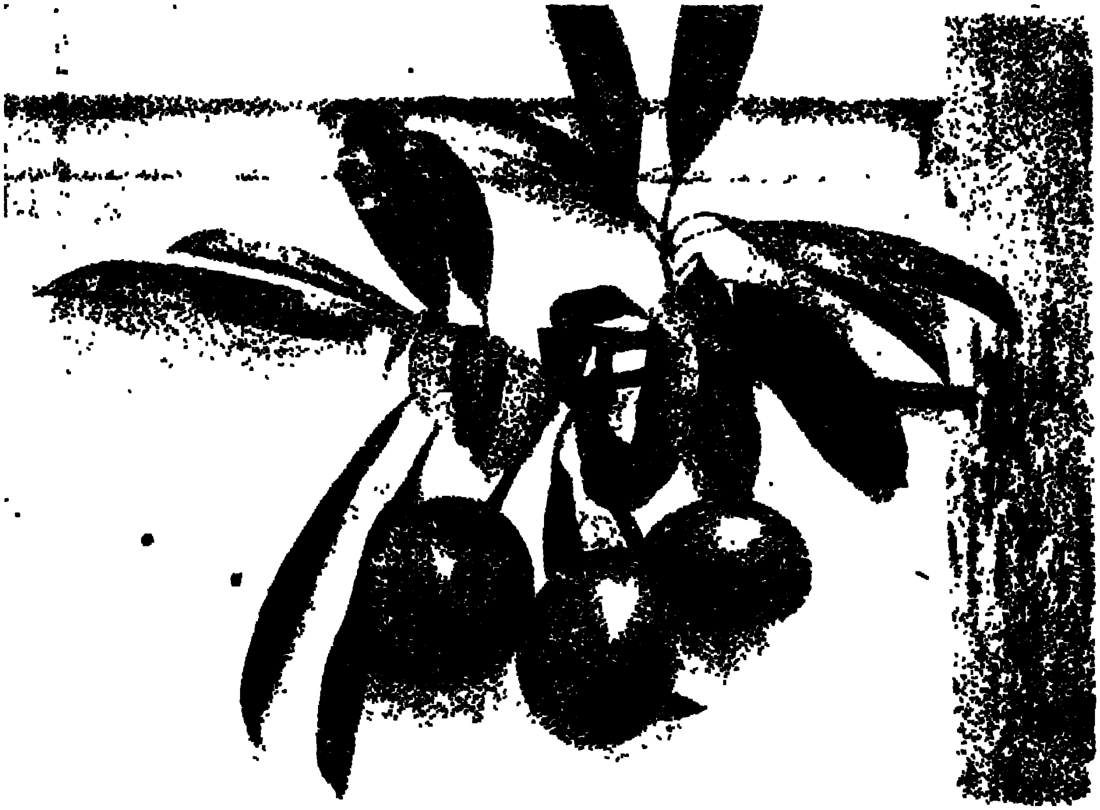

FIG. 9.—*Cerbera odollam* GAERTNER.

Cerbera thevetia. *C. thevetia*, the common yellow oleander of India, is a shrub about 6 to 12 feet in height, with yellow bell-shaped flowers and globular green fruit. It is highly poisonous, its action being due to a glucoside, thevetin, which exists in the milky juice pervading all parts of the plant. It is supposed that three seeds are sufficient to kill a man in twelve to fifteen hours, the symptoms being gastro-intestinal irritation, headache, dizziness, and pain in the throat. The pulse is very soft and slow—thirty to forty beats a minute, which Windsor says is characteristic; later it becomes weak, very rapid, and irregular. Death results from cardiac failure. The treatment is the same as for ordinary irritant poisoning.

Gloriosa superba. *G. superba* (Liliaceæ) is a well-known poison in India and Ceylon, while in Burma it is said to be used for suicidal purposes. Its active principle, superbine, is said to be allied to, or identical with, the scillitine of squills, and therefore the action of *G. superba* is not unlike that of squills The symptoms, which may appear in half an hour, are retching, violent vomiting, spasms, with contortions of the body and racking pains, with short intervals of relief from time to time Death may take place in four hours. The post-mortem reveals congestion of the brain and membranes, with extravasations of blood, congestion of the lungs, liver, and kidneys and inflammation of the mucous membrane of the stomach.

The treatment is that for irritant poisoning in general.

Hyoscyamus falezlez.— The Tuaregs are said to use *H. falezlez* to kill travellers.

Jatropha curcas *J. curcas* Linnaeus (Euphorbiaceæ), the jura-tree of India, has a seed which is called the 'physic nut,' from which the oil can be expressed which is an irritant to the skin and a purgative.

The symptoms of poisoning are vomiting, purging, abdominal pain, derangements of the special senses, muscular twitchings, and loss of memory. The treatment, after getting rid of as much of the poison as possible, is lime-juice and stimulants.

Melianthus (Melianthaceæ).- Various species of Melianthus are said to be very poisonous by Grey, who suspects the possibility of their use by South African Bushmen.

Melicocca (Sapindaceæ) occurs in British Guiana, where it is called Kinnup. In a two-year-old child it caused convulsive twitching of the hands and feet, fixed gaze, vivid flush on skin, distension of abdomen, suppression of urine, rise of temperature to 101° F. The poisoning was said to resemble that produced by belladonna. Other species are said to stupefy fish and also to be used as arrow poisons.

We may perhaps mention here that in this order are many excellent and edible fruits; thus, *Melicocca bijuga*, a West Indian tree, is cultivated in Brazil because of its agreeable, slightly acid berries, but, on the other hand, the leaves and branches of other species are poisonous.

Milletia sericea (Leguminosæ) is a poison of the Dutch Indies, causing severe diarrhœa, collapse, and death.

Morea collina.—*M. collina* (Iridaceæ), the wild tulip of South Africa, is said by Grey to have been used by a Bushwoman to poison a number of people, two of whom died.

The symptoms were severe vomiting and a feeling of constriction across the chest, feeble and intermitting heart, and a tendency to coma for hours before death. The post-mortem showed no rigor and no inflammation of the stomach. The heart musculature was flaccid, and the right side full of blood.

Nerium odorum, synonym *N. indicum* Mill. 1768 (Apocynaceæ), is the white oleander, and grows commonly in India, where it is a well-known poison. It is rarely used for homicidal purposes, but more generally for suicide, abortion, and accidental poisoning.

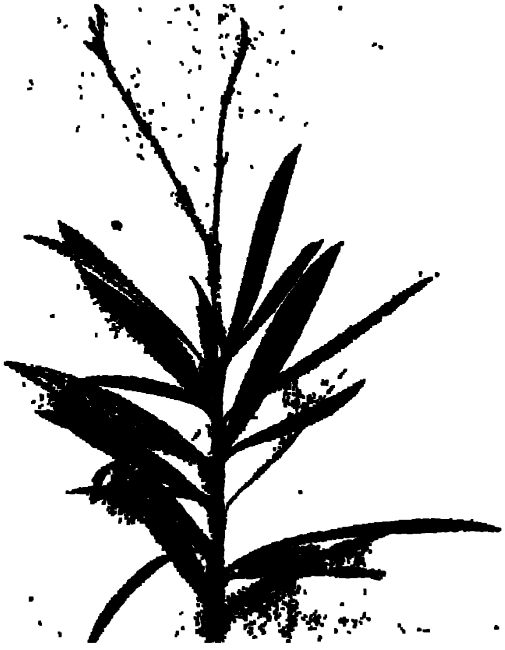

FIG. 11.—*Nerium odorum* SOLANDER.

The root is the portion used, but all parts are poisonous. The active principles are neriodorin, a powerful cardiac poison acting something like digitalis; karabin, a cardiac poison, with also a strychnine-like action on the spinal cord.

The symptoms are therefore (1) those of gastric irritation—viz., vomiting, pain in the stomach, frothing at the mouth from salivation, but as a rule without diarrhœa; (2) cardiac symptoms, producing at first a slow pulse, which finally becomes quick and weak—the respirations are rapid from the first; (3) strychnine-like symptoms of twitching of the muscles, tetanic spasms, with cramps and, at times, lockjaw.

Towards the end the patient becomes drowsy, then insensible, and finally dies from cardiac failure. The post-mortem reveals dilatation of the right side of the heart, which is full of blood, while the left side is empty, with subendocardial hæmorrhage, congestion of the liver, spleen, kidneys, and lungs, mucosa of the stomach and small intestine, while the large intestine and brain are normal. The patient must be treated on the same lines as for digitalis and strychnine poisoning.

The Oro.--The oro (a cactus) of Sierra Leone is a gastro-intestinal irritant, causing vomiting, diarrhœa, collapse [illegible] death.

Paullinia pinnata (Sapindaceæ) is said by Rho to be used by negro slaves in Brazil to poison their masters, and to depend upon an alkaloid, timboin, for its action. Adverting to our remarks on Melicocca, we may note that the seeds of *P. sorbilis* are the source of the 'Guarana' bread of Brazilian aborigines, used when travelling and as a remedy, being said to be a stomachic, febrifuge and aphrodisiac.

Sablier crepitans Linnæus, also named *Hura crepitans* (Euphorbiaceæ), grows in the Antilles, and has been imported into tropical Africa. Its fruit is purgative, and is believed to be used frequently for criminal purposes, being said to produce violent vomiting and purging, with tenesmus, constriction of the throat, and syncope. Ruiz, however, has thrown doubt on the possibility of its really being the cause of these criminal poisonings. It is to be noted that the same symptoms are produced by *Croton tiglium* Linnæus (Euphorbiaceæ), which is found in India, Cochin China, tropical America, and Africa.

Spigelia anthelmia Linnæus (Loganiaceæ) has the reputation of being very poisonous, and has been used criminally in tropical America, in Brazil, and the Antilles, where it is still used as an anth[illegible]c. It is said to produce somnolence convulsions, and death.

Strychnos.- Strychnos (Loganiaceæ) is a genus with several poisonous species, among which may be mentioned:

Strychnos nux vomica Linnæus.
Strychnos ignatii Bergmann.
Strychnos colubrina Linnæus.

Poisoning by the alkaloid strychnine is frequently met with in India, but is usually accidental. The symptoms of strychnine poisoning are bitter taste in the mouth, tetanic spasms, opisthotonus, risus sardonicus, and death from asphyxia or collapse. There are no characteristic post-mortem appearances, except congestion of the brain and spinal cord. The treatment is to empty the stomach by emetics, and to administer chloroform or chloral hydrate, and, when asphyxia threatens, to perform artificial respiration.

Thevetia ahovai.—*T. ahovai* (Apocynaceæ) is allied to the oleanders mentioned above, and has an alkaloid, thevetosin, said to cause gastric irritation and difficulty of breathing.

Urechite suberecta (Apocynaceæ) is the Savannah flower of Jamaica and other West Indian Islands, which was so celebrated in the days of the 'Obeah Man,' and about which so many tales were told. The truth is that there are two glucosides, urechitin and urechitoson, of which the former is like digitalis, and hence it has an accumulative action in small doses, which, if given to a person for a long time, will not cause any deterioration of health, but will cause, eventually, sudden death owing to the action on the heart. A full lethal dose, on the other hand, will kill in a few hours or a day or so.

2. *Suicide.*

Of all the poisons used for suicidal purposes, opium is by far the most usual, though *Nerium odorum*, *Cerbera odollam*, and *Gloriosa superba* are also at times employed, the former especially by women in India. Rarer poisons are *Calotropis procera*, *Cerbera thevetia*, aconite, prussic acid, and veratrine (meeta bish). The action of all these poisons is described either in ordinary works on toxicology or has already been mentioned.

3. *Infanticide.*

Infanticide exists in the tropics in two forms the first irrespective of sex, and said to be due in India (Waddell) to the high-caste Hindu prohibiting remarriage of widows; and, secondly, female infanticides, to prevent too many daughters growing up. A few of the more commonly used drugs may be briefly mentioned.

Opium is used in India by smearing the mother's nipples with the drug. There is little necessity here to describe the action of opium. All that need be said is to warn the practitioner that ayahs (native nurses) are apt to soothe a baby to sleep by dipping the finger in laudanum, and giving it to the baby to suck. Such treatment is highly deleterious to the child, and the intensely contracted pupils should make the practitioner suspect its use in an obscure case of illness.

Calotropis gigantea Robert Brown and *C. procera* Robert Brown (Asclepiadaceæ), called 'mador' in Hindustani and 'erukam' in Tamil, have been used in India for infanticide and abortion, rarely for suicide, and more rarely for homicide. The symptoms are vomiting, profuse salivation, severe tetanic spasms, extremely slow and stertorous breathing, and dilatation of the pupils. The active principle is a yellow bitter resin, but there is no alkaloid. The treatment is the same as for irritant poisoning.

Tobacco is also used as an infant poison.

4. *Abortion.*

Criminal abortion is very common in the tropics. In India it is said to be common among Hindu widows, because they are not allowed to remarry.

The drugs commonly used are:-

(*a*) *Reputed Emmenagogues.*—
Nerium odorum Solander.
Cerbera thevetia Linnaeus.
Carica papaya Linnaeus (seeds).
Daucus carota Linnaeus (carrot seeds).

(*b*) *Purgatives* (*Cucurbitaceæ*).—
Cucumis trigonus Roxburgh.
Momordica charanta Linnaeus.
Momordica cymbalaria Fenzl.

(*c*) *Irritants.*- Several inorganic irritants are used—arsenic, lead, mercury, copper, and quicklime. Browning informs us that copper sulphate has been used of late in Ceylon for this purpose, as well as tartar emetic, corrosive sublimate, large doses of quinine, and very large doses of Epsom salts and an aloes (socotrine) iron pill, in which the quantity of the aloes is very considerable.

Plumbago rosea Linnæus.
Plumbago zeylanica Linnæus.
Calotropis procera R. Brown.
Piper nigrum Linnæus (black pepper).
Ananas Tournefort, 1735 (unripe pine-apple)
Moringa pterygosperma Gaertner (bark).
Lasiosiphon speciosus Decaisne.

(*d*) *Supposed Ecbolics.*—
Bambusa sp.? juice of bamboo-leaves. The fruit is used.
Randia dumetorum Linnæus.
Cuscuta reflexa Roxburgh. (A decoction is used which also acts as an irritant.)
Seeds of *Celastrus paniculatus* Wight.
Seeds of *Anethum graveolens* Linnæus.

Plumbago zeylanica Linnæus and *P. rosea* Linnæus are evergreen shrubs about 2 to 5 feet high, in the root of which there is an active principle, plumbagin, which acts externally as a vesicant, and internally as an irritant and narcotic. It is used as a paste, or spread on wool on an abortion-stick.

The abortifacients which were commonly used in Ceylon were *Gloriosa superba* L., violent purgatives (including large doses of magnesium sulphate), and the twigs of the castor-oil plant, the last named being a mechanical irritant.

5. *Stupefying with Intent to Rob.*

Two drugs are much used in India and Ceylon for the purpose of stupefying with intent to rob—viz., *Datura fastuosa* Linnæus and *Cannabis sativa* Linnæus.

Datura fastuosa (Solanaceæ).—Poisoning by datura is common in India, having been used by the Thugs. The seeds are usually mixed with food or drink, and the symptoms, which develop rapidly, depend upon the dose, being generally those of a cerebral poison. First there is delirium, and later coma, but in both conditions the pupils are widely dilated. The delirium is peculiar; for example, the people affected may be found searching their bedding most vigorously for some lost article. When death occurs, it is due to cardiac failure. The fatal dose is not actually known, but may be about 10 to 15 grains of the seeds. Waddell puts the mortality at about 18½ per cent. The post mortem characteristics are wide dilatation of the pupils, congestion of the brain, meninges, and the lungs and other viscera.

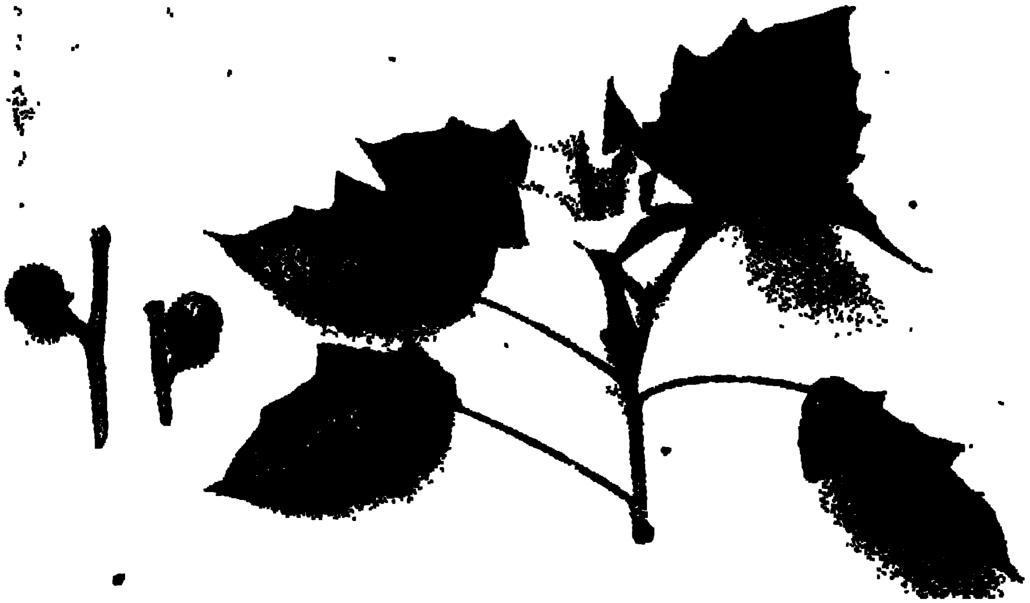

FIG. 12. *Datura fastuosa* LINNÆUS.

6. *Poisons used with Intent to Cure Disease.*

Decoctions of bark *Trianthema pentandra* Linnæus are used in the Sudan for the purpose of curing gonorrhœa; unfortunately, sometimes this remedy is worse than the disease, causing enteritis and death.

7. *Poisons used to Simulate Injuries.*

Plumbago rosea Linnæus (Plumbaginaceæ) and ***Anacardium occidentale*** Linnæus (Anacardiaceæ) are used to simulate bruises and other injuries in order to get innocent people into trouble.

8. *Aphrodisiacs.*

The aphrodisiacs, which are much in demand by tropical natives, may be divided into those of animal and those of vegetal origin.

Those of animal origin are *Meloe vesicatorius* (*Cantharis vesicatoria, Lytta vesicatoria, Musca hispaniola* are synonyms), which is well known, and *Mylabris cichorii*, a beetle called Pān-mao by the Chinese and containing 1 per cent. of cantharidine. In China and the Far East generally the testicles, spinal cords, etc., of animals, pounded and mixed with rice water, are eaten as aphrodisiacs.

Those of vegetal origin are numerous, and include *Panax quinquefolium* Linnæus (Araliaceæ), the powdered root of which, called by the Chinese Jenn-Chenn, is used; *Populus spinosa* (Amentaceæ), the Sèn-iâng hoâ of the Chinese, of which the buds are used; *Psorala corylifolia* Roxburgh (Leguminosæ), the fruit of which is used by the Chinese and Annamese; *Psorala glandulosa* Linnæus in Chili; *Amomum zingiber*, the ginger (Zingiberaceæ); *Caryophyllus aromaticus* Linnæus (*Jambosa aromatica* Miquel Myrtaceæ); *Pausinystalia yohimba* Karl Schumann, the celebrated yohimbehe or yumbehoa bark, from which the alkaloid yohimbine hydrochloride, used in 1 per cent. solution, dose 5 to 15 minims, or tablets with $\frac{1}{12}$ grain taken one three times a day, may be mentioned. The last is sometimes named *Corynanthe yohimbi*, but this is merely a synonym *P. trillesii* Pierre is also considered to contain yohimbine.* These trees grow in the Kameruns and the Congo.

Cordiceps sinensis is the mushroom called Tch'oungtis'aô by the Chinese, and is used as an aphrodisiac.

II. ACCIDENTAL POISONING.

Accidental poisoning happens fairly frequently; therefore a few examples may be given.

Certain common articles of food are poisonous until properly prepared; e.g., tapioca is the starch obtained from the root of *Manihot utilissima* Pohl 1821 (*Jatropha manihot* Linnæus—Euphorbiaceæ), commonly called the cassava, of which there are two varieties, the sweet and the bitter. The latter contains hydrocyanic acid in its milky juice, and is, therefore, poisonous until it is roasted, when the volatile acid is driven off, and the bitter cassava can then be used for food after squeezing out the juice and cooking the root. Waddell reports two cases of death from accidental poisoning by this root in 1898 in Madras.

Arisæma.—Vogt has reported the accidental poisoning of a Chinese woman by an unknown species of the genus *Arisæma* Martius, belonging to the family *Araceæ* Schott, 1832. She ate a small piece of the tuber, and in ten minutes became stuporous, and despite prompt and vigorous treatment, which included the washing out of the stomach, her abdomen became distended and she suffered from paralysis of the limbs, but eventually recovered.

The members of the Araceæ are well known to be poisonous, and *Diffenbachia sequina*, the dumb cane, which grows in the

West Indies and South America, will cause a painful swelling of the tongue if chewed.

The emanations from the flowers of *Arum dracunculus* cause dizziness, headache, and vomiting in some people.

Blighia.—The succulent aril of the akee tree, which belongs to the genus *Blighia* Koenig, synonym *Cupania* Plumer (Sapindaceæ) and called *B. sapida*, is used as an article of food in the West Indies.

It is, however, known that if eaten in an unsound condition it is poisonous, and recently Scott has shown that this is the cause of the *vomiting sickness* of Jamaica, as will be detailed in Chapter LXXII., p. 1695 of this book.

Capsicums (*C. annuum* Linnaeus, 1775 Solanaceæ), if taken in large quantities, may cause burning in the mouth and throat, vomiting, colic, diarrhœa, and even death. *C. frutescens* Linnaeus, 1753, may also be mentioned.

Cinnamomum zeylanicum Nees. Lewin states that cinnamon bark may be poisonous, while nutmegs (*Myristica fragrans* Houtt) are well known to be poisonous if taken in large doses.

Calotropis gigantea R. Brown (Asclepiadaceæ) has been known to cause fatal effects by administration non-maliciously of two dessertspoonfuls of its milk in a quantity of cow's milk. This plant is variously named 'mudar' in Bengal, 'vercumby' by Tamils, and 'warra' by the Sinhalese.

Chailletia toxicaria Don (Chailletiaceæ; native name 'magberi' or 'manuchi'), the powdered fruit of which is used for killing rats, has been described by Renner in Sierra Leone as the cause of poisoning in a Mendi carrier.

The symptoms were mainly vomiting, diarrhœa, trembling, general weakness, and inability to walk because the legs were paralyzed, the tendon reflexes having disappeared. Hyperæsthesia was present over the inner side of the thighs and legs, and pressure on the calf muscle gave severe pain. The bladder, rectum, and pupils were normal. The man recovered in about two months.

Renner remarks that this case is probably the clue to attacks of sudden paralysis of the lower limbs in young persons (twenty to forty years) of both sexes in Sierra Leone. When death ensues, it is from paralysis of the muscles of respiration.

Dioscorea.—Guerreras and de la Paz say that this genus, as well as *Jatropha*, *Anamista*, *Strychnos*, and *Datura* are the cause of poisoning in the Philippine Islands.

Fungi.—The presence of *poisonous* as well as *edible fungi* should be remembered in the tropics; although there is no literature known to us on the subject, still we have had the matter forcibly brought to our notice.

The fruit of ***Hippomane mancinella*** Linnaeus (Euphorbiaceæ), the manchineel tree of the Grenadine Islands, which has a delicious fragrance, is said to have been the cause of many sailors meeting their deaths, for it looks like an apple. The active principle is not known.

The symptoms are severe pain in the mouth and stomach, followed by collapse. The lips and tongue become swollen and blistered, the abdomen tender, the pupils widely dilated, while bullæ appear on the skin.

The treatment consists of stimulants and intramuscular injections of ether, with mouth-washes. Internally opium, bromides, chlorate of potash, bicarbonate of soda, or bismuth, made into an emulsion, may be given.

Fontainea pancheri, Heckel, 1870 (Euphorbiaceæ), is a tree growing in New Caledonia, the ingestion of the fruit of which causes symptoms analogous to those produced by *Hippomane mancinella*.

Illicium Guerreras and de la Paz have also drawn attention to poisoning from a decoction of sanki, which is the fruit *Illicium religiosum* v. Siebold, which belongs to the genus *Illicium* Linnaeus, of the family *Magnoliaceæ* De Candolle, 1818. Montel in Indo-China has also found it to be poisonous. The symptoms appear to resemble cholera, but diagnosis has to be made from strychnine poisoning, tetanus, and cerebro-spinal meningitis. The symptoms were vomiting, diarrhœa, thirst, unconsciousness, convulsions, cramps, profuse sweating, oliguria and anuria, small rapid pulse, cold extremities, paresis of the lower limbs, and exhaustion. The head is retracted, the eyeballs bulge, and the face becomes cyanotic when the respiration stops. In China and Japan it and its related species *I. anisatum*, the star anise, which is harmless, are called badiane.

The seeds of *Ricinus communis* Linnaeus (Euphorbiaceæ), the castor-oil plant, are poisonous, causing burning in the throat and abdomen, vomiting, purging (may be absent), and collapse. The fatal dose appears to be three seeds, and to kill in about forty-six hours. Post-mortem the principal feature is gastro-intestinal inflammation.

The treatment is emetics, stimulants, and hypodermics of morphia.

III. STIMULANT AND SEDATIVE POISONING.

Many drugs are employed all over the world to stimulate or to deaden the nervous system. These stimulants and sedatives have been used by man from time immemorable to whip up a flagging nervous system, or to deaden the effects of mental or bodily suffering.

Used judiciously and in a proper manner there can be no doubt that they alleviate human suffering, but if used injudiciously or immoderately, and especially if they are constantly taken, they become 'habit poisons,' and as such affect the cells of the body injuriously, and by so doing some of them become true 'racial poisons,' and as such have been mentioned in the section on Eugenics (see p. 118).

It is not our intent to write, except in the briefest manner, upon these poisons, as their effects are fully considered in special works and are also contained in all the ordinary textbooks dealing with general medicine. Notwithstanding this, we feel that a few remarks dealing with these drugs in the tropics are necessary.

Alcohol.—We have already referred to our belief that this is a personal and a racial poison, and we would warn our readers not to be misled by statistics on this point, and if they wish further information to refer to Adami on Karl Pearson (*vide* references). Alcoholism is unfortunately on the increase among tropical natives, and is doing great harm in the form of indigenous stimulants such as arrack, which is almost directly the cause of a large percentage of the violent crime in Ceylon, as was shown by the fact that the accident wards of the hospitals were nearly empty in the proscribed regions during the period of a social prohibition.

More dangerous, in our opinion, are the imported cheaper alcoholic drinks, such as the cheap whiskies, gins, and rums, which, being cheap, are drunk in quantity and greatly deteriorate native races. These bad effects are not due to fusel oil, which is not present in these cheap forms of spirit, which in many ways are the purest form of alcohol to be obtained, and hence their effect is truly due to alcohol and to alcohol only, and their real danger is simply because they are cheap. *Methyl alcohol* is a direct poison to man, a fact but little understood at the present time.

Opium is eaten in Persia, India, and Africa, and smoked in Malaya, Indo-China, and China, but for the latter process it has to be specially prepared. On the Eastern mind opium is said to have two possible effects: either it produces a sense of absolute blank, or it produces fancy dreams and visions. The effects of chronic morphinism are loss of appetite, emaciation, and exhaustion, and hence inability to think or work.

It is, however, probable that the effects of opium are not as bad as those of alcohol, and, used in moderation, it may not be more harmful than the use of tobacco.

Cocaine has been used much of late in India as an intoxicant or stimulant, to counteract the effects or in lieu, of opium, owing to the restrictions on the sale of opium. Unfortunately, children have begun habitually to use the drug. The cocaine is chewed with betel and chunam (slaked lime), and produces at first loss of sensation in the tongue and lips, followed by dryness of the mouth and fauces. The temperature does not rise, but the pulse becomes full and quick, and at this stage the inebriate likes to be left alone, and firmly closes his lips lest the saliva should flow out. His ears become hot and red, his cheeks pale, and the tip of his nose cold. Perspiration breaks out, and the maximum amount of the so-called hilarity or exaltation, due to overstimulation of the nervous system, now appears, but is speedily followed by depression, which induces the victim to take another dose. The teeth and tongue of the confirmed cocaine-eater turn jet-black, probably due to some chemical change produced by the action of lime and saliva on cocaine. Pernicious symptoms in the form of emaciation accompanied by insomnia, digestive disturbance, diarrhœa, deafness, diminution of urine, delusions and hallucinations, and even at times acute mania, may appear.

Indian hemp (*Cannabis sativa*) is used in India, Arabia, Persia, and elsewhere as a narcotic. It must be remembered that *C. sativa* grown in India has quite different properties from the same plant grown in Europe. In India there are four varieties sold: bhang, consisting of the dried leaves and stalks reduced to a powder; ganja, the flowering tops; charas, the resin from the leaves; and majun, a sweetmeat prepared with hemp. In Central Asia the resin is called haschisch.

Its action on man is first to produce a pleasurable excitement and later narcotism. In moderate doses it temporarily increases the feeling of strength and power. As an intoxicant it is much used, being eaten or smoked, and is said to be one potent cause of insanity in India. Waddell says that about 38·4 per cent. of Bengal lunacy can be traced to this source. It is asserted to be one of the causes of the strange phenomenon called 'running amok,' but this will be dealt with in detail later on, under diseases of the nervous system.

Kawa is an intoxicating drink prepared from the root of *Piper methysticum* Forster (Piperaceæ), which grows throughout Polynesia.

According to Lewin, kawa contains starch, flour, two inactive substances—kawain and yangonin—and 2 per cent. of resin, which is believed to be the active principle. But this resin, by treatment with ether, can be resolved into two separate substances, one of which has a weak, and the other a strong action on man. The drink causes a feeling of *bien etre*, but too much has an evil effect, with symptoms of inco-ordination and headache, and a desire for sleep, and may induce liver disease, dermatitis, and general debility. Taken in moderation it is said to be harmless, and also to be a cure for gonorrhœa, and, as such, was introduced into Europe.

Peyotl (pellote) is a narcotic used in Mexico, and derived from the cactus, *Anhalonium lewinii* Henn. It causes sleep with hallucinations.

Coriaria species—*C. ruscifolia* Linnaeus, the poison-foot of New Zealand, and *C. myrtifolia* Linnaeus (a native of Europe)—are considered to be intoxicant or poisonous, according to the dose. The symptoms are coma, convulsions, and dilated pupils. From *C. ruscifolia* the Maoris are said to prepare a wine and jelly.

Pituri (*Duboisia hopwoodi* F. Mueller—Solanaceæ) is a shrub growing in Australia and New Caledonia. In the former it is found in the neighbourhood of Carlo or Mungerebar on the Upper Mulligan, and from this in scattered patches eastwards. At Carlo live the Ulaolinga tribes, from whom the other tribes purchase the pituri by barter with spears, boomerangs, etc. About the beginning of March the pituri leaf is gathered and is sold in the form of half-green, half-yellow tea mixed with plenty of chips. The preparation is complex: it is first roasted in ashes, then wetted with water, then teased with the fingers, and all larger pieces removed. Then leaves of a species of wattle or gigeon are heated over a fire and finally burnt, the ashes being retained and mixed with the moist pituri on a 'pituri plate'—*i.e.*, a smooth surface—and finally manipulated by the fingers into small rolls, 2½ inches long by ¼ inch thick. These rolls are chewed by the natives, and are in great demand as a narcotic. Reserve rolls are carried at the top of the ear. The Australian native names are: 'Măja' (Walookera), 'ne-em-pa' (Yaroinga), 'un-da-kor-a' (Undekerebina), 'pi-tu-ri' (Ulaolinga), 'ti-rum-bol-a' (Karanga), 'ta-rem-bó-la' (Pitta-Pitta), 'moda' (Kalkadoon). The alkaloid piturine is identical with hyoscyamine.

Betel.—The chewing of betel is an extremely common practice in the East, where the leaves of *Chavica betle* (piper betel) are chewed with slices of the nut of *Areca oberacea* (Pinang or areca-nut palm) and mixed with lime. Betel stimulates the salivary glands and, it is said, those of the digestive organs. It diminishes the perspiration, and should be spat out and should not be swallowed. The irritation may be the cause of the commonest cancer of old people in these parts. In the young it may possibly be the cause of heart and nerve diseases.

Kola.—The kola nut so much used as a stimulant by the African native is the produce of several species of the genus *Sterculia* Linnæus, of which the principal are *St. tomentosa* Thunberg and *St. acuminata* Beaver, while *St. nitida* Vent, *St. ballayi*, *St. verticellata* Thorne, and *St sphærocarpa* may also be noted. This nut has been known since the days of Leo Africanus in 1556, when it was known in the Sudan as 'goro.'

It is supposed to be a nervous system and cardiac stimulant, it raises the blood-pressure and increases muscular power, and certainly with kola nut and water a Haussa can travel far and work hard, as we know personally.

Analyses have been made and a glucoside, 'kolamin,' has been obtained by Hilger and Knebel.

Guaraná.—This substance, which is made into oblong or round cakes, is sold in Brazil as guarana bread, being considered an indispensable requisite for travellers. It is made from the seeds of *Paullinia sorbilis* Martius (Sapindaceæ), which are pounded and sweetened. It is said to contain a white crystalline substance which Theodore Martius called 'guaranene.' The Brazilians consider guarana to be a stomachic, a febrifuge, and an aphrodisiac.

Maté.—Paraguay tea is called 'maté' from the cup out of which it is drunk, or better 'yerba,' meaning herb or plant. St. Hilaire was the first to find and name the *Ilex paraguariensis*, which Lambert in 1824 changed to *paraguayensis*, and this is accepted because St. Hilaire cancelled his original name. It is prepared by slightly scorching the leaves, which are then broken down and subjected to a strong pressure. A handful of this pressed foliage is infused in a small spouted vessel called a ' maté.' It is then sucked hot through the spout or bombilla, which is perforated on its lower side with small holes, which, while allowing the escape of the liquid, prevent the pieces of leaf following. It is drunk freshly infused, and is said to be an aperient and diuretic, and to become a habit with those who drink it.

Maté is much used in Paraguay, Uruguay, the Argentine, and Southern Brazil, but in the last-named *Ilex gongonha* Martius, and *Ilex theæzans* Martius are employed.

Coffee.—The deleterious effects of excessive tea-drinking are well known and need not be repeated, but it may perhaps be as well to invite attention to the excessive amount of Turkish coffee which is drunk in the Middle East.

Other Poisons.—In Malacca the leaves of *Mitragyna speciosa* Korth (Rubiaceæ) are said to be used in place of opium. From the leaves of *Bassia latifolia* Roxburgh and *B. longifolia* Linnæus (Sapotaceæ) intoxicating drinks are made. *Hyoscyamus muticus* is used as an intoxicant by the Baluches, and makes them dance like lunatics.

The juice of the fruit of *Anacardium occidentale* (Anacardiaceæ) is used after distillation in Goa as a drink.

IV. POISONS USED IN TRIAL BY ORDEAL.

POISONS D'ÉPREUVE (FRENCH).

Curious customs exist in savage lands of trial by ordeal, in which the patient is given a drug and then ordered to perform some act. Waddell records the history of an old Hindu woman who was supposed to be a witch. She was tried by ordeal, being given a poisonous drug (datura) in treacle, as it is a native belief that a witch can withstand poison. The result of the ordeal was that the poor woman died.

In Africa the greater part of these poisons belong to the Loganiaceæ, Apocynaceæ, Leguminosæ, and Solanaceæ, but the plant employed varies in the different regions, and many are still undetermined—*e.g.*, M'Faug may be a strophanthus, while M'Boundou is undetermined.

Rho gives an account of trial in West Africa by ' imbundi,' the sliced root bark of *Strychnos icaja* (Baillon), which is said to contain strychnine. The accused, after drinking a concoction of the root, is made to jump over a stick, and is pronounced guilty unless he is able to do this, or to pass urine on to a banana-leaf, both of which feats are usually impossible.

Christison mentions the Calabar bean of West Africa, *Physostigma venenosum* Balfour (Leguminosæ), as being used in trial by ordeal, the belief being that the innocent vomit and are safe, while the guilty retain the poison and die. Its antidote is atropine, administered hypodermically.

Erythrophlæum judiciale Procter; *Tanghinia venenifera* Poiret. (which contains a toxic base with an action like digitalin), and *Menabea venenata* Baillon, are used in Madagascar, and *Adenium somalense* Poiret in Somaliland, for purposes of trial by ordeal.

CHAPTER XI

ARROW POISONS

Preliminary - Africa - Asia - Philippine Island - Australasia - America - References.

PRELIMINARY.

FROM time immemorable peoples have used poisons to accentuate wound made by weapons, especially arrows. In 1857 Fontau discovered some arrow points in the Pyrenees which were grooved to receive poisons. These discoveries are said to date as far back as the Old Stone Age.

The arrows of primitive peoples produce wounds which are by no means usually fatal, and therefore, in attacking big game or in warfare, it is obvious that some poison which will insure the death of the victim fairly quickly will be valuable.

Usually these poisons, or the more potent of them, are only known to the fetish priests or chiefs, and are generally mixed with all sorts of animal extracts, the whole being made into a paste, and painted on the arrow heads.

If a special poison is prepared, as a rule some sort of precaution is also taken, so that the owner of the arrow may not be accidentally wounded. Thus, the Fra-Fra people, when preparing against the invasion of their country, obtained a very potent poison, which, however, they handled with great caution, though they boasted that they had an antidote. They kept these arrows, as a rule, in special quivers, and each arrow had a tiny stick tied to its shaft, so that it could be carefully lifted out of the quiver. Moreover, a tuft of red material was tied to the base of each of these sticks, so that there could be no mistake as to which were the specially poisoned arrows.

Arrow poisons may be classified into those of animal origin and those of vegetal origin. The most common animal arrow poisons are snake-venom, scorpions, spiders, red ants, and beetles, crushed and mixed with vegetal poisons. The Bushmen of South Africa and the natives of Togoland make an arrow-poison by burning and powdering the heads of adders and vipers, regardless of the fact that the burning must destroy the venom. The Bushmen of the Kalahari Desert make a poison from the larvæ of *Diamphidia simplex* Paringuey, which is thought to be really a toxin due to some micro organism growing in the decomposing larva. But animal poisons are not nearly so common as vegetal poisons.

The most important natural orders containing vegetal arrow-poisons are, firstly, the Apocynaceæ, which contains the genera Acocanthera, Strophanthus, and Adenium, all of which are common African poisons; secondly, the Loganiaceæ, with the genus Strychnos, which is of great importance in Asian poisons; thirdly, the Urticaceæ, with the important ipoh poison of Sumatra, Borneo, and Indo-China; and fourthly, the less important orders of the Ranunculaceæ, containing *Aconitum ferox* (Wall), used in India, the Leguminosæ, and the Euphorbiaceæ, containing some African poisons.

The actions of arrow-poisons are very varied, and may be classified into-

1. An action on the heart and muscles like that of digitalis.
2. An action on the peripheral nerve endings like that of curari.
3. An action on the nervous system and heart like that of aconite.
4. An action on the nervous system like that of strychnine.
5. An action resembling snake-venoms.

The general treatment of a poisoned arrow wound is as follows:

1. *Tie a tight band on the heart side of the wound*, if on a limb, to prevent absorption of the poison

2. *Remove the arrow as quickly as possible*

The difficulty in withdrawing the arrow-head is the presence of barbs, which can be prevented from doing mischief by thrusting the head through the skin on the far side of the limb there is no necessity to fear about the bloodvessels, for they will slip away from the arrow then cutting the shaft off, and drawing the head through on the far side, and the shaft on the near If it is in the body, a good plan is to enlarge the wound and pass down some sort of a cannula e.g., a hollow bamboo over the head, and then withdraw the whole arrow

3. *Wash the wound with permanganate of potash.*

Having withdrawn the arrow, wash the wound out thoroughly with a 3 per cent solution of permanganate of potash (if this cannot be done, cup the wound or suck it), in order to neutralize any snake-venom, and, indeed, any other poison capable of being oxidized.

4. *Keep the heart acting*

Give stimulants e.g., hypodermics of strychnine after the arrow is removed and the wound washed

5. *After-treatment.*

Treat the hurt as a poisoned wound A dose of antitetanic serum would be good, if available

Some of the principal arrow poisons require to be described in more detail.

Africa. The natural order Apocynaceæ contains, as already stated, several genera of plants which provide celebrated arrow-poisons much used by native peoples in Africa.

These genera are Acocanthera, Strophanthus, and Adenium.

Acocanthera Arrow-Poison.—The genus Acocanthera supplies the most important arrow-poisons of East, Central, West, and South Africa. The poison, which is called waba, wabajo, or ouabaio, was first fully described by Burton in 1856. It is prepared from the tree *A. schimperi* (Dec) in Abyssinia and throughout the greater part of East Africa, being used by the Wataita, the Wakamba, and probably other tribes. The special Fra-Fra arrow-poison of the Gold Coast is probably derived from some species of Acocanthera. In Erythræa and Yemen *A. deflersii* Schweinfurth is used, and in Somaliland *A. ouabaio* Cathelineau. These trees are 4 to 5 metres in height, with dark green foliage, white or red flowers, and violet-red fruit. The poison is usually prepared by making a decoction of the wood, and evaporating it down until it becomes a thick tar-like extract, which contains the active principle. This principle, which is a glucoside called ouabain, acocantherin, or wabain, is a powerful cardiac poison. In addition, the natives generally add snakes' heads and gall-bladders to the tar-like mass; but it is doubtful whether these really increase its virulence, though it must be admitted that sometimes there are symptoms analogous to snake-poisoning.

The thick extract of the wood containing any other additions, which individual peculiarity may consider necessary, is now painted upon the arrow-heads.

The action of the freshly prepared poison is very rapid, death taking place in a few minutes through stoppage of the heart, after a preliminary quickening of the respirations and convulsions. Sometimes pain is complained of in the lumbar region. The symptoms can be readily prevented by a 3 per cent. solution of permanganate of potassium The native remedy is believed to consist in eating some of the poison.

Another important Acocanthera poison is *A. venenata* Thunberg, which is employed by the South African Bushmen, and is said to be made from a decoction of the bark. The symptoms are rigors, without convulsions, and loss of muscular power, followed by death in a few minutes

Strophanthus Arrow-Poison.—Livingstone was probably the first to draw attention to a Strophanthus arrow-poison called kombi, used in Central Africa *Strophanthus hispidus* De Candolle is a very common plant in many parts of West and Central Africa, and is a common arrow-poison, but not nearly so deadly as that of Acocanthera. The other varieties used are *S. glabris*, *S. kambe*, *S. lanosus*, *S. ciabé*, *S. barika*.

The poison is obtained by cooking the seeds in water, and adding snakes' heads and leaves and roots of other plants. The injured man falls to the ground, and his breathing and pulse become gradually slower and slower, until the heart-beats suddenly cease, and death ensues, preceded by a convulsion in about ten to fifteen minutes. The heart stops in systole, and will not contract on stimulation. Strophanthus is used on the Congo, Lake Nyassa, Zambesi, Gaboon, Guinea Coast, Gold Coast, Cameroons, and Senegambia as an arrow-poison.

Adenium Arrow-Poison.—There are two species of Adenium used in Africa—viz., *A. boehmianum* Schinz and *A. somalense* Oliver.

A. boehmianum, which is a shrub about 1½ to 2 metres in height, is used by the Ovambo of German South-West Africa to prepare an arrow-poison called echuja. The thickest branches or roots are cut across and held over a fire, when the thick, viscid sap exudes in threads, and is collected by winding it round small pieces of wood. The arrow heads are now moistened by spitting upon them, and then smeared with the sap.

The active principle is echujin, which is a very virulent cardiac poison. The Somaliland species is equally virulent.

Erythrophlœum judiciale Proct.—Its active principle is an alkaloid, erythrophloein, which causes dyspnœa, first slowing and then quickening of the heart, and finally death from stoppage of breathing. It is used by the Pigmies of Central Africa; but the principal Pigmy arrow-poison is a mixture of this with strychnine, which will kill an elephant. Prompt treatment, however, is said to be able to save a man's life when wounded by one of these arrows.

Munchi Arrow-Poison. The Munchi arrow-poison, which is used by the Backorana clan in Northern Nyeni, is said to be nearly always fatal to man in about half an hour. The method of preparation is not known, but the poison is plastered in a thick layer on the long point of the barb. It is brittle, of a dark brown colour, with slightly aromatic odour, and is insoluble in cold or warm water, in normal saline or acidulated solution, but dissolves easily in alkalis—*e.g.*, 1 per cent. Na_2CO_3 solution. It has no alkaloidal properties, and does not reduce copper sulphate in alkaline solution. No fluorescence occurs with H_2SO_4, and there is only slight reducing power after prolonged boiling with mixed acids. It acts by paralyzing the heart and the striated skeletal muscles, but no distinct action on the muscle plasm can be detected. The toxic substance is thought to belong to the class of resinous acids.

Euphorbia candelabrum.—This is supposed to be one of the ingredients of the poison '*uciunga*' (meaning poison), used by the Wafiomi, Wagogo, of late German East Africa. The other ingredients are not known. According to Brieger, the active principle is exactly the same as in Acocanthera. Rho says the Wakamba use a similar poison.

Less important African arrow poisons are:—

(*a*) *Used by the Monbattu Dwarfs*—

1. Erythrophlœum guineense G. Don., belonging to the Leguminosæ, of which the bark is used.
2. Palisota barteri Bentham.
3. Combretum grandiflorum G. Don.
4. Strychnos icaja Baillon.

(b) Used by the Hottentots and South African Bushmen—

5. Hæmanthus toxicarius (Linnæus).
6. Euphorbia cereiformis (Linnæus).
7. Euphorbia virosa (Wight).
8. Euphorbia heptagona (Linnæus).
9. Euphorbia arborescens (Boissier).
10. Hyænanche globosa (Lamb).

Nigerian Arrow-Poisons.—Parsons finds that the common arrow-poisons are either strophanthus or strychnos.

Asia.—The best known of these poisons are those used in Malaya Sumatra, and Borneo, and prepared from the following:—

Ranunculaceæ—

Aconite (various species).

Urticaceæ—

Antiaris toxicaria Leschenault

Leguminosæ—

Derris elliptica Bentham.

Loganiaceæ—

Strychnos tieuté Leschenault.
Strychnos wallichiana Bentham.
Strychnos maingayi Clarke.

Rubiaceæ—

Lasianthus flavescens Korthals.

Dioscoreaceæ—

Dioscorea hirsuta Blume.

Aroideæ—

Amorphophallus campanulatus Blume

Apocynaceæ—

Tabernæmontana malaccensis Hooker.

Aconite.—The Mishmi arrow-poison of North-East India is derived from some species of aconite, perhaps *A. ferox* or *A. heterophylloide.*

Aconitum ferox Wall, belonging to the natural order of the Ranunculaceæ, is used by the Himalayan tribes from Assam to Kashmir as an arrow-poison, and several Sepoys have been mortally wounded in expeditions.

The poison is applied as a paste to the arrow, and is said to be mixed with septic blood to increase its effects (Waddell). It is also said to be used along the French and Chinese frontiers of the Indian Empire, and by the Ainos in Japan, but the latter are believed to mix it with tobacco.

Antiaris toxicaria.—*A. toxicaria* (Lesch) is a tree growing in Malaya, the sap of which provides the arrow-poison known as ipuh, ipo, ipoh, ternek, kyass, poön, upas, etc. It is used by the Sakais of Malacca, the Battaks of Sumatra, the Dyaks of Borneo, and the Mois of Cochin China. Brandwood's dart-poison, dajaksch, from Borneo, appears to be from the juice of *A. toxicaria.*

The earlier travellers in Malaya gave wonderful accounts of the upas-tree and its action, which were purely imaginary. Delisle and Magendie appear to have been the first to make experiments with the poison in 1810, and they were followed by Brodie in 1811, who showed that the heart-beats became weak and irregular before respiration or the mental faculties were impaired.

There appears to have arisen a confusion between the juice of *A. toxicaria* and *Strychnos tieuté*, which explains the finding by Hedbon and Welting of strychnine in upas antiar. Pelletier and Caventou, the discoverers of quinine, studied the chemistry of the poison, and in 1838 Mulder isolated the active principle as a crystalline body, which he called antiarin, which in 1868 De Vrij and Ludwig showed to be a glucoside.

Kiliani in 1896 investigated antiarin, and found its formula to be $C_{27}H_{12}O_{10}$. The physiological action of the poison has been investigated by a large number of observers, notably by Hedbon, Kiliani, and Seligmann, the last named observer giving a most excellent account of ipoh as used by the Kenyahs of the Baram district of Sarawak.

The poison is prepared from the inspissated juice of the tree, and is either used alone or is mixed with *S. tieuté*, snakes' heads, or other substances. The whole concoction is made into a paste with water, and applied to the heads of the arrows, which are then dried before a slow fire.

The poison acts on the ventricles of the heart, behaving like digitalis, and, in addition, causes paralysis of the cerebral nervous system and passing clonic spasms of the voluntary muscles.

Croton tiglium. Fraser considers that this is one of the Abors' arrow-poison, while the other is probably aconite, possible *A. ferox* and *A. heterophyllum*.

The Strychnos Arrow-Poisons. *Strychnos tieuté* Leschenault is the upas tieuté of Borneo, *S. wallichiana* Bentham is the ipoh aker, and *S. maingayi* the aker lampong of the natives of Malacca.

The poisons obtained from these plants are said to contain strychnine and curari. The symptoms are said to be paralysis of the muscles, abolition of the reflexes, and stoppage of the heart and respiration. The urine contains a substance which reduces Fehling's solution.

Manbhum Arrow Poisons. Anderson thinks that these poisons may possibly be manufactured in the following ways:—

1. By dipping the arrow-heads into rotten fish or meat, or into the highly decomposed human body, or into animal secretions equally decomposed.
2. By coating them with nux vomica and sulphide of arsenic.
3. By coating them with snake venom.
4. By dipping them in mud, so that they acquire the organism of tetanus.

Less important Asian arrow poisons are: *Guatteria veneficiorum* Mart, *Cocculus toxiferus* Mart, *C. amazonum* Mart, which are also used in India as arrow-poisons, the active principle being curari.

Philippine Islands.—The arrow-poison used by the Negritos of the Philippine Islands is *Rabelaisia philippinensis* Planch., which causes paralysis of the extremities, dyspnœa, convulsions, and cessation of the heart's action.

Australasia.—Le Dantec, quoted by Vaughan and Novy, says that the poisonous arrows of the natives of the New Hebrides are prepared by smearing the points, which are usually made from human bones, with, first, a vegetable resin, and then with slime taken from marshy places.

America.—The important American arrow-poisons used in the valleys of the Amazon and Orinoco belong to the Loganiaceæ, and are *Strychnos toxifera* Schomb., *S. crevauxii* Planchon, *S. castelnaeana* Baillon.

The active principle is curari, and, it is said, curin. Curari, or ourari, was first brought to Europe by Sir Walter Raleigh in 1595. The drug paralyses the motor end-plates, and causes death from failure of the respiration.

Less important American arrow-poisons are:—

(*a*) *Paullinia pinnata* (Linnaeus), used by native Indians of Brazil.
(*b*) *Piscidia erythrina* (Linnaeus), used in Brazil and Central America.

CHAPTER XII

POISONS USED IN FISHING, HUNTING, AND TRADE

Preliminary—Fish poisons—Poisons used in hunting—Cattle poisoning—Rat poisoning—Locust poisoning—Poisoning of birds—Trade poisoning—References.

PRELIMINARY.

In this chapter we consider in the briefest possible manner the use of poisons to kill fish, big game, cattle, rats, birds, and trade poisoning.

FISH POISONS.

Every now and again we have been appealed to for the purpose of explaining why a large number of fish have been found dead in a river or lake, and certainly in those which we have been able to investigate personally the causal agent has been poisoning of the waters.

It is a common practice all over the world to throw pieces of bark or leaves of trees and shrubs on to the water, in order to stupefy fish, and thus enable them to be easily caught.

The number of plants used for this purpose is very great, and though we have not thought it necessary to give a detailed list in this book, still, we consider that it is useful to give a few examples, as a knowledge of the subject is at times required.

The plants used in Ceylon for the purpose of intoxicating or killing fish are given in the following list supplied to us by Mr. Drieberg:—

1. *Anarmirta paniculata* (*A. cocculus* Wight and Arnott).
2. *Barringtonia acutangula* Gaertner.
3. *Euphorbia tirucalli* Linnæus.
4. *Lasiosiphon eriocephalus* Decaisne.
5. *Mæsa indica* Wall.
6. *Mundulea suberosa* Bentham.
7. *Randia dumetorum* Lamarck.
8. *Strychnos nux vomica* Linnæus.
9. *Walsura piscidia* Roxburgh.
10. *Derris uliginosa* Bentham.

Hydnocarpus venenatus Gaertner is also said to be used, and to be poisonous on account of the hydrocyanic acid it contains.

In India the following are used:

Anamirta cocculus Wight (Menispermaceæ).
Dolichandrone falcata Seemann (Bignoniaceæ).

In Java and Sumatra:—

Pittosporum densiflorum Putterlick (Pittosporeæ).
Tephrosia toxicaria Persoon
Tephrosia piscatoria Persoon.

In the Philippine Islands:

Sapindus rarak De Candolle (Sapindaceæ).
Harpulia arborea Radlkofer (Sapindaceæ)

In the Dutch East Indies:

Derris elliptica Bentham (Leguminosæ).
Pachyrhizus angulatus Richard

Both of these plants contain a non-nitrogenous substance, called respectively derrid and pachyrhizid, highly poisonous to fish. Derris-root will kill fish in a dilution of 1 to 25,000 of water, and derrid in 1 to 5,000,000

In the Comoro Islands

Tephrosia vogelii Hooker (Leguminosæ)

In the West Indies:

Piscidia erythrina Linnæus.

This plant, called the Jamaica dogwood, is used by throwing the leaves and entire branches into the water, when the active principle, piscidin, dissolves out and paralyzes the fish, which are easily caught floating on the surface

In Guyana:

Tapura guyanensis Aublet.
Ichthyothere cunabi Martius

In South America:—

Grewia asiatica Linnæus
Dichapetalum toxicarium Baillon.
Serjania ichthyoctona Radlk (the Timba of the Amazon).
Serjania lethalis St. Hillaire (the Timba of the Amazon).
Serjania piscatoria Radlk (the Timba of the Amazon).
Hydrocotyle javanica Ehrenberg.
Clibadium asperum De Candolle.
Jacquinia armillaris Linnæus

In Africa:—

Kiggelia africana Linnæus
Paulowilhelmia speciosa R. Brown.
Tephrosia vogelii Hooker.

In Sardinia:—

Œnanthe crocata Linnæus.
Daphne guidium Linnæus.

POISONS USED IN HUNTING.

In India the root of *Arum montanum* Roxburgh is said to be used to poison tigers, while aconite is employed for the same purpose against elephants, especially *A. ferox* Wall. In San Salvador the 'Cangoura,' *Rourea oblongifolia* Hooker, is employed.

CATTLE POISONING.

Cattle poisoning is a frequent method of revenge in India, and the drugs most commonly used are: Arsenious oxide, arsenious oxide with sulphite, arsenious oxide with oxides of lead, sulphides of arsenic only, oxides of lead only, sulphate of copper, nux vomica, *Cocculus indicus*, mercury, and sulphate of iron.

But, in addition, *Abrus precatorius* Linnaeus, *Cerbera thevetia* Linnaeus, *Calotropis procera* R. Brown, aconite, chopped hair, and snake-venom have been used. The list of Ceylon plants poisonous to man and cattle will be given below. It is important to remember that rinderpest and dysentery resemble arsenical poisoning, while poisoning with nux vomica may resemble tetanus.

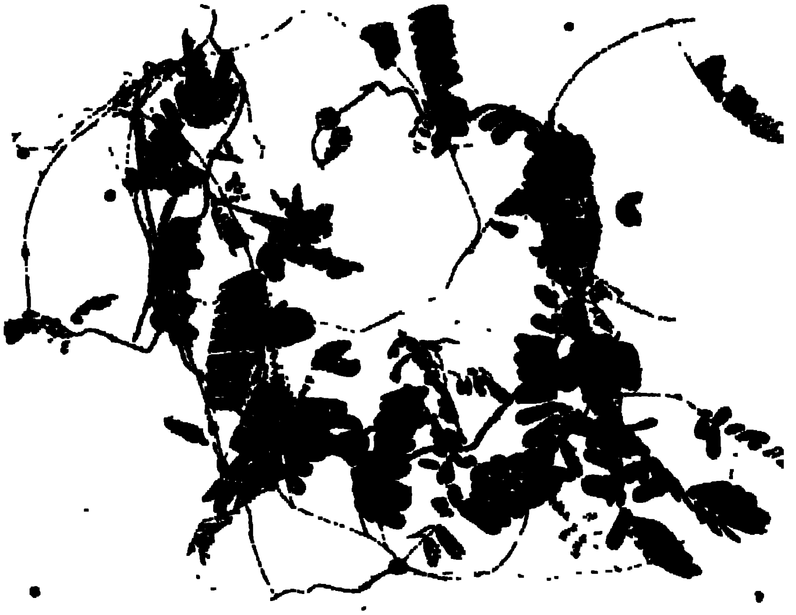

FIG. 13. *Abrus precatorius* LINNAEUS.

Grey says that *Lessertia annularis*, the Cneuta of the Karroo of South Africa, produces cerebro-spinal paralysis in sheep and goats, like *Gastrolobium*, the poison-pea of Australia. Only *Abrus precatorius* need be discussed here.

Abrus precatorius Linnaeus.—The juice of this plant, which belongs to the Leguminosae, is most irritating, and if injected under the skin of cattle proves rapidly fatal, by producing general depression, drowsiness, fall of temperature, and haemorrhagic lesions somewhat like those of snake-venom.

The decorticated seeds are made into a paste, which is worked into sharp-pointed little needles, and hardened in the sun. Two of these are inserted by their bases into a wooden handle, and then driven with great force into the animal's flesh.

The active principle is abrin, a tox-albumin resembling snake-venom, which causes thrombosis and death in from eighteen to twenty-four hours.

Ornithoglossum glaucum Salisbury, 1806.—This plant is the cause of accidental cattle poisoning in South Africa.

Much has been written of late years with regard to stock poisoning in Australia and elsewhere, but it is rather outside the work of this book to deal further with this matter, to which we give references at the end of this chapter. We, however, give a list, which we owe to the kindness of Mr. Drieberg, of Ceylon plants known to be poisonous to cattle:

1. *Ammannia baccifera* Linneus.
2. *Anamirta paniculata* (*A. cocculus*) Wight and Arnott.
3. *Arisaema curvatum* Thwaites.
4. *Chrozophora plicata* A. de Jussieu.
5. *Croton tiglium* Linnaeus.
6. *Diospyros montana* Roxburgh.
7. *Elaeodendron glaucum* Persoon.
8. *Euphorbia tirucalli* Linneus.
9. *Excoecaria agallocha* Linneus.
10. *Datura fastuosa* Linneus.
11. *Lagenaria vulgaris* Seringe.
12. *Lasiosiphon eriocephalus* Decaisne
13. *Lobelia nicotianaefolia* Heyne.
14. *Manihot utilissima* Pohl.
15. *Paspalum scrobiculatum* Linnaeus
16. *Plumbago zeylanica* Linnaeus.
17. *Rauwolfia serpentina* Bentham.
18. *Rhododendron arboreum* Smith.
19. *Ricinus communis* Linnaeus.
20. *Sapium insigne* Trimen.
21. *Tylophora fasciculata* Buch-Ham.
22. *Withania somnifera* Dunald.

RAT POISONING.

This is generally carried out by means of yellow phosphorus or arsenic.

The phosphorus is mixed with glucose to prevent spontaneous combustion, and then made into a paste with a fatty base such as lard; but it is advisable to vary, from time to time, the fatty base, as rats are very knowing and begin to suspect that something is wrong.

The poison is then spread on bread or made into bread pills, but it is often advised that people who do this should have their hands smeared with an ointment containing oil of aniseed, with which all utensils used for the poison should also be smeared.

Arsenic is often preferable to phosphorus, which is difficult to obtain and dangerous to work with. It should be treated in the same way as phosphorus, but it is as well to find the minimal lethal dose for the local rat before commencing rat poisoning on a large scale, and also to be ready with an antidote in case any person indulges in a dose.

Many rat poisons are known to natives, especially *Tylophora fasciculata* Buch-Ham (Asclepiadeæ), *Chailletia toxicaria* Don (Dichapetalaceæ), both of which are used in Africa, and *Dianella nemorosa* Linnaeus (Liliaceæ) in Malacca.

LOCUST POISONING.

Arsenic has been used with success by Mr. King, Government entomologist in the Sudan, and others as a poison for killing locusts in the 'hopper stage.' The arsenic is prepared in concentrated form in treacle and is diluted locally. Into the solution so made chopped fodder is placed, and, after soaking, is spread out for the hoppers to eat in desert parts. Spraying has also been used in cultivated areas. Mustard and the usual iron antidote are handy in case anyone takes a dose of the poison.

POISONING OF BIRDS.

Attempts have been made from time to time to diminish the sparrow pest in cultivated areas by poisons *e.g.*, strychnine—but with doubtful success.

Palicourea marcgravii (*Rubiaceæ*) St. Hilaire is said to be used for poisoning pigeons.

TRADE POISONING.

The trade poisonings are more fully dealt with in the chapter on *Dermatitis venenata*, but we may mention the following here:—

Vanilla Poisoning.

Vanillismus is poisoning by the dried fruit of *Vanilla planifolia* (Andrews), which causes colic, vomiting, and pains in the head and muscles. Men working with it may suffer from conjunctivitis, fits of sneezing, and a skin eruption called vanilla itch, characterized by swelling, followed in a few days by scaling. There is, however, great doubt as to what is the real cause of these symptoms. Probably some of them are due to a mite in the vanilla.

Lacquer Poisoning.

Lacquer is obtained from a brown treacle-like balsam, which exudes when incisions are made into the lacquer-tree, *Rhus vernicifera* De Candolle.

The disease is acquired in two ways: either by direct contact with the lacquer, or through the fumes arising from it by evaporation, but only as long as the lacquer is not dry, for the poison, whatever it is, disappears on drying.

The symptoms, which develop in a few hours, are fever, with tension and œdema of the skin of the face, limbs, and generative organs, nasal and conjunctival catarrh, while a papular eruption appears on the œdematous skin of the legs and forearms.

The treatment consists in washing the skin thoroughly with soap and water, and applying soothing applications, such as cold lotions, or *Lotio Plumbi subacetatis*.

As prophylaxis the Chinese rub the hands and face with rapeseed oil in which a ham has been boiled, and wear a linen mask for the face and a leather apron for the body. After work the exposed parts are rubbed with a decoction of chestnut, pine bark, saltpetre, and amaranth.

The above precautions are taken in China, but in Japan no such prophylaxis exists.

NOTE.—Camel poisoning caused by the hydrocyanic acid contained in immature dura is well known in the Sudan.

REFERENCES.

The best account of these poisons is given by Ishio (1914) in the second edition of Mense's 'Handbuch der Tropenkrankheiten,' 517-615. CHAPTER XIII

POISONOUS FOOD

Preliminary— Animal food poisoning—Products normally present—Fuguismus—Post-mortem decomposition—Vegetal food poisoning—Lathyrismus—Lolismus—Paspalismus—Atriplicismus—Fabismus—Fagopyrismus—References

PRELIMINARY.

FOOD poisoning, technically called bromatoxismus, may be divided into two classes:—

1. Animal food poisoning.
2. Vegetal food poisoning.

1. ANIMAL FOOD POISONING.

Animal food poisoning is called zootrophotoxismus, and may be due to—

(*a*) Products normally present in certain animals, but poisonous to man.
(*b*) Poisonous food having been eaten by an animal prior to its being killed for food.
(*c*) Products abnormally produced in the living animal.
(*d*) Post-mortem decomposition.

But of these we need only concern ourselves with the first and the last.

Products Normally Present.—Poisoning by products normally present in the animal is called 'siguatera,' and is generally due to fish, though it may also be caused by Molluscs, Crustaceans, and Cœlenterates.

The most dangerous fish are those living among coral reefs, and particularly those which are bright-coloured. It is possible that the poisonous properties may be due not so much to the fish itself as to the fact that it has eaten decomposing food, such as dead medusæ, corals, etc.

Fretz and Branch have noted fish poisoning in 1915 in St. Christopher and Nevis, and think that it is due to the *Barracouda* (*Sphyræna*), while McNaughton reports similar poisoning from the Gilbert and Ellice Islands.

Certain species of the genus Clupea (Cuvier), particularly *C. thrissa* (Osbeck) are noted as being very poisonous, but there is considerable doubt about this matter, as no scientific work has been done on the subject. The symptoms are gastro-intestinal irritation, which may lead to collapse and death. Another fish which is only poisonous at certain seasons is a so-called sardine *Clupea*

FIG. 14.—*Clupea longiceps* (*Sardinella neohowii*).

longiceps (*Sardinella neohowii* Val), found off the coasts of Ceylon, and which, according to Tennent, caused much sickness years ago.

Other poisonous fish are *Tetrodon hispidus*, the 'muki-muki' or death-fish of Hawaii, and the file fishes, of which *Stephanolepsis*

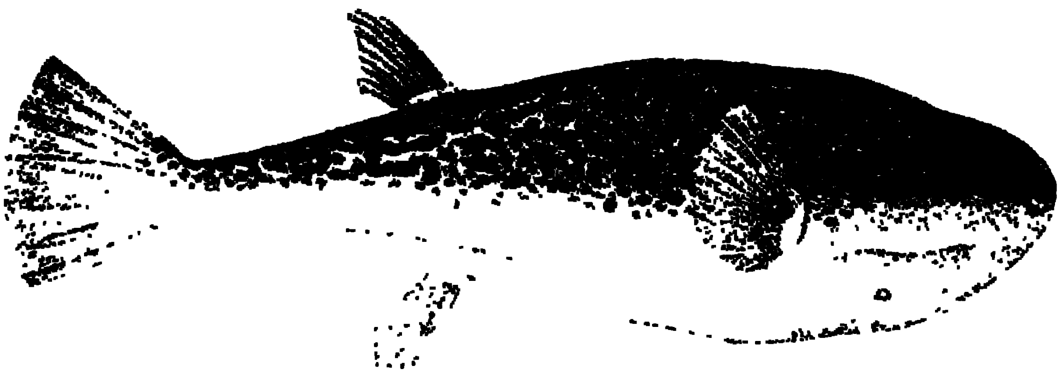

FIG. 15.—*Tetrodon vermicularis* SCHLEGEL.
(From Savtschenko's 'Atlas of Poisonous Fish')

hispidus L. may be mentioned as an example. Poisoning with Tetrodon has, however, been more accurately studied, and may be referred to at greater length under the term Fuguismus.

Fuguismus.

The Japanese term 'fugu' includes several species of fish belonging to the genus Tetrodon, of which the important species are *T. vermicularis*, *T. rubripes*, *T. lævigatus*, *T. chrysops*, *T. rivulatus*, *T. lunaris*, *T. pardalis*, *T. porphyreus*, *T. poicelonotus*, *T. stellatus*, and *T. sticonotus*, which are said by Scheube to be often used for suicidal purposes. *T. pennantii* has also been found to be the cause of poisoning in a case in Burmah.

The poison appears to lie in the ovaries and testicles, which, according to Tabara, contain—1. Tetrodin—a crystalline base; 2. Tetrodonic acid—a white, waxy body. Both are poisonous, but the acid is said to be more so than the base.

The symptoms, which begin in three to fifteen minutes after eating one roe, are, according to Scheube, an unpleasant sensation in the stomach, abdominal pains, burning in the fauces, nausea, severe headache, collapse, and fainting. Death may occur in a few hours from paralysis of the heart or respirations. The mortality is high, being said to be more than 68 per cent.

The treatment is to empty the stomach with an emetic and to give stimulants, especially hypodermics of strychnine.

Post-Mortem Decomposition.

Post-mortem changes are much more rapid in the tropics than in the Temperate Zone, and, therefore, food is quickly apt to become poisonous. Meat is especially liable to become infected with saprophytic or pathogenic micro-organisms, especially *Bacillus paratyphosus* B (Schotmüller) and the bacillus of Gaertner, more rarely *B. paratyphosus* A (Schotmüller). These micro-organisms give rise to ptomaines, which cause symptoms of irritant poisoning (kreotoxismus), which may be so severe as to resemble those of cholera. The treatment is to remove the poison by emetics if necessary and purgatives, in the meanwhile keeping up the heart's action by means of warm applications, stimulants, and cardiac tonics. When collapse sets in, saline hypodermic injections should be given. As soon as the acute symptoms subside, the bowel should be disinfected with small doses of calomel, salol, or naphthol.

2. VEGETAL FOOD POISONING.

Sitotoxismus, or vegetal food poisoning, is caused by many kinds of vegetal food, and ought to be well known, but, unfortunately, is by no means on a scientific basis in the tropics.

Ergotism, well known in the temperate regions, is not important in the tropics; but, on the other hand, there is lathyrism, believed to be due to *Lathyrus sativus*, and other species of the same genus—loliismus, due to *Lolium temulentum*; and paspalismus, due to *Paspalum scrobiculatum*—which are known to occur in India. Less known is atriplicismus, which is described in China.

Kirke has drawn attention to poisoning by *Cystisus cadjan*, by which he probably means *Dolichus catjana* (Linné), named *Vigna catjang* (Walp.) by Dragendorff, and also by *Dolichos filosa* (Klein), which is the same as *Vigna filosa* (Savi), both of which are used as foods. With regard to the former, the native name of which is urhur or toar, he says it mainly affects the poorer classes, as they do not remove the outer skin before eating it. The symptoms in the order of appearance are as follows:—Urticaria, sense of heat in the stomach, redness of the lining membrane of the mouth, apparent elongation of the teeth (by this must be meant shrinking of the gums), discoloration, bronzing of the skin, sponginess of the nails, burning of the hands and feet, a dry, harsh, cracked condition of the cuticle of the hands and feet, and deep longitudinal cracks in the heels. Rheumatic pains, with thickening of the periosteum, especially of the shins, and changes in the joints are also noticed.

Dolichos filosa, called 'oordh dal,' is said by Kirke to be poisonous only if eaten with the husks, when it causes colic, indigestion, and as secondary results rheumatic pains, harshness and dryness of the skin, with cracks. It is said to be a staple article of food among all classes, except the highest and the lowest.

Lathyrismus.

Synonyms.- Platterbsenkrankheit (Ger.); Meurd Djilben (Algeria); Latirismo (It.).

Definition.- Lathyrismus is an intoxication caused by the ingestion of *Lathyrus sativus* Linnaeus and other species of the same genus, and characterized by symptoms of spastic paraplegia.

History.- It is believed that Hippocrates was acquainted with the disease, because he mentions that people at Ainos who fed continually on pulse suffered from weakness in the legs. In 1671 the Grand-Duke of Würtemberg issued an edict forbidding the eating of bread made from vetch-seeds, as it had been noticed that those who ate such bread suffered from a peculiar stiffness of their legs, although they seldom died. In 1784 an epidemic was recorded in Tuscany, when, through scarcity of food, the people were compelled to eat chick-peas. Tozzetti, while studying this epidemic, came to the conclusion that only the people who had for at least three months eaten bread made of two parts chick pea to one part of rye or wheat became ill. He then planted some of the chick-pea seeds, and, when they grew up, identified them as *Lathyrus sativus* (L.). In 1824 Desparanches came to the conclusion that the seat of the lesion was in the lumbar cord. In 1833 the disease was first recognized in India in the Saugor territories, where, on account of three successive famines in 1829-31, the people were compelled to eat vetches, which are called kesari dal, or teori. Outbreaks took place in Sind, Chota Nagpur, the Central Provinces, and in the Himalayas. It apparently became very prevalent, for Irving says that in one district 6 per cent., and in another 3·19 per cent., of the inhabitants were affected. It still exists in India.

Climatology. The disease depends upon social rather than climatic conditions, for people will not eat the vetches unless compelled by famine. It is known in India, Algiers, Italy, and France.

Ætiology. There appears to be a consensus of opinion that the disease is due to eating bread composed largely of flour obtained from seeds of some species of Lathyrus belonging to the natural order Leguminosæ. The species most commonly suspected is *Lathyrus sativus* Linné, which grows in India; but *L. cicera* L. (red vetch), *L. clymenum* L. (Spanish vetch), *L. tuberosus*, and *L. aphaca* have all been regarded as possible causes. It is, however, by no means evident what substance or substances in these plants cause the symptoms. Teilleux obtained a resin which caused tetanic spasms and paralysis of the posterior limbs in rabbits. Bourlier obtained an extract which killed birds and frogs. Asher obtained from *L. cicera* a volatile alkaloid, which he called lathyrin, which was doughy in consistence, alkaline, insoluble in water, slightly soluble in ether, soluble in chloroform, and which on evaporation formed needles; but he did not perform any experiments with the substance, the action of which is therefore unknown. It is believed by some that Lathyrus is not poisonous unless the seeds are decomposed or contain some parasitic growth, while others hold that the symptoms are not due to Lathyrus at all, but to *Agrostemma githago* (the corn-cockle) or *Lolium temulentum* (the darnel). In 1883 Astier separated out an alkaloid, *lathyrin*, which Stockman in 1917 showed to be the poisonous principle, which is present in only small amount and only in the seed itself.

Animals are by no means immune from the baneful effects of the plants, for ducks become paralyzed and may die after eating the seeds; while pigs and horses also su the latter showing acute or chronic symptoms which are said more [illegible] less to correspond to lathyrismus. On the other hand, bulloc and buffaloes are considered to be immune.

The great predisposing c e in man is scarcity of food, whether due to famine or poverty, th of which compel the unfortunate people to eat vetches instead of ordinary food. If the disease is brought about by fa it may assume epidemic proportions; if by poverty, it may be simply endemic. Young people are more liable to be poisoned than old persons, and men more than women, perhaps because they eat more food.

Morbid Anatomy.—The pathology and morbid anatomy need investigation. When this is done, it is probable that some lesion of the pyramidal tracts—*i.e.*, of the upper motor neurones—will be found.

Symptomatology.—The incubation period is not known, and the disease comes on so insidiously that the patient often attributes it to a chill which he may have experienced a day or so previously.

Prodromata are often said to be absent, though it is more probable that digestive disturbances, colicky pains, and diarrhœa do occur, but pass unnoticed.

One of the first symptoms to arise is pain in the back and weakness in the legs, which increase until symptoms of spastic paraplegia appear. The patient now complains of girdle sensations, and walks with difficulty. The gait is characteristic, for the feet are turned slightly inwards, and are dragged or raised with difficulty from the ground. The joints appear so weak that it is difficult to proceed any distance without falling, while the body has a peculiar up and down motion. There is no ataxy, and no vasomotor phenomena, but the legs waste very much. The arms are not, as a rule, involved, though the hands may tremble. The superficial and deep reflexes are increased, and ankle clonus is present. The electrical excitability of the affected muscles is diminished, but the reaction of degeneration is absent. Incontinence of urine and impotence are early and common symptoms. The mind is unaffected.

The disease does not itself end fatally, but a definite improvement is seldom seen except in incipient cases.

Diagnosis.—Lathyrism must be distinguished from ergotism by the absence of gangrene, from beri-beri by the absence of implication of the peripheral nerves and the heart, and the absence of dropsy.

Prognosis.—The disease itself is not fatal.

Treatment.—Mild cases may be considerably benefited by being given good food and warm clothing, together with counter-irritation to the spine, and bromide of potassium internally in 15-grain doses three times a day. Strychnine is harmful.

Prophylaxis.—The only possible prophylaxis is the distribution of good food to the poor in times of famine.

Loliismus.

Loliismus is an intoxication caused by the ingestion of the seeds of *Lolium temulentum* Linnæus in bread.

History.—Loliismus has been known since Roman times, and is said by Orfila to have occurred in Genoa during the blockade of the year 1800. Kingsley of Roscrea described an outbreak in 1854, in which thirty persons suffered severely. Similar cases have been reported in India from the Punjaub, where the herb is called 'mostaki,' and from the North-West Provinces, where it is called 'moschni.'

Ætiology.—The exact method by which *Lolium temulentum* causes disease is not known. Dr. Cordier experimented on himself by taking 6 drachms of the seeds early one morning, and asserts that the result was inability to think, indistinct vision, torpor, debility, and drowsiness, followed by efforts to vomit, and later by tremors of the limbs, great depression, difficulty of speech, and vomiting. Bley separated a bitter principle, which he called loliin, but the action of this does not appear to have been investigated properly. Freeman states that the seeds owe their poisonous properties to an associated symbiotic fungus, which he carefully describes, and says that it is probably identical with that found in other species of Lolium. He says that it is a disputed point how far ergot and other fungi may be concerned in the production of the disease.

Climatology.—It occurs in the Punjaub and the North-West Provinces of India, and in Europe.

Pathology and Morbid Anatomy.—Not known.

Symptomatology.—The affected persons become very giddy, and stagger about as though drunk, and at the same time suffer from violent tremblings in the arms, legs, and tongue, impairment of vision with dilated pupils, green vision, great prostration, and in some cases vomiting. Sometimes there is a sense of burning heat in the mouth and throat, and a small irregular pulse.

Diagnosis.—The diagnosis may be effected by considering the symptoms and examining the bread, when the starch granules of Lolium may be seen.

Prognosis.—The disease does not end fatally.

Treatment.—Castor oil must be given to remove the poison, and at the same time stimulants must be used to counteract the collapse.

Prophylaxis.—Bread should not be made with the seeds of *Lolium temulentum.*

Paspalismus.

Paspalismus is an intoxication caused by eating bread made from flour derived in part from the seeds of *Paspalum scrobiculatum* Linnæus.

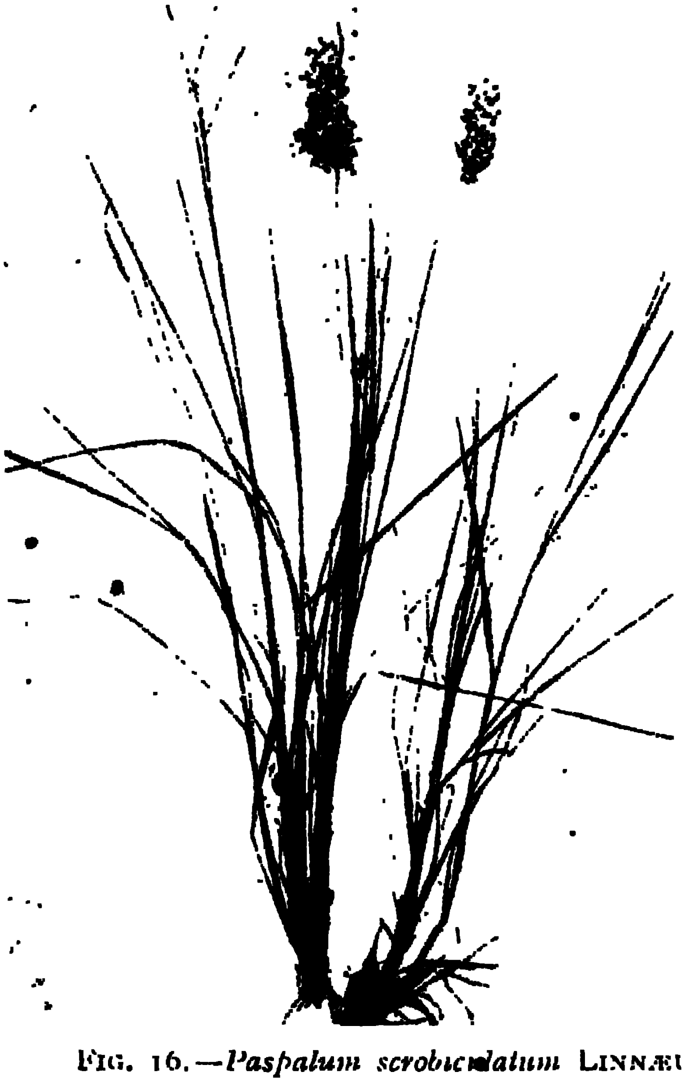

FIG. 16.—*Paspalum scrobiculatum* LINNÆUS.
Seeds show separately at the top of the illustration.

History.—Poisoning by *Paspalum scrobiculatum* occurs in India, where it was reported as far back as 1879, and probably was known earlier.

Ætiology.—Some authorities doubt the genuineness of this disease, for, as Waddell points out, the symptoms are so like loliismus that it is quite possible that some mistake may be made as to the causation.

Diagnosis.—This is made by noting the period of the year and by tracing the history of the ingestion of beans or the smelling of the flowers, and also by the family and geographical incidence.

From malaria it is diagnosed by the absence of the parasites and the negative reaction as regards complement deviation with malarial antigen

From quinine hæmoglobinuria it may be recognized by the absence of a history of the drug being taken.

Treatment. Apparently there is little known under this heading, which obviously calls for the administration of calcium salts (see Chapter XLI., p. 1213)

Prophylaxis.—Avoid eating raw or cooked fresh beans in Sardinia, and avoid the scent of the flowers. As the attacks recur it would be interesting if someone would try the administration of calcium salts to susceptible people living in Sardinia during the dangerous period of the year.

Fagopyrismus.

White animals fed upon buckwheat and exposed to the sun develop erythematous lesions of the skin and nervous symptoms.

CHAPTER XIV

VENOMOUS ANIMALS: PROTOZOA TO ARTHROPODA

Protozoa—Cœlenterata—Echinodermata—Platyhelmia—Nemathelminthes—Arthropoda—Arachnida—Scorpionidea—Aranea—Acarina—Chilopoda—Hexapoda—Anopleura—Hemiptera—Hymenoptera—Lepidoptera—Diptera—Coleoptera—Mollusca—References.

VENOMOUS ANIMALS.

Many species belonging to the various classes and orders of the animal kingdom possess glands which secrete chemical substances injurious to man and the higher animals. The exact nature of these chemical substances is but little understood at present, though of late years much advance has been made in the knowledge of their action, which seems to be of a nature similar to that of bacterial toxins.

It will be best to consider these venomous animals in the order of their zoological classification.

PROTOZOA.

Rosenau and his collaborators have succeeded in producing a malarial paroxysm in a healthy man by injecting blood-serum taken from a malarial patient during the cold stage of the fever, and previously filtered through a Pasteur-Chamberland filter. Casagrandi and De Blasi have also described a hæmolytic toxin, concerning which more will be said when malaria is discussed.

Laveran and Mesnil have shown that *Sarcocystis tenella* produces a toxin, sarcocystin, of which 0·1 milligramme will kill 1 kilogramme of rabbit with choleraic symptoms, while a less dose will produce fatal cachexia. It is, however, less toxic to other animals.

CŒLENTERATA.

The Cœlenterata include anemones, corals, and jelly-fishes, which are capable of stinging by means of certain special cells called cnidoblasts, which enclose nematocysts—*i.e.*, little sacs—the invaginated neck of which is continued into a long, hollow, spirally coiled filament, surrounded with poisonous fluid. When stimulated, these cysts explode, and the filament is ejected and pierces the skin of the animal attacked, and so introduces the poison.

Zoantharia.- Stings from anemones cause itching and burning and skin eruptions. In its worst form this is exhibited in *la maladie des plongeurs* (*pêcheurs d'éponges*) of the Mediterranean. According to Dr. Skévos Zervos, the first symptoms are itching and intense burning in the place where contact with the anemone has taken place. A papule then appears, surrounded by an area which at first is red, but may become blue and finally black, and may spread over the surrounding skin to a distance proportional to the virulence of the poisoning. The skin sloughs, and leaves a suppurating ulcer. Dr. Zervos has produced the symptoms of this disease in a dog by rubbing an actinia, held in forceps, along its abdomen.

C. Richet has separated two poisonous principles from *Anemone sulcatus*, viz., thalassin and congestine. Thalassin is not very toxic, producing cutaneous redness, intense congestion of mucous membranes, pruritus, and sneezing. Congestine is much more virulent than thalassin, for a dose of 2 milligrammes per kilogramme will kill a dog in twenty-four hours. Thalassin is, however, antagonistic to congestine, for a dog inoculated with the former will resist an otherwise mortal dose of the latter.

The application of fat to the skin is said to be a preventative to the venomous action of the anemone.

Millepora. Jones has described an acute erythema, with severe pain, followed by papules, pustules, and desquamation, as the result of stings by the hydroids of the hydrocoralline millepores (*Millepora alcicornis*, *M. complanata*, and *M. verrucosa*) in Malaya, where the corals are known as ' Karang gatal,' or itchy corals.

Trachymedusæ. The jelly-fishes of European waters, such as *Rhizostoma pulmo* of the Mediterranean and *R. cuvieri* of the English Channel, are well known to cause local redness, swelling, and urticarial eruptions.

The jelly-fishes of the tropics produce the same symptoms, but with greater severity. The pain is agonizing, and there is collapse, with local swelling and redness.

The treatment is to give stimulants internally, and to apply alkalis, such as dilute ammonia, to the affected area. Usually recovery is quick, and there are no after-effects.

Meyer describes a case of poisoning due to the well-known *Physalia pelagica* (the Portuguese man-of-war), in which there was severe inflammation and fever. A similar case caused by *Cyanea capillata* has been recorded by Forbes.

Porter and Richet obtained a liquid from Physalia containing an active principle, hypnotoxin, which, when injected into animals, caused somnolence and finally death, due to cessation of respiration.

ECHINODERMATA.

The Echinodermata possess poison glands which supply a venom to certain modified spines, but this only affects small animals.

The Cuvierian organs of certain Polynesian species of the holothurians (allied to *Holothuria argus*) are said to cause inflammation of the skin, and, if any of the secretion gets into the eye, even blindness.

The spines of the common sea urchin of the Red Sea are poisonous, causing painful wounds, which require a long time to heal.

PLATYHELMIA.

Dibothriocephalus latus, which causes a profound anaemia, is suspected to secrete some form of poison, and, indeed, this theory is supported by certain experiments of Schaumann and Tallquist. These investigators found that if the worms were subjected to tryptic digestion, and then mixed with food and given to dogs by the mouth, or extracted with normal salt solution and injected hypodermically, an exhaustion which ended in death was sometimes produced. In one case there was a great reduction of the red blood-corpuscles. Rabbits, however, were not affected.

Tænia saginata has been investigated by Messineo and Calamida, who consider that they have found evidence of the presence of a poison which can be obtained by pulverizing the tænia with sand and extracting with normal saline solution This extract was then filtered and injected into animals, but the symptoms were not characteristic. Picou and Ramond consider that the extracts they obtained showed a decided bactericidal action.

On the other hand, the rupture of an echinococcus cyst is well known to produce symptoms of poisoning, but the chemical nature of the poison is not known. The symptoms in man are urticaria, if the dose is small; peritonitis and severe cardiac symptoms, leading to fatal collapse, if the dose is large. Injected into animals, the liquid acts as a cardiac poison causing death by stoppage of the heart in diastole, together with various other symptoms, such as a fall of the blood-pressure and temperature.

NEMATHELMINTHES.

Ascarides produce a volatile body with a peculiar and disagreeable odour, very irritating to the mucous membranes, especially to the conjunctiva. This odour is most noticeable in making post mortems upon persons suffering severely from these worms. Arthus and Chanson have injected rabbits with the liquid squeezed out of living human ascarides, and produced collapse and death within ten minutes of a dose of 2 c.c.

Cattaneo obtained a substance toxic to guinea-pigs by allowing ascarides to live in sterile broth. Cao, Jammes, Mandoul, and Boycott, however, failed to obtain any evidence of the toxicity of ascarides.

With regard to *Ancylostoma duodenale*, there has been much discussion as to whether it produces a toxin or not. The experiments of Whipple and Preti seem to establish the presence of a hæmolytic principle in the alimentary canal of the worm, and those of Loeb and Smith of a principle inhibiting the coagulation of the blood and secreted by the cephalic glands, but these substances appear to be of importance to the worm for the purposes of digestion, and not to be of sufficient strength to act upon the host. According to Alessandrini, however, the cephalic glands secrete a true toxin. The evidence which has been gathered together points also to the possibility of the toxicity of the ankylostomes being partly due to the absorption of bacteria or their products into the circulation of the host through lesions in the intestinal mucosæ caused by the bites of the worms.

ARTHROPODA.

The Phylum Arthropoda includes a number of types, which are characterized by their capability of stinging. The forms which we are about to describe occur in Class III., Arachnida, Class V., Chilopoda, and Class VI. Hexapoda, of the classification given in Chapter XXVIII.

CLASS III. THE ARACHNIDA.

As the definition and classification of this class is given in Chapter XXVIII., we have only to consider the recognition of the three orders with which we are concerned here.—

I. Abdomen segmented—
    Tail stout and armed at the end with a sting. (Scorpionidea.)
II. Abdomen unsegmented—
    (*a*) Abdomen connected with the cephalothorax by a short narrow stalk. (Aranea.)
    (*b*) Abdomen fused with the cephalothorax. (Acarina.)

1. Scorpionidea.

Scorpions abound in the tropics, where they grow to a large size, and are much feared because of the poisonous properties of their sting. The method of striking is to bring the tail forward over the body of the scorpion, so that the curved spine on the last segment (telson) of the tail penetrates into the skin and inflicts the wound. On either side of this curved barb is an opening through which the duct from a poison gland discharges the venom.

It is probable that the poison of different kinds of scorpions differ qualitatively and quantitatively, but on this subject little is known. Certainly the sting of the small European scorpion (*Euscorpius europæus*) has but slight action, causing only local pain, redness, and swelling, while the larger one of South Europe (*Buthus occitanus*) causes severe pain and phlegmonous swelling of the whole extremity, and such remote symptoms as vomiting, faintness, tremors, and cramps in muscles, while the larger tropical species kill not merely children, but even adults. According to Cararoz, as many as 200 persons die annually from scorpion-sting in the neighbourhood of Durango in Mexico. In Africa scorpion-stings are of frequent occurrence, but death is rare.

Historical.—Maupertuis in 1731 and Redi in 1779 appear to have been the first to study the effects of scorpion-venom by experiments, though the ancients were well acquainted with the sting and its effects, and had woven wonderful legends as to the origin of these animals. Redi experimented upon a pigeon and a dog, but the real study of the venom began with Guyon 1864, Paul Bert 1865, Delange 1866, and Valentin in 1876, and was followed up by Joyeaux-Laffine in 1883 and many others. A full literature is given in Faust's 'Die Tierischen Gifte.'

Classification.—This is unsettled, but Pocock gives the following:—

I. Pentagonal cephalothoracic sternum—
  (*a*) Single pedal spur. (Pandinoidæ Thorell, 1876.)
  (*b*) Two pedal spurs. (Vejovidæ Thorell, 1876.)

II. Triangular cephalothoracic sternum—
  With two pedal spurs, of which the anterior is bifurcated. (Buthidæ Simon, 1879.)

III. Short, wide, antero-posteriorly compressed cephalothoracic sternum—
  Two pedal spurs. (Bothriuridæ Simon, 1880.)

Geographical.—Scorpions occur all over the world, but the largest and most dreaded are found in the tropics. They live under stones, under the bark of trees, in sand, and also in houses, which they leave at dusk. Some of the best known are:—

1. *Euscorpius carpathicus* Linnaeus, Vejovidæ (3 to 3·5 centimetres long): Italy, Tyrol, South France.

2. *Buthus occitanus* Amoreux, Buthidæ (8·5 centimetres long): Italy, Greece, Spain, North Africa.

3. *Buthus afer* Linnaeus, 1764 (16 centimetres long): Africa, Asia.

4. *Buthus quinquestriatus* Hemprich and Ehrenberg, 1828: Upper Egypt and the Sudan.

5. *Scorpio maurus* Linnæus, 1758 Egypt, Tunis.

6 *Prionurus citrinus* Hye, 1828. Desert near Cairo and Alexandria.

7. *Prionurus amoureuxi* Savigny: Sudan.

8. *Androctonus funestus* Hemprich and Ehrenberg, 1828 (9 centimetres long): North and Middle Africa.

9. *Heterometrus indus* Geer. 1778: Ceylon.

Anatomical.—The body of the scorpion is divided into a cephalothorax or prosoma, behind which comes an abdomen subdivisible into a broader portion, or mesosoma, and a narrower, metasoma, with five segments, which is popularly called the tail. At the end of this metasoma there is a postanal curved spine, called the telson, inside which lies the paired poison gland. The appendages of the scorpion are: 1. Small three-jointed chelicerae, which are used for holding prey. 2. Large six-jointed pedipalpi, which are used for seizing prey. 3-6. Four pairs of seven-jointed walking legs.

Scorpions seize their prey with the pedipalpi, hold them close to the mouth by means of the chelicerae, and sting them, if necessary, by bringing the metasoma forwards over the mesosoma and cephalothorax, and inserting the tip of the telson well into the animal's body, and allowing it to remain there until the poison has had time to act. The telson consists of two portions—a broad swollen part (the ampulla) and a narrow portion (the spine), near the extremity of which are two small openings for the escape of the venom. The two poison glands lie inside the ampulla, one on each side of the middle line. Each gland is covered with a sheet of muscle on its mesial and dorsal aspects. This muscle, which is called by Wilson 'the compressor,' is inserted by its edge mesially along the ventral inner surface of the wall of the telson, and by a broader insertion laterally. The compressor muscle squeezes the poison out of the gland, along the duct, and through the opening in the spine into the victim. The epithelium of the gland shows three distinct types of cells: the mucous cell, the fine oxyphile granular cell, and the cell with very large granules.

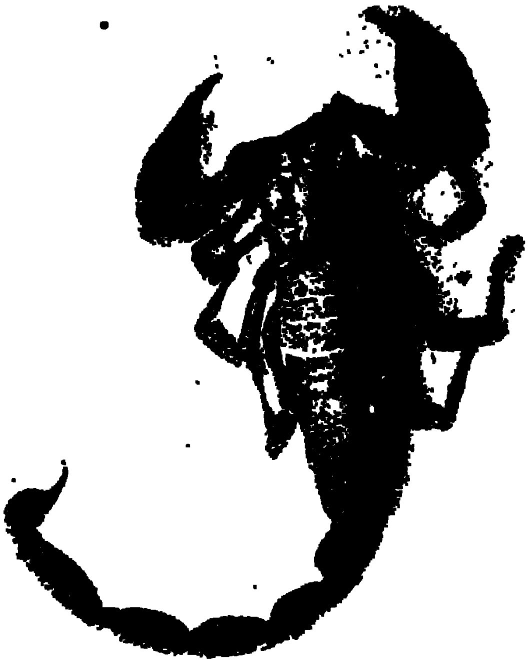

FIG. 17.—*Heterometrus indus* (B

(A scorpion commonly found in Ceylon.)

The Venom.—Scorpion-venom is a clear, faintly acid fluid of a somewhat thick or oily consistence, and possessed of an extremely faint yellowish colour. It contains no structural elements, but crystals form in it if evaporation takes place. On an average it contains about 28 per cent. of solids.

Wilson gives the following figures for the venom of *Buthus quinquestriatus*:—

Specific gravity	1·092
Solids	20·3 per cent.
Ash	8·4 "

Proteids form part of the solids, and it is believed that the active principle is either a nucleo-proteid, acid albumin, or a primary proteose. The effects described by various authors would, however, indicate the presence of toxins, one resembling the neurotoxin of snake-venom, and another a hæmolysin, for Kyes has described a typical lecithide producing hæmolysis like the lecithides of cobra-venom. Calmette has also shown that the venom of *Buthus occitanus* is neutralized by cobra antivenene. There would, therefore, appear to be some resemblance between scorpion-venom (or, at all events, the venom of *Buthus occitanus*) and cobra-venom. It is, however, impossible to make any definite statements, as the condition of our knowledge with regard to this poison is most unsatisfactory.

Iwano says that the poison is a protein, of which there are two kinds, one soluble in water and the other in dilute acids, and from these crystalline bodies can be prepared. Lecithin and cholesterin are also present in the venoms, which can be destroyed by pepsin and trypsin, permanganate of potash, and calcium hypochlorite. It seems to be very like snake-venom, and it is time that researches on modern lines were made.

Joyeux-Laffine thought that the venom first increased reflex action, and then caused paralysis of the nervous system, and that death was due to a curari-like poisoning of the end-plates of the respiratory muscles; but Valentin found these were quite intact, and that the muscles contracted well when their nerves were stimulated by electrical or mechanical stimuli.

As regards the action on the blood, coagulation, hæmorrhage due to change in the capillary walls, and hæmolysis have been observed, as well as agglutination of the red corpuscles, which are said to form viscous masses, and thus to block the bloodvessels by embolism.

These observations were made by Jousset de Bellesme on *Lilla viridis*, a frog remarkable for its lack of pigment, and therefore specially suitable for such a purpose. If confirmed, they would show the presence of fibrin ferment, hæmorrhagins, hæmolysins, and agglutinins in scorpion-venom, and would make it resemble very closely snake-venoms. Sanarelli, however, was not able to observe any change in the red cells beyond hæmolysis, which he saw in the blood of fishes, amphibia, and birds.

In conclusion, we may therefore assume the presence of a neurotoxin acting on the central nervous system, and the presence of hæmolysins, until further experiments give us more exact information.

Minimum Lethal Dose.—The minimum lethal doses for dry *Buthus afer* venom is, according to Calmette, 0·05 milligramme for white mice, and 0·5 milligramme for rabbits.

That the venom must be very toxic for small animals is shown by the fact that the minimum lethal dose for a guinea-pig is 0·1 milligramme per kilogramme, which gives a toxic value of 10,000,000 for *Buthus quinquestriatus*; but, as may be imagined, the toxicity of different venoms varies considerably, and the difference may be not merely quantitative, but qualitative.

Effects of the Venom.—It must be remembered that the venom is not merely a means of defence for the scorpion, but it is also the method by which it kills its prey, which usually consists of small animals; and, further, that, in order to be toxic, the venom must be injected subcutaneously or intravenously, for by the mouth it is harmless.

When experiments are performed on animals, the following symptoms appear:

1. Local irritation and pain.
2. Muscular twitchings, chiefly of the head and neck.
3. Jumping movements.
4. Lachrymation.
5. Increased orbital, nasal, and salivary secretions.
6. Muscular spasms, especially of the hind-limbs, but also in all muscles.
7. Erection of the hairs.
8. Passage of liquid faeces (often absent).
9. Erection of penis and emission of semen.

The venom of *Scorpio maurus* causes death in small birds within two minutes to half an hour from failure of the respiration. If the venom of a scorpion is placed on the conjunctiva of a rabbit, violent ophthalmia results.

In man, the symptoms depend upon the size and nature of the scorpion. Thus, the sting of the small (3½ centimetres) *Euscorpius europæus* causes only pain, redness, and local swelling, whereas the larger tropical scorpions cause very intense pain of a burning character radiating from the skin, associated often with violent convulsions, mental disturbance, and hallucinations, profuse perspiration, and secretion of saliva, and perhaps vomiting. The pulse is weak and quick, and the respirations hurried and shallow. These symptoms gradually diminish in three to eight hours, and by about nineteen to twenty-four hours the person is usually normal. This, however, is not always so, for death may ensue due to collapse or stoppage of the respiration, effects which are more likely to happen in small children than in adults. Thus, Wilson states that the mortality in children under five is 60 per cent. for *Buthus quinquestriatus*, but the mortality diminishes as the age increases. Of course this is simply due to the greater dilution of the poison in the body of the adult.

In addition to the above symptoms, some authors have described trismus, but it is probably due to infection with the bacillus of tetanus. The erection of the penis noted in experiments on animals has been seen in man by Delange and Guyon in Algeria. A paralysis of the lingual and hypoglossal nerves has been noted by Posada-Arango. Lymphangitis and adenitis are described as part of the local effect of the sting.

The above symptoms would indicate the action of a neurotoxin acting upon the nervous system, and causing first of all increased reflex action and convulsions, and later paralysis of the medullary nuclei; for if Valentin's observations are correct, there are no paralyses of the motor nerve-endings.

Effect on the Scorpion.—At the present time it is not believed that a scorpion commits suicide when in difficulties by stinging itself in the head with its own sting, because, though not absolutely immune to its own venom, it possesses a high degree of immunity against it. Accidental but not intentional wounding of an individual by its own sting is said to be known.

Immunity.—A natural immunity exists in the jerboa (*Jaculus jaculus* L.) and in the desert rat (*Gerbillus pyramidum* Geoffr.), and a partial immunity in the zerilla (*Ictonyx libyca* Ehrenberg).

According to Balfour, fakirs at times possess an acquired immunity, but this has not so far been obtained in any animal. Calmette has reported that the serum of a horse immunized against cobra-venom can neutralize the venom of *Buthus occitanus*—a fact which Metchnikoff has confirmed; but Nicolle and Catouillard have found this serum useless against the venom of the Tunis scorpion (*Scorpio maurus*).

Diagnosis. The history of the case and the single puncture on the affected part makes the diagnosis generally easy.

Prognosis. [illegible] is st[illegible]g, the prognosis is good, as death is known to be rare, but not so in children. The prognosis, therefore, varies with the age, and can be judged by the following table from Bray, quoted by Wilson, which gives the deaths at Omdurman in 1902 as follows:—

Under one year	5
One to five years	9
Five to fifteen years	7
Total	21

Deaths of adults, however, are known, but generally take place in a few days, not quickly.

Treatment.—In the treatment, the first thing to do is to give a full dose of the serum, and then to apply a proximal ligature and to treat the wound with permanganate of potash, as described under the heading of Snake-Bite.

Washing and bathing with a weak solution of ammonia may also be tried, and stimulants should be given.

Colonel Duke recommends that 5 to 10 minims of a 5 per cent. solution of cocaine be injected subcutaneously close to the sting in an adult, and 1 to 5 minims in infants and children. Eucaine or stovaine might be preferable, and can be imported from any chemist in sterile capsules ready for hypodermic injection. Simpson recommends the local application of a paste of ipecacuanha.

2. Aranea.

The Aranea, or spiders, are found all over the world, but by far the largest are in the tropics, and their peculiarly repulsive appearance has given rise to numerous fables, both ancient and modern, with regard to their poisonous properties.

Historical.—The study of spider-stings may be said to be modern, and to begin with Blackwell in 1855, but it was Kobert in 1893 who gave the fundamental data concerning these poisons. He maintains that, in addition to the secretion of the poison gland, there is a toxalbumin which permeates every portion of the body of the animal, and in some species of animals is mixed with the venom. He considers that the secretion of the poison gland only gives rise to local symptoms, and that the general symptoms are due to this toxalbumin, and that it is because of this admixture in *Latrodectus* that the bite may cause severe symptoms and even death in human beings. The common European garden spider (*Epeira diadema*) only causes local irritation, because the toxalbumin, though present in the body, is not mixed with the poison of the poison gland. He also describes a hæmolytic action in both *Epeira* and *Latrodectus*.

Sachs has contributed a paper in which he carefully studies this hæmolysin, which he calls arachnolysin, and Wilson has recently written an excellent monograph on the spider-bites.

Classification.—Spiders are divided into two suborders as follows:

I. Spinning organs situate far anterior to the anus. Eleven tergal plates on the dorsal surface. (Mesothelæ.)

II. Spinning organs situate just in front of the anus. No tergal plates visible. (Opisthothelæ.)

The Opisthothelæ are the only forms which concern us, and they are divided into tribes as follows:—

A. Only anterior pair of spinning organs present. (Megalomorphæ.)

B. Two pairs of viramous spinning organs present. (Arachnomorphæ.)

The Megalomorphæ include

I. Without large maxillary process on the base of the palp—
    1. Feet furnished with apical tufts or pads of hair. (Aviculariidæ.)
    2. Feet not so furnished. (Ctenizidæ.)

II. With large maxillary process on the base of the palp. (Atypidæ.)

The bird-eating spiders 'Mygale' come under the Aviculariidæ.

The Arachnomorphæ include:—

The Epeiridæ with *Epeira diadema*, the Theridiidæ with *Latrodectus*, the Lycosidæ with the Tarantula spider.

Geographical.—All genera of spiders appear to be poisonous, but the most important are: *Latrodectus mactans*, Chili; *L. scelio*, the katipo of New Zealand; *Theraphosa avicularia* L., South America; *T. blondi* Latr.; *T. javanensis* Walck.; *Chiracanthium nutrix* Walck.; *Theridium tredecim guttatum* F., France and Italy;

T. ugubre Koch, Kara kist of Russia; *Segestria perfida* St.; *Chætopelina olivacea; Lycosa tarantula* L.; *L. singoriensis* Laxman; *Epeira diadema* Walck.

Anatomical.—The body of the spider is sharply divided into cephalothorax and abdomen. The pairs of appendages are six in number:—(1) The two-jointed cheliceræ; (2) the six-jointed leg-like pedipalpi; (3-6) the seven-jointed legs. The poison gland usually lies in the basal joint of the chelicera, ensheathed in connective tissue, inside which there are two spirally arranged layers of non-striped muscle surrounding a basement membrane which bears two to three layers of polyhedral cells, surrounding the lumen of the acinus. From the gland the duct runs forwards into the distal hook-shaped joint, upon the apex of which it opens.

The Venom.—The venom, which is useful to the spider, enabling it to kill the small animals upon which it lives, is an oily, translucent, lemon-yellow-coloured liquid, with an acid reaction and a hot, bitter taste. It has proteid reactions, and gives the xanthoproteic reaction. It is difficult to obtain it in any quantity. Wilson recommends triturating the gland with distilled water (0·5 c.c. being used for each gland), and then filtering, when an extract suitable for experimental purposes is obtained. These extracts are rendered harmless by heating to 90° C., and the active principles are said not to dialyze. The chemical peculiarities and the active principles of the venom are little known. Kobert, as has already been pointed out, considers that there are two poisons:—(1) A toxin secreted by the poison gland, and only causing local symptoms; (2) a toxalbumin distributed through the body (not originating from the poison gland), and causing general symptoms The first exists alone in *Lycosa tarantula, L. singoriensis.* The second largely predominates in *Latrodectus*.

Kobert and Sachs have found and studied a hæmolysin, arachnolysin, in the venom of several kinds of spiders, and Sachs has been able to immunize a guinea-pig against this toxin, and produce an active serum. Arachnolysin acts upon the red cells of man, rabbit, ox, mouse, and goose, but not on those of the horse, dog, sheep, and guinea-pig.

Spider-venom is also said to increase the coagulability of the blood. The venom of *Theridium lugubre* is believed to act injuriously on the isolated frog's heart, even when diluted to 1 in 100,000, but it is not known whether this is due to action directly upon the heart-muscle or upon the local nervous apparatus. The walls of the capillaries are also said to be damaged by spider-venom, and to allow an increased amount of transudation, and hence the hæmorrhages and œdema seen about the wound. It is asserted that the venom acts deleteriously upon the mucous membrane of the stomach and intestines, causing redness and swelling, and even hæmorrhages, which perhaps are due to some attempt at excretion of the poison by these organs. It is also thought that the venom acts upon the central nervous system, but whether the cramps and convulsions are really due to action of the poison upon the nerve cells, or merely to the altered blood conditions, has not been decided.

The reader is particularly asked to compare these actions on the nervous system (neurotoxin ?), on the mucosa of the stomach, on the capillary wall, on the blood and red cells, with the venoms of the scorpion and of the snakes, which they strongly resemble.

Acquired immunity can be produced in animals by injections of non-lethal quantities of venom.

Minimum Lethal Dose. The minimum lethal dose for cats is 0·20 to 0·35 milligramme of the dry venom per kilogramme of the body-weight. Dogs are less sensitive, and hedgehogs still less, while frogs require fifty times the quantity of poison which will affect warm-blooded animals.

Effects of the Venom. In general, the symptoms of spider-bite rather resemble those of the scorpion, and are divisible into (1) local, (2) general. Local inflammation is generally present, but may be absent, and severe pain is felt at the site of the wound. The general symptoms are those of collapse coming on gradually, with sometimes convulsions, or rarely a typhoidal condition ensues, which may remain for weeks. Many other symptoms may also be noted, such as nausea, rigors, cold sweats, dyspnœa, fever, delirium, paralysis, and coma terminating in death. Inflammation of the stomach and intestines, coagulation of the blood, and local hæmorrhages and œdema, are the principal features of a post-mortem examination. The symptoms of the bites of the different spiders will now be briefly described.

Bite of Latrodectus mactans.—The symptoms of this bite are local pain, which does not appear till some little time after the bite, but becomes agonizing, and may last for a couple of days. In addition, tetanoid symptoms may set in, but usually end in recovery in about ten days.

Bite of Latrodectus scelio. This is the katipo spider of New Zealand. The symptoms begin in about thirty minutes with the formation of a white vesicle surrounded by a red halo, and severe pain at the site of the bite. The general symptoms include, first, stiffness of the muscles about the mouth and jaw, so that it is difficult to open the mouth or to speak, and impossible to swallow. The pulse becomes very slow (12 to 14 to the minute), and there is extreme pallor of the face and body, with coldness of the extremities, which are quite flaccid. Respiration becomes slower and slower, and death may take place at this stage, or an illness lasting about six weeks, and somewhat resembling typhoid, may ensue, which may end either in death or recovery.

Bite of Theridium lugubre.—This bite is characterized by smarting pains, no redness or swelling, cold sweats, restlessness, dizziness, mental anxiety, depression, vomiting, cyanosis, convulsions, status typhosus, and, unless improvement sets in, death in three days.

Bite of Theraphosa avicularia.—The Theraphosæ come under the commoner heading of Mygale, and cause prolonged inflammation and extensive cicatrization. *Theraphosa javanensis* is reported to kill men.

Bite of Chætopelina olivacea. The local symptoms are great pain, redness, swelling, but whether a general effect (curari-like poisoning of the voluntary muscles and death from stoppage of respiration) takes place is very doubtful.

Bite of Lycosa tarantula.—The bite of this spider produces wheals surrounded by a red areola, but no general symptoms result, and tarantismus only exists in popular imagination. The tarantula dance was probably introduced as a cure, with the purpose of keeping the patient on the move, so that he should perspire, and thus get rid of the poison. The tradition of the Middle Ages was that the bite caused the dance frenzy, *Chorea saltatoria*, or tarantismus, which was supposed to lead to such violent exertion that death resulted unless the victim was soothed by music.

The Bite of Epeira diadema.—The bite of the common garden spider has been recently proved by Kobert and Sachs to be poisonous.

The Bite of a Bengal Spider.—Fink has recently described a herpetic eruption on the face of Bengalee children due to a spider bite; for this he recommends fumigating the face with the smoke evolved when lumps of mustard-oil cake, burned in a charcoal fire, are dropped into a basin of cold water.

Diagnosis.—Bee-stings, scorpion-bites, and ordinary skin bacterial infections must, of course, be distinguished from spider-bites, with which, without doubt, they have been often confounded. The local symptoms and the history ought to be some guide.

Prognosis.—This is generally good.

Treatment.—Prevent absorption by the proximal ligature, open the wound by an incision, and apply alkaline solutions—*e.g.*, weak solutions of ammonia or carbonate of potash, or equal parts of spirit of ammonia and water as a wet dressing. It appears to us that a strong permanganate of potash solution ought to be given a trial.

3. Acarina.

The Ixodoidea, or ticks, are well known to cause severe symptoms by their bites, apart from the introduction of any parasite such as a *Piroplasma* or *Spirochæta*.

The anatomy of these arthropods is given in detail in Chapter XXVIII., p. 689, to which reference should be made, but a few remarks are necessary concerning the act of biting, which has been studied by Nuttall.

The tick pierces the skin by means of the teeth on the digits of its chelicerae. The digit is capable of being extended by an internal muscle, and turned outward by an external muscle. These movements, occurring alternately, cause the teeth to cut the skin, and as the chelicerae work deeper and deeper, the hypostome is dragged into the wound, and by its recurved teeth keeps the tick in position. The palps but rarely enter the wound. During this act of biting it is believed that the salivary glands pour a considerable amount of secretion into the victim, but the nature of this fluid and its action requires further investigation. Nuttall, drawing attention to the immunity following bites, says that it is probable that this secretion is toxic in its action.

The Effects of the Venom.—With regard to the Argasidæ, *Argas persicus* Oken has an evil reputation in Persia, where its bite is said to cause severe pain, fever, lassitude, delirium, convulsions, and even at times death in new-comers, while natives are immune.

Bordier considers that these symptoms are due to the injection of a poison, but this would hardly appear to be likely, as Lounsbury found in his own case in South Africa that the bite caused only slight itching. If the symptoms are properly described in Persia, it would indicate that the tick introduced some parasite into the new-comer which caused a definite disease to which the native had acquired an immunity.

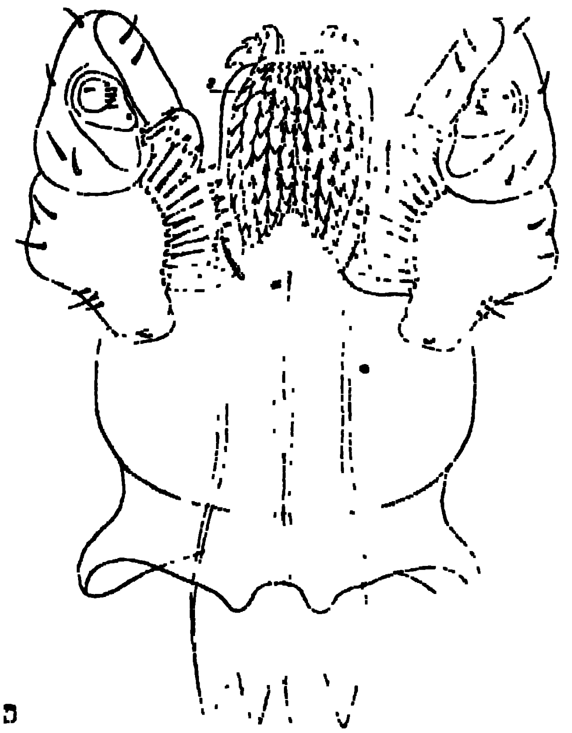

FIG. 18.—VENTRAL ASPECT OF THE MOUTH-PARTS OF A TICK (*Hæmaphysalis punctata* CANESTRINI AND FANZAGO).

(After Nuttall, Cooper, and Robinson, *Journal of Parasitology*.)

1, Chelceræ, showing teeth; 2, hypostome, showing rows of recurved teeth; 3, palp.

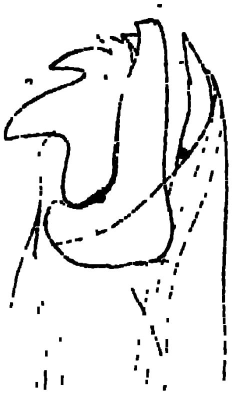

FIG. 19.—CHELICERA FROM THE SAME TICK.

(After Nuttall, Cooper, and Robinson, *Journal of Parasitology*.)

1, Internal digit; 2, external digit.

Argas reflexus Fabricius may cause local pain and swelling, with sometimes an erythematous eruption, while the site of the bite is marked for years by a cicatrix. The bite of *A. brumpti* Neumann is also severe.

Ornithodoros moubata Murray inflicts a very painful bite, with much swelling and the formation of raised hard wheals, in Europeans, which may last several days.

Ornithodoros turicata Dugès may cause swelling and numbness all over the body, with vomiting and diarrhœa, accompanied by an urticarial eruption and profuse perspiration, with rigors, fever, headache, and backache if the poisons enter a vein. Locally, an ulcer may form at the site of the bite. *O. talaje* Guérin Méneville causes severe itching and pain.

With regard to the Ixodidæ, *Ixodes ricinus* causes severe dermatitis, which may be followed by pustules and abscesses, with œdema, lymphangitis, and lymphadenitis, associated with fever.

Treatment.—The treatment of tick-bites is first to detach the tick, which is by no means easy, as the recurved teeth of the hypostome hold on to the wound very firmly. The best plan is to rub any oil into the ventral surface of the tick, thus interfering with its respiration, and compelling it to detach itself from the host. With regard to *O. turicata*, it is advised to apply the actual cautery, as the effects of the bite are so severe. According to Wellman, *Ornithodoros* bites should be treated by bathing in very hot water, after which bicarbonate of soda should be applied in strong solution. Itching may be allayed by a menthol ointment (1 to 2 per cent.).

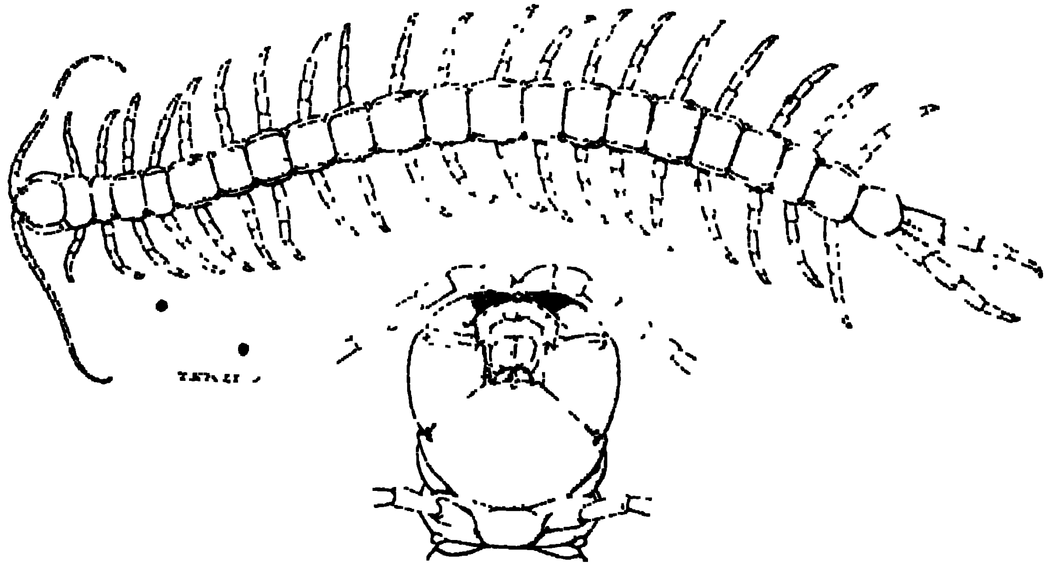

FIG. 20.—*Scolopendra morsitans* Linnæus.

As regards prophylaxis, badly infected native huts should be burnt, while ordinary houses may be fumigated with sulphur or carbon bisulphide, or sprayed with kerosene or boiling water. Beds must always be raised from the ground, and the feet of the bedstead placed in water containing kerosene, while pyrethrum powder may be dusted between the coverings of the bed. Wellman insists that natives should not be allowed to sleep in or near the quarters of Europeans.

2. CHILOPODA.

The class Chilopoda includes the Scolopendridæ, or centipedes, which are animals with a head and a uniformly segmented trunk, possessing numerous legs. They are very common all over the world, but the tropical species are much larger than those which inhabit the Temperate Zone. They live under stones in shady places, especially in woods. The poison apparatus of the centipedes is formed by the appendages of the first trunk segment being modified so as to form a large pair of jaws, at the base of which the poison gland lies. The duct of this gland opens on the apex of the claw, and therefore, as there are two jaws, a centipede-bite will show two minute punctures or drops of blood.

The venom is primarily intended to kill their prey, which consists of small insects and larva

Geographical. The most noted species are *Scolopendra cingulata*, France, Spain, Italy; *S. gigantea* Koch, *S morsitans* L., *S. heros*, Africa, India, Indo-China, Equatorial America; *Geophilus longicornis* Leach, Mid-Europe.

The Venom. The venom is an acid opalescent liquid, but little miscible with water For experimental purposes it can be obtained by treating the lower lip and the hooks with normal saline solution.

When injected into the veins of rabbits, it causes an immediate paralysis, with coagulation of the blood, while under the skin it forms a large abscess.

Effects of the Venom. The poison causes local and general symptoms. At first there is itching, but this is quickly followed by intense pain, which extends all over the limb A red spot appears at the site of the bite, which enlarges and becomes black in the centre, and sometimes there are lymphangitis and lymphadenitis The general symptoms are great mental anxiety, vomiting, irregular pulse, dizziness, and headache.

Diagnosis. The diagnosis is obtained by the history and the presence of the two minute punctures.

Prognosis. The prognosis is good, though small children have been known to die from the effects of a sting. Adults, as a rule, recover in about twenty-four hours at the most

Treatment. Bathe the part well with a solution of ammonia (1 in 5 or 1 in 10). After bathing, apply a dressing of the same alkali, or if there is much swelling and redness, an ice-bag.

If necessary, give hypodermic injections of morphia to relieve the pain. At a later period, fomentations may be required to reduce the local inflammation.

3. HEXAPODA.

The Hexapoda, or insects, contain many species injurious to man.

The orders to which the principal venomous species belong are: (1) Anopleura; (2) Hemiptera; (3) Hymenoptera; (4) Lepidoptera; (5) Diptera; and (6) Coleoptera.

1. Anopleura.

This order includes the lice, which cause much irritation by their bites. The nature of the venom, however, is not known, and the lice are of more importance as carriers of disease, and will therefore be dealt with more fully in Chapters XXX. (p. 749) and XXXV. (p. 872).

2. Hemiptera.

The Hemiptera (Chapter XXXI., p. 761) include the families of the Clinocoridæ, or bugs, and the Reduvidæ, or cone noses. In the latter family is classified *Phonergates bicoloripes* Stål, which, according to Wellman, produces a very painful bite in man in Angola. Another member of this family, as yet not named, has been described by King in the Sudan, where it bites human beings on the hands and wrists, producing small red lumps, which, however, soon disappear. It is said to be closely related to *Phonergates bicoloripes*.

BUGS.—These hemipterons secrete a strongly alkaline poisonous secretion in their salivary glands. This poison flows down the ducts of the stylets, and passing into the wound made by the bite, dilates the capillaries, causing an increase of blood in the area bitten. This, of course, is advantageous to the insect, allowing it to obtain a quantity of blood in a short space of time. Clinically the poison causes red blotches and local swellings.

It is, however, more convenient to discuss these venomous insects along with other parasites in Chapter XXXI., p. 761, as it enables a more systematic description to be given, especially as the nature of the venom is quite unknown.

3. Hymenoptera.

In this order come the bees, wasps, and ants.

APIDÆ.

The members of this family which sting are well known, and it is by no means infrequent to hear of animals and even at times human beings in the tropics suffering severely from bee-stings, and more rarely dying from the effects.

The species generally credited with evil effects are: *Apis mellifica* L., the hive-bee; *Vespa vulgaris* L., the wasp; *V. germania* Fabr.; *V. crabo* L., the hornet; *V. orientalis*, the hornet; *Bombus hortorum* L., the bumble-bee; *B. lapidarius* L., and *Xylocopa violacea*, the wood-bee.

Historical.—The venom of the bee was first studied by Brandt and Ratzeburg in 1833, then by Paul Bert in 1865 and Carlet in 1884, but the chemical nature was first investigated carefully by Josef Langer in 1897, and in 1904 Phisalix made experiments on sparrows.

Anatomical.—The body of the bee is divided into head, thorax, and abdomen, from the posterior end of the last of which projects the sting in the form of a chitinous sheath, narrow posteriorly and wider anteriorly. This sheath contains two barbed darts, and into its wider portion (which possesses a cleft by which air can penetrate into it) two or three ducts from glands open. The principal opening belongs to the duct of the 'acid gland,' and opens anteriorly into a sac—the poison reservoir—which leads into a long, slender, coiled tubular gland, either bifid anteriorly or subdivided into two glands. This long gland ramifies amongst the contents of the abdomen. The second opening, which lies alongside the first, belongs to a small, irregular, tubular gland called the alkaline gland, or gland of Dufour. The third opening, when present, leads into a lanceolate or ovoid accessory poisonous gland.

The Venom.- The venom freshly extruded from the bee's body weighs from 0·2 to 0·3 milligramme, and is a transparent acid fluid with a bitter taste, a peculiar aromatic smell, and a specific gravity of 1·1313. It contains about 30 per cent. of solid matter when dried at the room temperature.

The acid reaction is believed to be due to formic acid, and the smell to volatile substances, but neither of these have any connection with the poisonous properties of the venom.

The preparation of venom in quantity was carried out by Langer as follows: Several thousand fresh stings with their venom-sacs were placed in 96 per cent. alcohol, which was in due course filtered off, when the stings were dried at 40° C., then pulverized and extracted with water. The resulting extract, which, when filtered, was a clear yellowish-brown fluid, was then precipitated by 96 per cent. alcohol. The precipitate, after washing with alcohol and ether, was dissolved either in ordinary water or in the same acidulated slightly with acetic acid. From this solution Langer obtained an albumin-free active body after repeatedly precipitating with a few drops of concentrated ammonia and again dissolving as above. The active principle is, therefore, not albuminous, and is thought to be an organic base, the nature of which, however, is not known. This poison is destroyed or its activity lessened by oxidizing agents, such as potassium permanganate, and also by ferments, such as pepsin and rennin.

Subcutaneously injected, the venom produces great local irritation, but heating to 100° C. for fifteen minutes destroys this effect.

Intravenous injections into dogs produce convulsions, trismus, nystagmus, emprosthotonos, and death from respiratory failure. This action is believed by some authors to be due to a neurotoxin, but the blood after death is very fluid, and the red corpuscles are destroyed, indicating a marked hæmolysis, while all the organs except the spleen show hæmorrhages and hyperæmia; so that the effects may not be due so much to the action on the nervous system as to that on the blood. The convulsive effects can be destroyed by heating to 100° C. for thirty minutes, when the poison becomes merely narcotic. All effects are annulled by heating to 150° C. for fifteen minutes.

The venom, therefore, contains:

1. Inflammatory poisons, which are thought to come from the acid gland.
2. Neurotoxins:—
   (1) Convulsive, thought to be derived from the alkaline gland.
   (2) Narcotic, secreted by the acid gland.
3. Hæmolysins.

With regard to the last, Morgenroth and Carpi have shown that a lecithide is formed which is 200 to 500 times more hæmolytic than the venom alone. There is, therefore, a similarity between this poison and cobra-venom.

The only marked features recorded in human post-mortems are hyperæmia of the meninges and bloody exudation into the ventricles of the brain.

Immunity.—There appears to be no doubt that bee-keepers often attain a considerable amount of immunity against the venom.

Thus, Langer says: Out of 164 bee-keepers, 11 were immune from the first; while of the 153 at first sensitive, 126 became more or less immune, and 27 did not. Of the 126 more or less immune persons, 14 said that they were not affected even when several stings were inflicted quickly one after the other.

Bee immunity, however, is only passing, and does not last, and the keepers say that the first sting in the early part of the year may produce a strong effect.

Calmette has immunized a mouse, so that it could resist doses of the venom which would surely have been mortal otherwise.

The Effects of the Venom.—Usually the symptoms are merely local, and limited to pain in the part, redness, and swelling of the skin, and disappear in a few hours. Suppuration is rare, and blood-poisoning very rare, only taking place occasionally if the sting is on the eyes, ears, lips, or in feeble old people.

Slight fever may result in sensitive people, and sometimes general constitutional symptoms, such as nausea, faintness, great weakness, vomiting, precordial distress, difficulty in breathing, coldness of the extremities, with an eruption on the skin like measles, or with wheals. These symptoms may pass on to delirium, unconsciousness, and more rarely death.

Vespa orientalis causes semi-unconsciousness, the face becoming pale and cyanosed, the skin of the extremities cold with a clammy sweat; respiration becomes shallow and sighing; the pulse quick (130 to 140), irregular, and barely perceptible. On recovery from this state of shock, the patient complains of a sensation of tightness in the throat, and œdema may develop in the neck and face, as well as slight fever (100° to 102° F.), all symptoms disappearing in twenty-four hours.

The ordinary bee may at times cause severe symptoms, of which the following is an example: a lady was stung in the forehead, and in four minutes swelling of the eyelids and lips began, which rapidly spread to the arms, and was associated with acute abdominal pain. The hands became rigid in the position of *main en griffe*, and pain and stiffness was felt in the throat, together with difficulty in speaking. There was also vomiting and a sense of chilliness, followed by exhaustion. Recovery was rapid.

Diagnosis.—There is usually no difficulty in this, the history being clear.

Prognosis.—Usually the prognosis is very good; the only dangers are in children and old feeble persons, and in multiple stings.

Treatment.—The usual treatment is by applications of weak solutions of ammonia, which answers well. Carbolic acid (1 in 20 or 1 in 10) is satisfactory if applied immediately after the sting. Potassium permanganate may be tried.

Calmette advises a solution of calcium hypochlorate (1 in 60) or eau de Javel (1 in 100). When there is much swelling, apply iced compresses or an ice bag. When general symptoms develop, strychnine injections may be used.

FORMICIDÆ.

Ants may appear rather insignificant in the Temperate Zone, but in the tropics they are most active, and their bites are very painful.

Many ants—*e.g.*, *Myrmica* and *Ponera*—have a poison apparatus analogous to that of the bees, which has just been described.

The Venom.—The venom is well known to contain formic acid, but there must be more than this in the venoms of the tropical species, though nothing is known on the subject.

The Effects of the Venom.—The symptoms are usually only local—that is to say, pain, inflammation, and swelling at the site of the bite—but in the case of the large tropical ants general symptoms of faintness, shivering, and temporary paralysis may be produced. Indeed, dried red ants made into a paste have already been noted as an arrow-poison (Chapter XI., p. 180).

In Ceylon there is a species of very small ants which infest the beds and bite people while asleep, producing urticarial pomphi.

Treatment.—Apply weak solutions of ammonia, carbolic solution (1 in 20), or camphorated alcohol, to the part. As a preventive measure against the ants infecting beds, spread some powdered camphor in the beds and sheets.

4. Lepidoptera.

Caterpillars of many butterflies are well known to be venomous in the tropics, causing marked skin eruptions, and even a feeling of illness associated with a slight rise of temperature.

Wellman reports that in Angola the most common stinging caterpillar is that of the tiger-moth (Arctiidæ), called locally 'ochipia'—that which burns—which produces an angry eruption associated with much pain. Another belonging to the Limacodidæ, called 'Epuvi,' he describes as causing urticaria. A third, belonging to the Liparidæ, also causes severe local, and at times reflex nervous symptoms. We are acquainted with stinging caterpillars in Ceylon and the Gold Coast, but we have not determined the species. In the former, a bombyx larva living on the *Hibiscus* plant is apt to cause skin irritation. In India, the 'komlah' of the Terai is liable to cause intense irritation if it touches the skin. According to Brooke, the larvæ of *Neæra lepida* and *Adolia* are known to be venomous. Recently Bleyer has described caterpillars belonging to the Bombycidæ of Brazil which possess peculiar stinging organs, the venom from which produces locally urticaria and dermatitis, as well as general symptoms which are best treated by the local application of a 2 per cent. solution of menthol in æther, chloroform, and rectified spirits, and by the administration of a mixture containing liquor ammoniæ acetatis.

Porthesia Chrysorrhœa.—The caterpillar of this brown-tailed moth is reported from America (Massachusetts and New Hampshire) as causing a peculiar skin eruption, which Tyzzer says is caused by the penetration into the epidermis of peculiarly modified microscopic hairs called the nettling hairs, which are sharply pointed and barbed. These hairs are specially arranged for penetration, and possess an irritating substance which can be destroyed at 115° C. The other hairs are innocuous. The poison causes necrosis of the cells of the epidermis, together with the formation of small vesicles and inflammation of the corium

The **Symptoms,** which are generally those of an urticarial dermatitis, but occasionally erysipelatous-like, may be divided into two groups: (1) *severe,* due to contact with the caterpillar; (2) *mild,* due to hairs blown into the air and lodging in skin or under-garments. But it must be remembered that some people are very sensitive and others almost immune.

Treatment.—The best treatment is to clear away the hairs with a little alkaline lotion (bicarbonate of soda 2 per cent.), and then to apply an ointment of ichthyol (10 per cent.).

5. Diptera.

The classification of the Diptera is given in Chapter XXXII., p. 775, to which reference should be made.

Culicidæ. The irritation of mosquito bites is most noticed by the new-comer to the tropics, for as years go by a kind of partial immunity is acquired, and the bites are much less noticed. Some people appear to have a partial natural immunity to the bites, but this is uncommon.

Only the female mosquito bites and sucks blood, which is supposed to be required for the nutrition of the eggs. When the female mosquito alights upon the skin, it does not always bite at once, but may move from one part to another, apparently testing the different parts of the skin by its labellæ *

Having selected a given area of skin, it moves the palpi away from the proboscis dorsally, and at the same time rotates the labellæ on their hinge-joints outwards.

The labium is now pressed against the skin, and is bent into the form of a bow, convex posteriorly. An opening in the skin is then made, in which the mandibles and maxillæ work like saws, while the head of the mosquito can be seen rocking from side to side.

---

* For the anatomy of the proboscis see Chapter XXXII., p. 776.

During this process respiration is going on quietly, but at times, according to Schaudinn, a violent contraction of the abdomen is noticed, which is said to be due to the carbonic acid in the superficial layers of the skin, for he found that when carbon dioxide gas acted upon mosquitoes a like contraction was produced.

As this process is proceeding, an irritating substance, the chemical nature of which is not known, is injected under the skin, and it is evident that this happens before the mosquito begins to suck blood for the irritation is present when the insect ceases to bite before drawing up the blood.

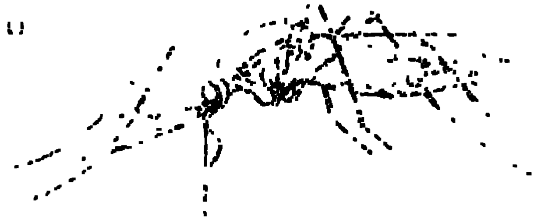

FIG. 21 AN ANOPHELINE MOSQUITO (*A. maculipennis* MEIGEN) IN THE ACT OF BITING.

(After Nuttall and Shipley, *Journal of Hygiene*.)

Note that the proboscis does not enter the wound and that it is bent convex posteriorly. Note the distension of the abdomen as seen by the space between the terga and the sterna. In the natural condition this space would be bright red from the blood in the abdomen.

There has been much dispute as to where this substance comes from, but this appears to have been settled by Schaudinn, who triturated the isolated salivary glands in salt solution, which he applied to a wound with negative result. On the other hand, when

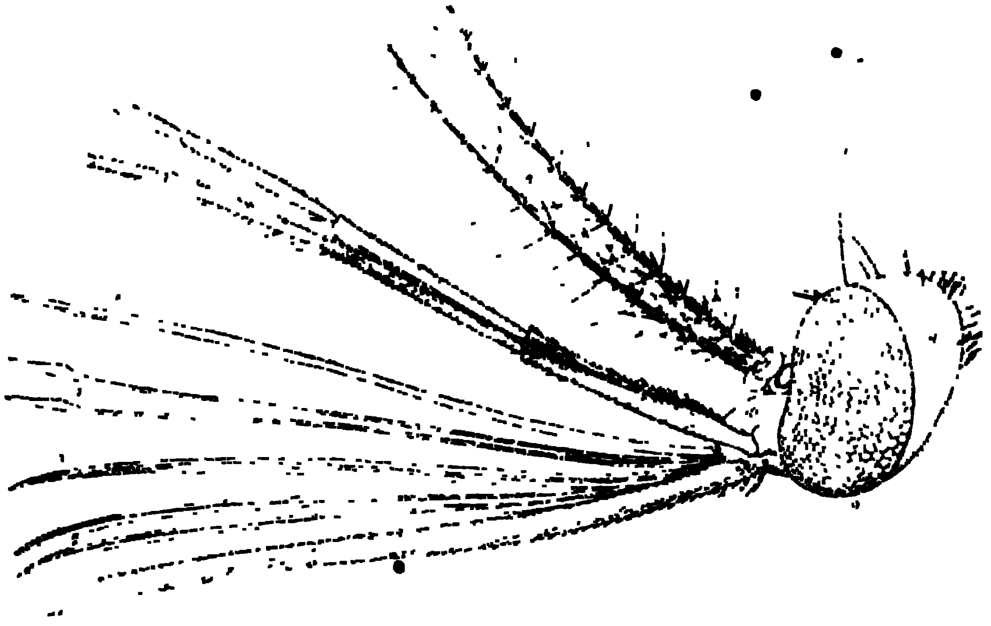

FIG. 22.—HEAD OF *Anopheles maculipennis* MEIGEN.

1, Labium; 2, maxillæ; 3, hypopharynx; 4, mandibles; 5, labrum; 6, palpi; 7, antennæ; 8, occiput; 9, eye; 10, clypeus.

he applied the isolated œsophageal diverticula to a scratch, he obtained the characteristic irritation and redness. These œsophageal diverticula contain gas-bubbles and bacteria or moulds. The bubbles were shown by Schaudinn to contain carbon dioxide by applying baryta-water to the diverticula, when a precipitate was obtained. The fungi need further investigation, but they or their products appear to be the real cause of the irritation, for when Schaudinn pressed the carbon dioxide out of the sac the signs characteristic of the bite were still produced. It appears probable, therefore, that the powerful abdominal contraction mentioned above expels the gas, bacteria, and fungi from the œsophageal diverticula and the saliva from the salivary glands

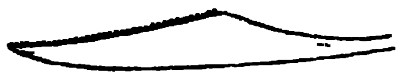

FIG. 23.—ANTERIOR END A MANDIBLE.

(After Nuttall and Shipley, *Journal of Hygiene.*)

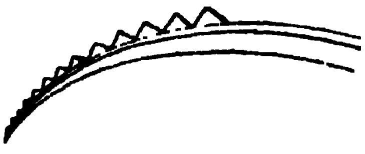

FIG. 24.—ANTERIOR END OF A MAXILLA.

(After Nuttall and Shipley, *Journal of Hygiene.*)

It is possible that the chemical products of the fungi, by causing local irritation, bring more blood into the particular area of skin affected, and thus enable the mosquito to get her supply quickly, for feeding only takes two to three minutes, during which time some mosquitoes will so overfill themselves with blood that it may be ejected *per anum*. The use of the carbonic acid is probably to prevent the coagulation of the blood, which is drawn up the large blood-tube formed by the labrum epipharynx and hypopharynx by the suctorial action of the pump-like pharynx.

(After Nuttall and Shipley, *Journal of Hygiene.*)

1, Mouth and buccal cavity; 2, pharynx; 3, œsophagus; 4, dorsal and ventral œsophageal diverticula; 5, proventriculus; 6, salivary glands; 7, narrow portion of ventriculus; 8, so-called stomach; 9, malpighian tubules; 10, intestine; 11, rectum; 12, anus.

Symptoms.—Shortly after a mosquito has bitten a person, a sensation of itching is experienced in the affected part, which on examination is seen to be inflamed and reddish, while a wheal not unusually develops, especially in persons new to the tropics. Sometimes a papule or even a nodule may form on the site of the bite, while more rarely scratching leads to secondary infection and the formation of boils, lymphangitis, or lymphadenitis.

Treatment.—The itching may be relieved by dilute solutions of ammonia (Scrubb's Ammonia is a favourite remedy), or by a 5 per cent. solution of carbolic acid, or 1 per cent. alcoholic lotion of menthol. Inflamed bites may be cleaned with 1 in 40 carbolic lotion, and afterwards dressed with boracic ointment. Local septic poisoning should be treated by boracic or carbolic fomentations, while boils and abscesses must be opened.

Prophylaxis.—The prevention of mosquito bites will be discussed in the chapter on Malaria (Chapter XI.).

Other Diptera.—Numerous flies other than the Culicidæ cause irritation by their bites, such as fleas, but the nature of the venom not being well known, they will be considered together in Chapters XXXII., p. 771, XXXIII., p. 814, and XXXIV., p. 857.

In Cape Colony there is a superstition that the 'bee moth'—*i.e.*, death's-head moth, *Acherontia atropos* Linnaeus—is poisonous. This is not so.

6. Coleoptera.

Beetles and their larvæ are capable of inflicting severe bites or wounds by means of stiff hairs. *Silvanus surinamensis* L., the saw toothed grain beetle, is said to bite people. Wellman describes the larva of a beetle, which the natives of Angola call 'ochisia,' which means 'to be left alone,' whose bristles will even penetrate the skin of the sole of the foot, causing pain, inflammation, and even sloughing, when trodden upon

BLISTER BEETLES.—Chalmers and King in 1917 have drawn attention to the beetles *Epicauta sapphirina* Macklin, 1845, and *Epicauta tomentosa* Macklin, 1845, as the cause of 'seasonal vesicular dermatitis' in Khartoum, while P. H. Ross had studied in 1916 the same complaint in Nairobi, where it was caused by *Pæderus cribipunctata* Epp (*sic*), and P. da Silva had traced in 1912 similar outbreaks in Brazil to *Pæderus columbinus* de Laporte, 1832; Eysell to *Pæderus peregrinus* Fabricius, 1801, in Malaysia, and Rodhain and Houssian to a species of the genus *Pæderus* Fabricius, 1775. Finally, Roubaud has stated that *Epicauta flavicornis* Dujardin, 1838, is the cause of the same complaint in Senegal.

The whole subject, however, belongs to Chapter XCVI., the Dermatozoiases, and is only mentioned here for the purposes of reference.

It will be noted that the various authors only mention two genera—viz., *Epicauta* Dejean, 1803, which belongs to the family *Cantharidæ* Leach, 1817, and *Pæderus* Fabricius, 1775, belonging to the family *Staphylinidæ*, which latter lack the appendage on the ventral aspect of the claws which is so characteristic of the former.

The life-history of these beetles is very complicated, and much of it is spent under the ground, hence the seasonal factor in the eruption caused by cantharidin, which is present in the fluid exuding from the insect, and especially from what may be termed the knee-joint, when irritated.

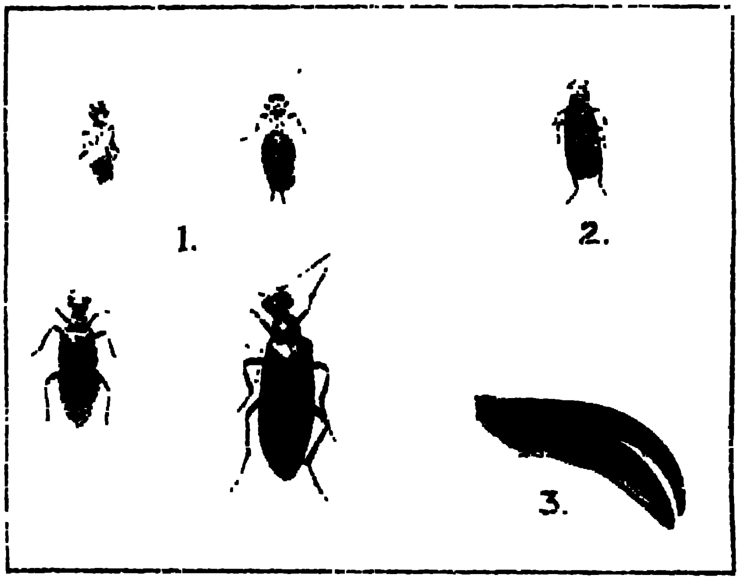

Fig. 26. Blister Beetles.

1, Upper and smaller *Epicauta tomentosa* Macklin, 1845, and the lower and larger *Epicauta sapphirina* Macklin, 1845; 2, *Mylabris nubica* de Marseul, 1857; 3 a claw of *E. sapphirina*, to show the long appendage which is usually closely applied to it.

MOLLUSCA.

A venomous snail of unknown genus and species is described in the Solomon Islands. These snails possess radulæ provided with pointed tubular teeth, armed anteriorly with a barb. These teeth are connected with a poison gland, and are capable of injuring men and producing severe wounds. Bites of the cones and augers (Terebridæ) are said to be poisonous.

CHAPTER XV

VENOMOUS ANIMALS (*continued*) PISCES AND AMPHIBIA

Pisces – Zoological classification – Geographical distribution – Poison by bite – Poison by stings – Amphibia – References.

PISCES.

ALL over the world, but especially in tropical seas, there are fish which for purposes of defence secrete poisonous fluids from special glands. These fish have been but little studied, and still less is known about the nature of their venom and its physiological action. A great deal, however, is known by residents in the tropics about wounds inflicted by these fish, and the doctor practising therein is bound sooner or later to come across not merely persons who know a good deal in a general way about the subject, but those who either are suffering or have suffered from the poisoning. It is therefore necessary that the tropical practitioner should have some knowledge of venomous fish.

The subject might be studied by classifying the fish zoologically, and then taking them seriatim and describing their poison and its effects; but though a zoological list will be given, this does not seem so satisfactory as to follow Bottard in his special classification based on the manner in which the fish inflicts the poison.

Venomous fish may be classified into:–

Class I. Fish which poison by their bite.
Class II. Fish which poison by barbs (spines) connected with special glands.
Class III. Fish which poison by a secretion prepared by the skin glands. This class is illustrated by the lamprey, which is only known to produce poisoning when eaten.

It will be understood from the above classification that venomous fish are to be distinguished from poisonous fish—*i.e.*, from fish which cause symptoms of poisoning when their flesh is eaten—for the flesh of venomous fish can be eaten with impunity. The poisonous fish and their effects have been briefly described in Chapter XIII., p. 193, under the heading Poisonous Food.

During the spawning season the quantity and the virulence of the poison of venomous fish generally increase, and, indeed, some genera—*e.g.*, Cottus—are only venomous at that time. Poisonous glands, being protective, occur more commonly in weak and small rather than in large fish, hence they are more frequent in bony than in cartilaginous fish, which latter are usually of large size. Venomous fish are often conspicuous by form or colour.

Historical.—The history of our knowledge of venomous fish has been well written by Faust, who points out that it was Aristotle, the Father of Ichthyology, who first established the fact that fish could produce poisoned wounds, and that after his day information on this subject appears to have been very uncertain, and doubts were cast upon the facts ascertained by him. Modern knowledge began in 1841 by Allman writing a paper on the stinging properties of the lesser weaver (*Trachinus vipera*), which, he said with all reservation, was probably due to a poison-gland at the base of the opercular valve. Further researches were made by Byerley in 1849, Günther from 1864 to 1881, Corre 1865-81, Gressin 1884, and Savtschenko, who produced his excellent atlas in 1886. It is, however, Bottard, in his thesis on 'Les Poissons Vénimeux' in 1889, who first gave a clear account of these fish, and he has been followed by Courtière in 1899, Briot in 1902-04, and Evans in 1907. The nature of the poison or poisons, and its or their physiological effects, still require considerable research.

Effects of the Poison.—As far as investigations have gone, it appears as though the venoms of the different fish only varied quantitatively, and not qualitatively. The effects are local and general. The local effects consist in painful sensations, swelling of the part, which may spread over the whole limb, suppuration, and even gangrene. The general symptoms appear to be due in the first instance to the action of the venom on the central nervous system, which shows itself in excitation, and later insensibility and paralysis. An action on cardiac muscle has also been recorded. In man death has been known to occur from wounds of *Synanceia brachio*.

Persons Chiefly Affected.—The persons chiefly affected by the venom are cooks and fishermen, but the latter are well aware of the danger.

Diagnosis.—Diagnosis is to be obtained by the history of the injury.

Prognosis.—This is usually good, but prompt treatment is needed.

Treatment.—The treatment of a poisonous wound due to a fish must be based upon the following principles:—

1. Prevent as far as possible the poison entering the general circulation.
2. Neutralize the poison as far as possible locally.
3. Treat the general symptoms.

1. *Prevent the Poison entering the General Circulation.*—The wound will usually be on an arm or a leg, and therefore it will be quite

easy to apply proximally a tight bandage with the same precautions as mentioned under Snake-Bite (see p. 274).

2. *Neutralize the Poison Locally.*—This should be done by opening the wound and letting it bleed while washing it with 1 per cent. solution of permanganate of potash, or by rubbing in crystals of the same substance, and then applying fomentations and aseptic dressings.

3. *General Treatment.*—The pain must be relieved by hypodermics of morphia, and nervous symptoms by bromides; syncopal attacks by stimulants and hypodermics of strychnine; failure of respiration by artificial respiration.

Zoological Classification.

The venomous fish may be classified as follows:—

- Subclass I. Elasmobranchii.
  - Order 3. Selachii.
    - Suborder 3. Raii.
      - Family Myliobatidæ.
        - Myliobatis aquila Linnæus.
          - Aetobatis narinari Euphrasen.
      - Family Trygonidæ.
        - Trygon pastinaca Cuvier and other species.

- Subclass V. Teleostei.
  - Grade A. Physostomi.
    - Suborder 2. Cyprini siluriformes (Ostariophysi).
      - Family Siluridæ.
        - Plotosus anguillaris Bloch, 1793.
        - Saccobranchus fossilis Bloch.
    - Suborder 4. Anguilliformes (Apodes).
      - Family Murænidæ.
        - Muræna helena Linnæus.
  - Grade B. Physoclisti.
    - Suborder 10. Acanthopterygii.

- Division 1. Perciformes.
  - Family Acanthuridæ.
    - Acanthurus luridus.

- Division 7. Trigliformes (Scleroparei).
  - Family Triglidæ.
    - Trigla hirundo Linnæus.
  - Family Scorpænidæ.
    - Synanceia brachio Cuvier and Valenciennes, 1826.
    - ,, verrucosa Schneider.
    - Scorpæna grandicornis Cuvier and Valenciennes, 1826.
    - ,, diabolus Cuvier and Valenciennes, 1826.
    - ,, porcus Linnæus.
    - Pterois antennata Bloch.
    - Pelor filamentosum Cuvier and Valenciennes, 1826.
  - Family Cottidæ.
    - Cottus scorpius Linnæus.

Division 8. Blenniformes.

Family Trachinidæ.
Trachinus draco Linnæus.
,, vipera Cuvier and Valenciennes, 1826.
,, radiatus Cuvier and Valenciennes, 1826.
,, araneus Riss.

Family Uranoscopidæ.
Uranoscopus scaber Linnæus.

Family Callionymidæ.
Callionymus lyra Linnæus.

Family Batrachidæ.
Batrachus tau.
,, grunniens Bloch.
Thalassophryne reticulata Gunther.
,, maculosa Günther.

Addendum.--Serranus outabili (Cuv. and Val.) and Holocanthus imperator (Bl.) are looked upon as possibly poisonous, but there is no definite evidence. The Siluridæ are believed to be poisonous, because some of them possess sac-like organs opening into the axillæ of the pectoral fins, on which there are powerful spines.

Geographical Distribution.

The geographical distribution of venomous fish is in temperate and tropical —

Teleostomi.

Plotosus anguillaris ..	Indian Ocean
Muræna helena	Mediterranean.
Acanthurus luridus ..	Tropical Atlantic
Trigla hirundo	English Channel.
Synancēia bracho .. .	Tropical Pacific
,, verrucosa ..	Indian Ocean.
Scorpæna grandicornis .	Waters of the Antilles.
,, diabolus	Indian Ocean and Tropical Pacific
,, porcus	Mediterranean.
Pterois antennata	Seas of the Indies and Equatorial Pacific.
Pelor filamentosum .	Waters of l'Isle-de France.
Cottus scorpius	Seas of Europe, Asia, and North America.
Trachinidæ.. .. .	Waters of Europe.
Uranoscopus scaber .	Mediterranean.
Callionymus lyra . .	Waters of France.
Batrachidæ..	Waters of Tropical America and India.

Leaving, however, the zoological classification, we will consider the venomous fish according to Bottard's classification, excluding Class III.

CLASS I.

FISH WHICH POISON BY THEIR BITE.

The type of this class is the genus *Muræna*, all of which possess powerful teeth capable of inflicting severe bites. According to Calmette, there are more than one hundred species in tropical and subtropical seas. *Muræna helena* L. is found in the Mediterranean, and *Muræna moringa* Cuv. in the tropical Atlantic.

The poison apparatus consists of a pouch lying above the covering of the palate lined with epithelial cells, secreting the venom. This pouch is capable in larger species of holding about ½ c.c. of poison, and possesses three or four strong conical teeth curved with an anterior convexity. These teeth are not grooved or channelled, but are easily moved and erected, and are enclosed in a sheath formed by the mucosa of the palate. The poison collects between the teeth, and simply flows down them into the wound.

The venom has not been studied, except so far as to show that it has some digestive action. The effect on man is not certainly known, but is supposed to lead to syncope.

Another fish, the bite of which is much dreaded, is *Tetrodon fluviatilis*, which is found in the waters of Indo-China, and frequently attacks the natives, especially children.

CLASS II.

Fish which Poison by Means of Stings associated with Poison Glands.

Bottard classifies the poison apparatus of this class into three groups:—

1. Apparatus entirely closed, and therefore before the poison can escape a membrane must be ruptured:

Synanceia brachio.
,, verrucosa.
Plotosus anguillaris.

Apparatus partially closed:

Thalassophryne reticulata.
,, maculosa.

3. Apparatus in more or less direct communication with the exterior:—

Trachinus vipera.
,, draco.
,, radiatus.
,, araneus.
Cottus scorpius.
,, bubalis.
,, gobio.
Callionymus lyra.
Scorpaena porcus.
,, scrofa.
Pterois antennata.
Pelor filamentosum.
Acanthurus luridus.
Uranoscopus scaber.
Trigla hirundo.

The poison glands are generally placed at the base of the dorsal or anal fins, or under spines on the operculum. The gland communicates with one or more rays of the fins. The barbs may be:—

1. Grooved, but having the groove converted into a canal by a membrane, which must be ruptured for the poison to escape.

2. Canalized by channels which lead to apertures near its tip.

This arrangement of the rays agrees with the types of poison apparatus mentioned above.

Section 1. Poison Apparatus Entirely Closed.

The apparatus is connected with the dorsal fin, and is passively defensive—that is to say, the fish cannot eject the poison unless the barb is broken.

EXAMPLES.—*Synanceia* (*brachio* and many other species); *Plotosus arab.*

Synanceia (*brachio and many other species*).—This fish, called 'rapau de mer' in Réunion, 'laffé' in Mauritius, 'ikan Satan' in Java, and 'nohu' in Tahiti, is distributed through the waters of the Indies, Cochin China, New Caledonia, and the Pacific Ocean.

Its poison apparatus is connected with the dorsal fin, which has thirteen barbs, each of which is supplied with two poison reservoirs, to which belong ten or twelve tubular glands. It cannot eject the poison itself, but if trodden upon by the naked foot, the barbs enter the skin, and the poison is pressed mechanically into the wound. The venom is limpid, bluish, and slightly acid. The symptoms are severe pain, spreading up the limb. The sufferer becomes violent, throwing himself from side to side, and even asking to have his foot cut off. Sometimes syncope and death may take place. In other cases abscesses and symptoms of blood-poisoning may be noted. The skin surrounding the wound becomes bluish, and may slough, in which case repair takes a very long time to be completed.

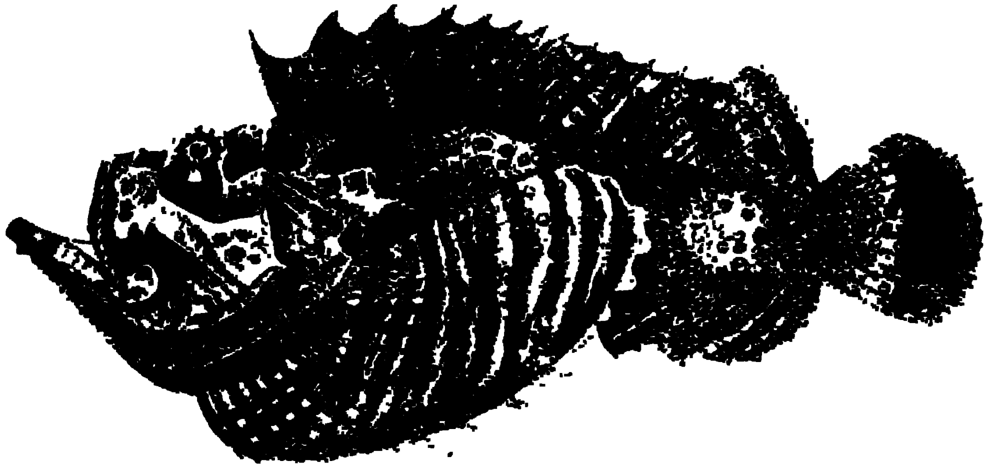

FIG. 27.—*Synanceia verrucosa* SCHNEIDER.
(From Savtschenko's 'Atlas of Poisonous Fish.')

Plotosus anguillaris.—This fish, called 'machoira' in Réunion and Mauritius, 'sanbilang' in Malay, 'koormat' in Abyssinia, is found in the waters of India, of the Seychelles, and other places mentioned above. The poison apparatus is connected with the dorsal fin, and the conditions which bring about the wound, together with the symptoms, resemble those of *Synanceia*.

Saccobranchus fossilis.—This fish is found in the waters of India and Ceylon, and wounds caused by its pectoral fins are much dreaded by the natives, as they produce severe inflammation and even tetanic symptoms.

Section 2.—Poison Apparatus Partially Closed.

The types of this section are *Thalassophryne reticulata* Günther, which is found near Panama, and *T. maculosa* Günther, which is chiefly found in the Gulf of Bahia (Brazil).

In these fish the poison apparatus is double, there being hollow barbs on the gill covers and on the back close behind the head. The barb on the gill cover, which is bent somewhat upwards, is conical in shape and pierced by a central canal, which is connected with a poison reservoir situated at the base of the barb. The cells lining this sac are probably those which secrete the poison. The venom, therefore, is capable of flowing along this canal without being forced by muscular exertion. The barbs on the dorsum of the fish consist of two spines pierced, as in the case of the opercular spine, by canals which communicate with poison reservoirs. When the barbs are erected, the poison flows out of the peripheral openings of the central canals, and thus can enter any wound caused by them. The nature of the venom and its physiological action are not known, but it is supposed that it will be like *Synanceia* and *Trachinus*, though there is no ground for this supposition.

The poison apparatus of *Batrachus tau* of the waters of North America and *B. grunniens* of those of the Antilles are said to be identical (Calmette) with that just described for *Thalassophryne*.

Section 3.- -Poison Apparatus in more or less Direct Communication with the Exterior.

This section contain [illegible] number of fish, [illegible]e best studied of which is *Trachinus draco*.

Trachinus draco.- This fish pos[illegible] two sets of poison apparatus, the one a barb on the oper[illegible], and the other connected with the dorsal fin. The barb on the operculum possesses a groove which is converted into a canal by a fine membrane, which leaves an opening near the point of the spine. This barb, which is slightly erectile, pierces the operculum. At its base lies the poison gland, partly covered by an adductor muscle, which helps to press the poison into the canal and to erect the spine. When the barb enters the flesh of another animal, the above mentioned membrane is stripped off and the poison enters the wound.

The dorsal apparatus consists of from five to seven spines joined together by a membrane, which is adherent almost to their tips. Each barb has a deep double channel, the two grooves of which join towards the base of the spine, and form a conical space, of which the walls are covered with cells which secrete the poison.

The first symptoms are very severe pain of a burning or lancinating character. The part then tingles and becomes painfully numb, and this may spread along the limb, and appears to travel along the nerves, though the joints are particularly tender. This is followed by palpitation, fever, delirium, vomiting, and syncope. The area affected becomes swollen and inflamed, and if neglected may suppurate or even turn to gangrene. The symptoms may last from two to three hours to several days.

The venom has been studied by Günther, Gressin, Bottard, Briot, and Phisalix. It has also been studied by Evans, who, after washing the fish, collected it by means of an aseptic hypodermic syringe, then dried it *in vacuo*, reduced it to a fine powder, and finally dissolved it in normal saline or in water. He collected the poison from about 2,000 fish. The venom is clear, transparent, and very slightly acid. Hypodermically injected, it causes mortification and local paresis, necrosis, and hæmorrhage. Intravenously injected, it causes failure of the heart and respiratory paralysis, associated with first a rise in the blood-pressure, which is followed later by a marked fall. It also appears to have a hæmolytic effect, which is supposed to be due to its amboceptors uniting with endocomplements (lecithin) in the red cell. It will thus be seen that the poison in some respects resembles snake-venom. The venom is lethal to fish, frogs, and mammals. Thus, 0·015 gramme of dried venom killed a frog, and 0·02 gramme a mouse.

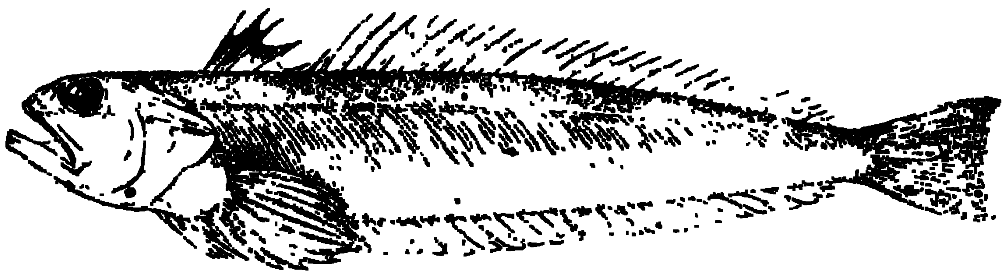

FIG. 28.—*Trachinus draco* LINNÆUS.

According to Briot, who has succeeded in immunizing rabbits, the venom contains a ferment capable of digesting proteid.

Trachinus radiatus.—Pohl has studied the poison of this fish, and finds that it stops the heart in diastole. The effect of applying the poison to the heart of the frog is to first produce strong contractions, which gradually become weaker and weaker, until they cease and the heart stands still in diastole. The poison has, however, no effect on skeletal muscle.

Cottus.—The genus *Cottus*, widespread in the Northern Hemisphere, possesses a poison apparatus which resembles that of the genus *Trachinus*, but is less developed, and consists of poison glands lying in culs-de-sac in the opercular spines. The cells of the gland only secrete the venom during the spawning season, from November to the end of January.

Callionymus.—In *Callionymus* the operculum terminates in three conical spines like a trident, and in addition possesses another spine directed upwards, and these are supplied in the spawning season with a small quantity of venom from the gill membrane, which, according to Bottard, has little effect on man.

Scorpæna scropha. In this fish the poison apparatus is said to exist not merely in the dorsal fin, but also in the operculum.

In the dorsal fin, the first three rays, which project about one-third of their length beyond the membrane of the fin, are grooved posteriorly by three channels, which are converted into canals by a fine membrane, and communicate with the poison gland.

On the operculum there are three small spines, of which the longest alone is connected with a poison gland.

When handled incautiously, a poisoned wound may result from one of these poison spines entering the skin. The action of the poison has been studied by Pohl, Brunton and Briot. Brunton describes the effects of the poison as being exactly the same as that of *Trachinus draco*, and Pohl thinks that the poison acts on the heart in the same manner as he describes for *Trachinus*.

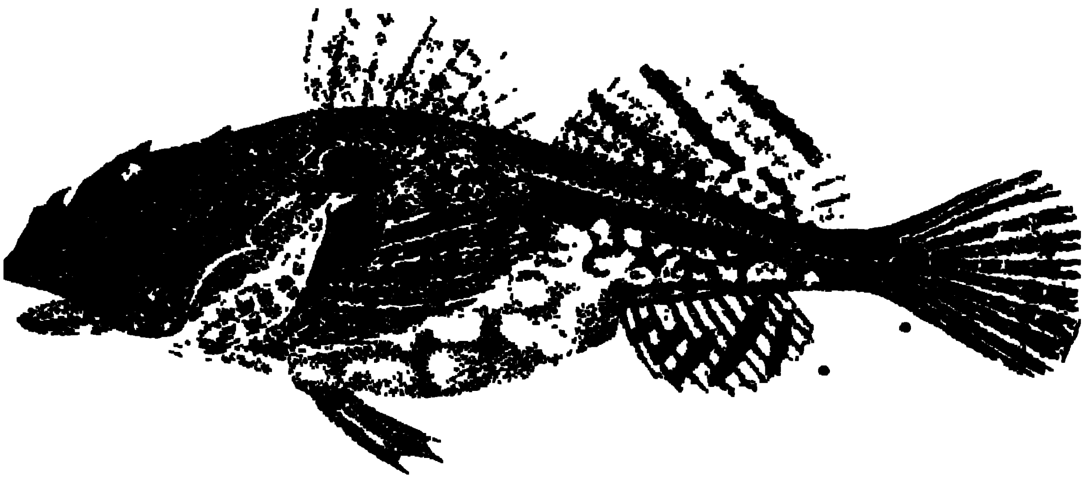

Fig. 29.—*Cottus scorpius* Linnæus.

(From Savtschenko's 'Atlas of Poisonous Fish.')

On the other hand, Briot thinks that it is quite different from *Trachinus*, and that the effects produced are by secondary infection of the mechanical wound caused by the spines. Brunton's description of the symptoms in man might possibly be due to *Trachinus* only, as he does not mention specifically whether it was *Trachinus* or *Scorpæna* which affected the person. His experiments on animals with both fish appear, however, to have caused the same symptoms. He pressed the spines of the poison organs against the hind-limb of a guinea-pig or a rat. In a few minutes the animal began to suffer pain and twitching in the injured limb, followed by tremors and convulsions (if disturbed), and later by death from collapse.

The description which he gives of the symptoms in human beings for either *Scorpæna* or *Trachinus* is given below, but reference to his original paper will, we think, convince the reader that he is really dealing with a *Trachinus* sting.

The symptoms of an attack may be described thus:—

A sharp prick is felt as the spine enters the skin, and this is followed in a few minutes by burning and itching, which shortly become stabbing pains, increasing in violence and passing up the limb. The sufferer now lies down and writhes and cries in agony, while sweat breaks out on his brow, and flashes of light pass in front of his eyes. He begins to feel a sensation of suffocation, and puts his hand to his throat and heart, while the pulse is felt to be intermittent. Presently he loses sight of the bystanders, and in a little becomes delirious, crying out and suffering from convulsions. This condition may lead to collapse and death, or, after lasting several hours, may gradually subside, but the convalescence is slow, and the patient may take several months to recover.

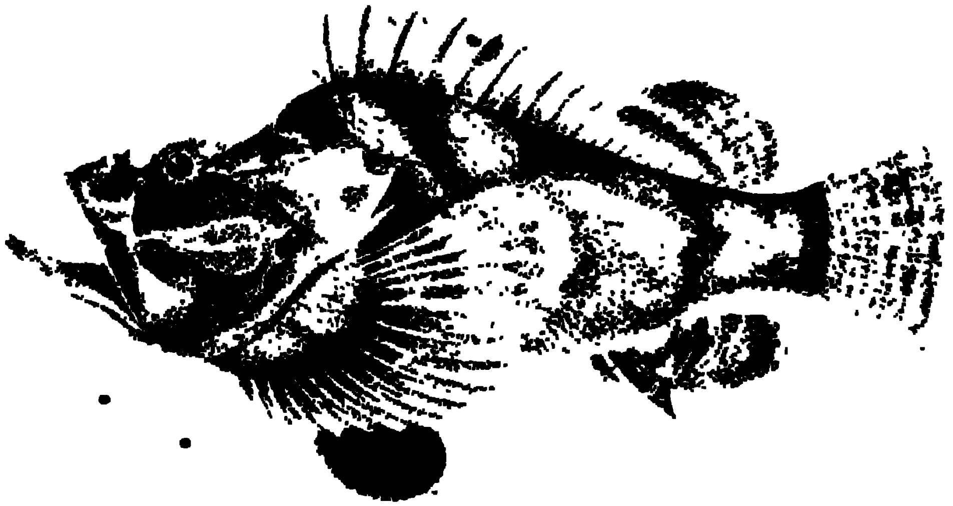

FIG. 30. *Scorpæna diabolus* CUVIER AND VALENCIENNES.
(From Savtschenko's 'Atlas of Poisonous Fish.')

The local conditions show at first merely the prick of the spine, but the aperture may be pigmented by the covering membrane already alluded to. The puncture does not bleed, but the skin around for about ½ inch is whiter than usual, and outside this redness appears, but soon all the surrounding skin is red, turning as time passes darker and darker, till it becomes black and œdematous. The prick now discharges fluid. In a day or so the affected area sloughs and separates, leaving a deep wound. Sometimes a spreading gangrene ensues, which necessitates amputation. In milder cases the part remains painful and swollen for about three days before recovery.

Pterois antennata.—The poison apparatus is connected with the dorsal fin, and is said to resemble that of the Scorpænidæ.

Pelor filamentosum.—In this fish the poison apparatus is connected with the dorsal fin, and resembles that of *Pterois* and *Scorpæna*. With regard to *Pelor japonicum* Cu. and Val., Scheube says that he knew of a case in which a sting on the thumb resulted in phlegmonous and gangrenous symptoms so severe that the arm had to be amputated.

Acanthurus luridus.—*Acanthurus luridus* possesses a poison apparatus connected with the dorsal and anal fins like that of *Scorpæna.*

Elasmobranchii.—Associated with the poisonous fish of the *Teleostei* must be placed those of the *Elasmobranchii*, of which the sting rays (Trygonidæ) and eagle rays (Myliobatidæ) alone produce toxic symptoms by blows with the tail, which carries a spine. These Rays are found all over the world, and we have received information as to their effects from persons who have been in British Guiana, in Australia, and in Ceylon, in which island stings are well known on the west coast, particularly about Dutch Bay.

Dr. Crevaux has studied Rays from the Orinoco, and has shown that their barbs are canalized and the canals connected with poison reservoirs. This poison is said to be so severe as to be able to kill a man in forty-eight hours. The symptoms of *Aëtobatis narinari*, called the Bishop ray, and of *Trygon pastinaca* (from Japan), are violent pain, a tendency to syncope, with locally a rapidly forming swelling, which soon becomes the seat of a violent inflammation and even at times gangrene. The symptoms of the sting, as observed by us in Ceylon, are local pain and swelling. The general symptoms are not severe. *Trygon sephen* and *T. walga* Müll. and Hen. are known in Indian waters.

A large number of these *Elasmobranchii* have not got special poison glands, and the venom must come from the ordinary skin glands.

Amphibia.

Toads and salamanders have been celebrated for ages as venomous animals, the poison being found in their parotid glands and skin. In toads Faust has shown that there are two poisons—(1) an acid, bufotalin, and (2) a neutral body, bufonin, the former being the more active. It is, as a rule, scarcely toxic to man, only irritating the mucous membranes, especially the conjunctiva; but to small animals it is toxic.

In salamanders Zalesky and Faust have found two bodies, one an inorganic base—salamandarin—and another an alkaloid—salamandaridin; but this poison and the digitalis-like poison of Bert and Dulartre in frogs are not of sufficient practical interest to concern us here.

According to Vulpian and Caparelli, *Triton cristatus* (Laur) gives a creamy secretion from the glands of the skin at times which is poisonous to many animals, but the chemical nature of which is not known.

CHAPTER XVI

VENOMOUS ANIMALS (*concluded*)—REPTILIA AND MAMMALIA

Reptilia: Ophidia—Historical—Classification—Geographical distribution—The act of striking—The venom—Entry of the venom into the body—Minimum lethal dose—Effects of the venom—Excretion of the poison—Immunity—Diagnosis—Prognosis—Treatment—Prophylaxis—Lacertilia. *Mammalia*. References.

REPTILIA.

THE Reptilia include two groups which are of interest to medical men in the tropics—viz., the Ophidia and the Lacertilia; but the former is infinitely more important, as it includes the venomous snakes.

OPHIDIA.

Definition.—*Reptilia* with limbs absent or vestigial; without movable eyelids, or ear openings, with retractile elongated forked tongue, transverse anus, paired copulatory organs, and elastic ligament in place of symphysis menti.

Remarks.—The bite of certain snakes causes ophidismus, or snake poisoning.

Historical.

The history of the study of snake bite, and their effects may be divided into three periods:

1. Period of ancient theories.
2. Period of one venom.
3. Period of more than one venom.

1. **Period of Ancient Theories.** The ancients were acquainted with a number of snakes, which they described under the terms *Echis* and *Colubra*, but it is not known definitely to what species these referred. *Echidna* was a term used to denote the female viper.

They were acquainted with the main symptoms of a snake-bite, and had many remedies, including the tying of a ligature around the part followed by cupping after scarification, and the administration of wine and theriac, the last mentioned being a celebrated remedy which, among other substances contained the burnt body of the viper. Celsus recommends the sucking of the wound, but only if there are no ulcers on the gums, palate, and other parts of the mouth.

2. **Period of One Venom.** In 1664 Redi studied the effects of viper-bites by experiments on animals, and Moise Charas, in 1669, noted the important fact that the blood of animals bitten by vipers was coagulated, and came to the conclusion that the symptoms and death were due to this coagulation.

In 1767 Abbé Felix Fontana made a number of observations on animals bitten by vipers, and in 1796 Russell published an account of his experiments on Indian snakes. In 1821 Davy gave an account of the effects on animals of the bites of three Ceylon snakes.

In 1843 Prince Lucien Bonaparte published his important discovery that the venom of the adder contained an active substance, which he called viperine, or echidnine, capable of being precipitated by alcohol

In 1845 Brainard showed that if an animal dies at once after the bite of a rattlesnake, the blood will be found to be clotted, but if it lives for some time it will be fluid.

In 1860 Weir Mitchell laid the foundations of modern investigations into snake-venom in his classical paper on the poison of *Crotalus durissus*.

In 1867 Sir Joseph Fayrer began his work on Indian snakes, which resulted in the publication of his magnificent atlas on the Thanatophidia of India in 1872, and several papers by himself and Sir Lauder Brunton in 1873-75.

About the same time Vincent Richards published some valuable remarks on snake poisons and their antidotes

In 1883 Wall wrote a most excellent little book on the colubrine and viperine snakes of India.

In 1886 appeared a most masterly paper by Weir Mitchell and Reichert, in which they state that the active principles are globulins and peptones (proteoses). These researches indicating a proteid nature for the venom were confirmed by Wolfenden and Kanthack, and did away with Gautier and Blyth's ideas as to their alkaloidal nature.

In 1892 Martin alone and with Smith studied the venom of Australian snakes (*Hoplocephalus* and *Pseudechis*), and concluded that the venom contained three proteids an albumin and two proteoses (proto and hetero), the latter, however, being alone virulent.

In the meanwhile observers had not been backward in making attempts to find the physiological antidote suggested by Weir Mitchell and Reichert, for in 1887 Sewall showed that by repeated injections of the venom of *Crotalus*, pigeons could be gradually rendered resistant against strong doses of that poison; and a little later Reichert obtained the same result with regard to the venom of the French viper. In 1892 Calmette published the first of his celebrated series of investigations, showing that successive inoculations of heated venom produced in animals a certain degree of resistance to quantities of the poison otherwise surely fatal. Calmette worked largely with the cobra, and produced in rabbits and guinea pigs a true immunity. He further concluded that animals vaccinated against the cobra also withstood with impunity mortal doses of the venom of the viper and other snakes (*Bungarus*, *Cerastes*, *Naja haje*, and *Pseudechis*).

Phisalix and Bertrand also studied the question of obtaining an immunity against the bite of the viper. Fraser of Edinburgh, in 1895, confirmed these results of Calmette. Since then there has not been the slightest doubt that Calmette' serum is of the greatest value in certain cases, especially against cobra-venom.

In 1881 permanganate of potash was recommended as an antidote by Professor de Lacerda, of Rio de Janeiro, and by Badaloni in Italy in 1882-84, and lately this remedy has again been strongly recommended by Rogers, of Calcutta, and there appears to be no doubt as to its efficiency; but the question of remedies will be dealt with in their proper place.

It will thus be seen that at the close of this period there is a general belief that the venom of all snakes has virtually the same active principles, which are thought to be proteids, and that, though they may differ in amount, and hence their effects be different, still, it is only a quantitative, and not a qualitative, difference; and, further, that one antivenene is effectual against all kinds of venom.

3. **Period of more than One Venom.**—The third period, extending up to the present, is that in which there is the conception that there are at least two definitely separate types of venom, one of which may be called the colubrine type, having as its example *Naja tripudians*, and the other the viperine type,

which may be exemplified by the *Vipera russellii*. In addition, however, there are venoms which show characters belonging to both types.

Weir Mitchell alone and with Reichert indicated that there was a difference between viperine and colubrine poisons; and C. J. Martin, working on *Pseudechis*, a colubrine snake, discovered the intravascular clotting, and suggested that the sudden death caused by *Vipera russellii* might be due to this cause, which hypothesis Lamb and Hanna confirmed.

The difference in the working of these two classes of venoms is still further accentuated by the researches of Rogers, and later by those of Lamb, which clearly prove that Calmette's antivenene will neutralize the colubrine, but not the viperine, venom.

In 1902 a most valuable paper appeared, by Flexner and Noguchi, showing that, in addition to the neurotropic principles, the venom contained agglutinins for the erythrocytes and for the leucocytes which were probably identical, and lysins for erythrocytes and leucocytes which were separate.

They also pointed out that venom contained hæmorrhagins, and lessened the bactericidal powers of the blood. They showed that antivenene neutralizes venom by removing the hæmolytic and antibacteriolytic actions. These results have been confirmed and extended by Kyes, Sachs, Lamb, and others.

The position at the present time is that, though snake-venom is extremely complex, still, three kinds of venom may be recognized:—the colubrine type, the viperine type, and the mixed type. In this last both colubrine and viperine types are represented, but one is predominant. It is probable that the main action of both types is on the nervous system, but that other principles in the venom may mask this important action.

With regard to treatment, there is no doubt as to the value of Calmette's rum in cobra-poisoning, and Lam [illegible] cobra and *Vipera russellii* poisoning, thoug [illegible] method of ligatu [illegible] incision, together with the application of permangana [illegible] potash, is sti [illegible] the most practically useful method of treatment.

Classification.

The order Ophidia includes a large number of families, of which only two are of importance to the tropical practitioner—viz., Colubridæ and Viperidæ.

FAMILY COLUBRIDÆ BOULENGER, 1890.

Definition.—*Ophidia* with ectopterygoids (transpalatines) and supratemporals present with teeth in both jaws, but without coronoids, while the prefrontals are not in contact with the nasal bones.

The Colubridæ are divided, in works on snake poisons, into the non-venomous and the venomous, and the latter are joined with the vipers to form a subclass of the order Ophidia called Thanatophidia, or poisonous snakes; but this classification is by no means satisfactory, as will presently be shown. There is no external character, easily ascertainable, by means of which every poisonous snake can be recognized and distinguished from a harmless snake. All rules given to the contrary break down sooner or later, but the mouth can be opened and the poison-fangs can usually be easily seen.

The usual classification of the Colubridæ is into three series:—

1. **Aglypha Poisonous Colubridæ possessing solid ungrooved teeth.**—The Aglypha are usually stated to be non-poisonous, but the observations of Phisalix and Bertrand on *Tropidonotus* (sp. ?), and Alcock and Rogers on *Zamenis mucosus* and *Tropidonotus piscator*, prove that the saliva of these species is poisonous to rats,

mice, and guinea-pigs. Thus hypodermic injections of the saliva of the two last-named snakes will cause convulsions and death from failure of respiration in rats and mice.

Therefore the saliva, though it may not be known to have affected even a child, must be looked upon as poisonous, and the Aglypha must be grouped with the other Colubridæ and the Viperidæ under the head Thanatophidia.

The Aglypha are divided into three subfamilies: Acrochordinæ, Colubrinæ (rat-snakes), and Dasypeltinæ (African egg-eating snakes).

Some of the important species are *Tropidonotus natrix*, the common British snake, and *Coronella austriaca*, a rare snake found in South England. *Tropidonotus fasciatus* is the North American water moccasin, *Zamenis mucosus* the Indian rat-snake, and *Dasypeltis scabra* is the African egg-eating snake:

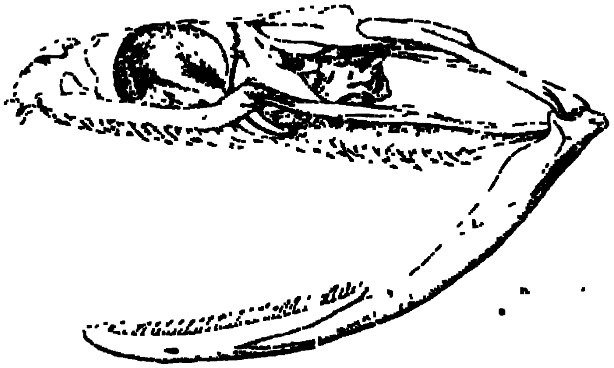

FIG. 31. SKULL OF *Tropidonotus natrix* LINNÆUS.

All the teeth are solid, there are no grooved or perforated fangs hence the name *Aglypha*, but the saliva may be poisonous. Note the length of the maxilla

2. **Opisthoglypha -Poisonous Colubridæ with one or more of the hinder teeth of the upper jaw grooved.** -Early last century there was a great controversy as to whether these snakes were poisonous or not, and it is generally stated nowadays that, though poisonous, their venom is weak, and that the position of the poison-fangs at the back of the mouth prevents the bite from hurting man. Quelch has, however, recorded cases in which bites on the fingers from *Erythrolamprus æsculapii* L. and *Xenodon severus* have caused severe inflammation.

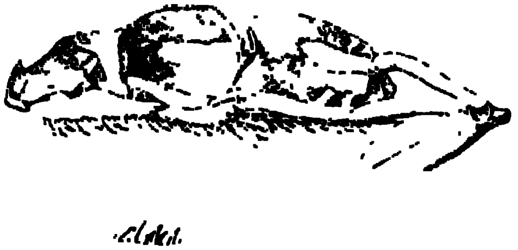

FIG -SKULL OF *Cœlopeltis monspessulans*

Note the fangs in the rear ot the upper jaw; hence the name *Opisthoglypha*. These fangs are grooved.

The following list is given by Faust of those known to be poisonous to animals: *Cœlopeltis monspessulans* Herm., *Trimorphodon biscutatus* D. and B., *Tarbophis savignyi* Descr., *Dryophis prasinus* Russl., and *Leptodira annulata* L.

The Opisthoglypha are divided into three subfamilies:-

(1) *Dipsadomorphinæ—Opisthoglyphida with well-developed mouth, and nostrils situated at the side of the head.*—They include the Indian tree-snakes.

(2) *Elachistodontinæ—Opisthoglyphida with rudimentary teeth on the palatine and pterygoid bones.*—Their venom is said to be so weak and their poison-fangs so unfavourably situated that they are not to be considered as dangerous to man. They include the Indian egg-eating snakes.

(3) *Hemalopsinæ—Opisthoglyphida with nostrils valvular and situated on the upper part of the snout.* They are all water-snakes.

3. **Proteroglypha.—Poisonous Colubridæ with the front teeth in the upper jaw well developed to form fangs, and grooved anteriorly. The bases of these fangs are connected with ducts which lead from well-developed poison glands.** These snakes are well known to be highly dangerous to man and animals. They are divided into three subfamilies—Elapinæ and Hydrophinæ.

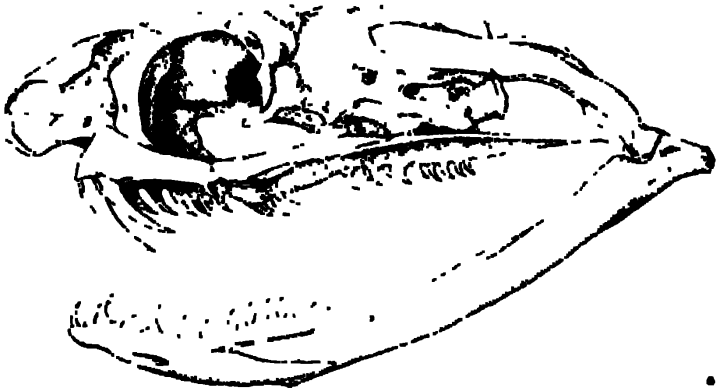

FIG. 33.—SKULL OF *Naja tripudians* MERREM.

Note the pair of short rigidly attached fangs situate in the front of the upper jaw, hence the name *Proteroglypha*. These fangs are grooved. Note the shortening of the maxilla.

Elapinæ—Proteroglypha living on land, and possessing a cylindrical tail.—Among these are classed the cobras, whose proper name is cobra-di-capello—*i.e.*, the snake with the hood, so called because, when excited, it expands the skin behind the head by throwing outwards the cervical ribs.

Buddhists regard these snakes with reverence, because one with seven heads is said to have placed its expanded hoods over Buddha's head, and thus to have protected him from the glare of the mid-day sun.

The genera of the Elapinæ (Boulenger) are: *Naja* Laurenti; *Bungarus* Daudin; *Hemibungarus* Peters; *Callophis* Gunther; *Doliophis* Girard; *Boulengerina* Dollo; *Elapechis* Boulenger; *Aspidelaps* Fitzinger; *Walterinnesia* Lataste; *Dendraspis* Schlegel; *Ogmodon* Peters; *Glyphodon* Günther; *Pseudelaps* Duméril and Bibron; *Diemenia* Gray; *Pseudechis* Wagler; *Denisonia* Krefft; *Tropidechis* Gunther; *Notechis* Boulenger; *Rhinoplocephalus* F. Muller; *Brachyaspis* Boulenger; *Acanthophis* Daudin; *Elapognathus* Boulenger; *Rhynchelaps* Jan; *Furina* Duméril and Bibron; *Elaps* Schneider; *Sepedon* Merrem; *Micropechis* Boulenger; *Hoplocephalus* Cuvier.

Naja tripudians Merrem, the cobra with one spot, or a pair of spectacles on its hood, is common in India and Ceylon. *N. bungarus*

Schlegel., the king cobra, or hamadryad, is not so common, but is feared because of its size, and because it is said to attack people. *N. haje* L. is Cleopatra's asp, and is well known as a resident of Egypt and North Africa. *N. regalis* Schl., is found on the Gold Coast. *N. nigricollis* Reinhart is found on the Gold Coast and in Sierra Leone.

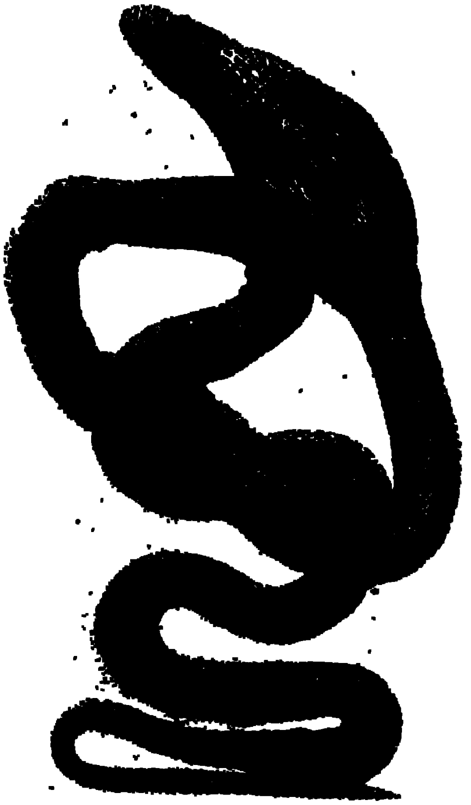

FIG. 34.—*Naja tripudians* MERREM, 1781. THE COBRA.
Note the pair of spectacles on the hood.

The kraits are also included in this family, and are: *Bungarus candidus* L., the true krait, and *B. fasciatus* Schn., the banded krait, with yellow and black bands, both of which are common in India, while *B. ceylonicus* Gthr. is the carawalla of Ceylon. The Elapinæ are the only poisonous snakes of Australia, and include *Notechis scutatus* Ptrs. and *N. pseudechis*, and *Acanthophis antarcticus* Shaw, the death adder, recognized by the spines on its tail.

FIG. 35.—SIDE VIEW OF THE HEAD OF THE COBRA.

Elaps corallinus Wied, the coral snake, with black and red bands separated by narrow rings of a yellow colour, is found in Columbia, British Guiana, Venezuela, and Brazil

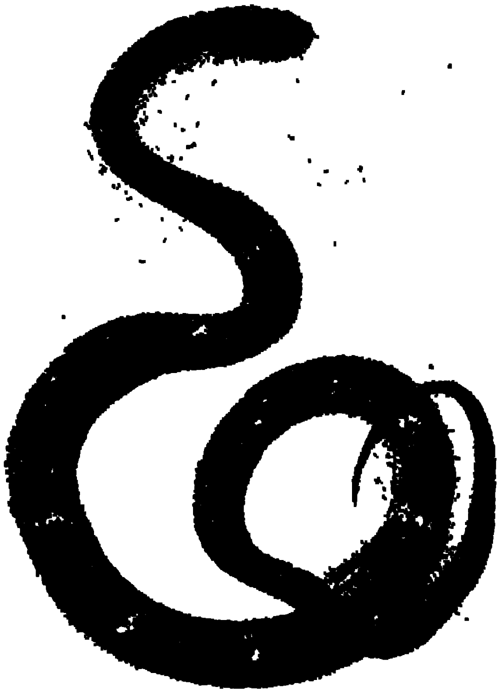

FIG 36.—*Bungarus ceylonicus* GÜNTHER.
This is the Carawalla of Ceylon.

The *Sepedons* are hooded snakes like cobras (*Sepedon hæmachates* Lacép. of South Africa), and are supposed to throw their venom so far that there is a danger of it getting into the eyes of animals and human beings, and causing severe conjunctivitis.

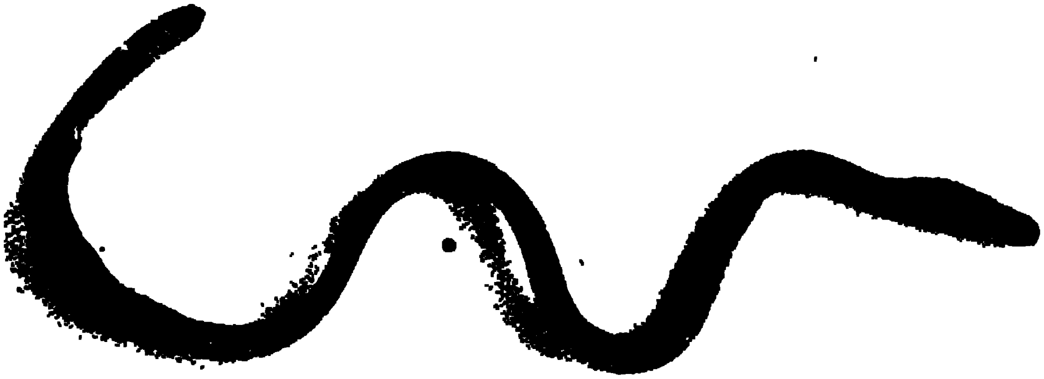

FIG. 37.—*Hydrus platurus* LINNÆUS.
This is a typical sea-snake. Note the flattened spotted tail.

None of these snakes are found in Europe or America.

Hydrophinæ—Proteroglyphæ living in the sea, and possessing a flat tail.—These snakes can be seen swimming in families far out in the Indian Ocean, but are also found in all Eastern tropical seas.

FIG. 28.—*Vipera russellii* SHAW.

This is the Tic Polonga of Ceylon

The genera of the Hydrophinæ (Boulenger) are:—*Distera* Lacépède, *Acalyptus* Duméril and Bibron, *Hydrophis* Daudin, *Enhydrina* Gray; *Hydrelaps* Boulenger; *Hydrus* Schneider; *Thalassophis* Schmidt; *Enhydris* Merrem; *Platurus* Latreille; *Aipysurus* Lacépède.

The best-studied species is *Enhydrina valakadien* Boie. Another species, *Distera semperi* Garm., lives in fresh water in the Philippine Islands. It is, of course, dangerous to fishermen.

FAMILY VIPERIDÆ BONAPARTE, 1840.

Definition.—The vipers are characterized by their triangular head and their tubular poison-fangs (hence the name Solenoglypha), with are situated anteriorly in the mouth, and are provided with a wide foramen, piercing the base anteriorly for connection with the duct of the poison gland. They possess a stout body and short tail, and are all viviparous.

The Viperidæ are divided into:—

- **Crotalinæ** Boulenger.—Vipers with a deep pit, probably sensory in function, situated between the nostril and the eye on each side of the head.
- **Viperinæ** Boulenger.—Vipers without such a pit.

Crotalinæ.—The Crotalinæ include the rattlesnakes, so called because they have a number of horny rings which fit into one another at the end of the tail.

The genera of the Crotalinæ (Boulenger) are:—*Crotalus* Linnæus; *Sistrurus* Garman; *Ancistrodon* Beauvois; *Lachesis* Daudin.

There are two divisions of rattlesnakes in America—*Crotalus* and *Sistrurus*—distinguished by the former having many small, and the latter only nine large, scales on the top of the head.

The best-known rattlesnakes are *Crotalus horridus* L., *C. scutulatus* Kenn. of Texas, *C. confluentus* Say, of the Pacific, *C. durissus* L., and *C. cerastes* Hallow.

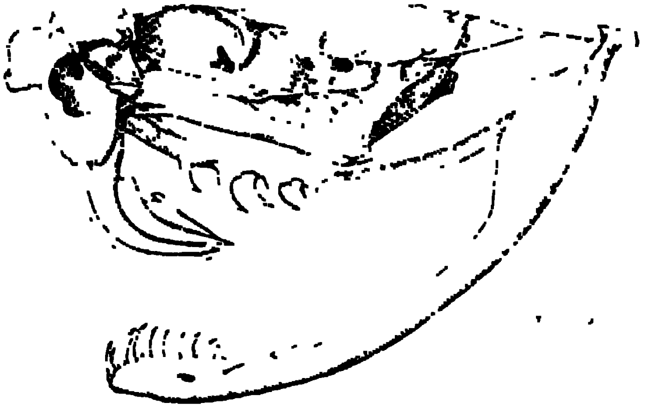

FIG. 39.—SKULL OF *Crotalus horridus* LINNÆUS.

Note that in place of the long horizontal maxilla of the other three skulls there is only a small vertical movable maxilla on each side of the anterior part of the skull. It can be recognized by carrying the enormously developed fang which is canalized and is virtually a hypodermic needle for the injection of the venom. Note the reserve fangs, which should lie flat against the skull.

FIG. 40.—SIDE VIEW OF THE HEAD OF A RATTLESNAKE (*C. horridus*).

FIG. 41.—END OF THE TAIL OF *C. horridus* TO SHOW THE RATTLE.

Other genera are *Ancistrodon*, with *Ancistrodon piscivorus* Lacép., the water moccasin, and *A. contortrix* L., the copper-head, *Lachesis*, with *Lachesis lanceolatus* Lacép., the celebrated fer de lance of Martinique; *L. anamallensis* Gthr. and *Sistrurus*, with *Sistrurus ravus* Cope and *S. miliarius* L.

Viperinæ. The true vipers include: *Vipera berus* L., the adder of England; *V. russellii* Shaw, the handsome viper of India and Ceylon; *Bitis arietans* Merr., the puff adder of the Gold Coast; *Cerastes cornutus* Forskål, the horned viper of North Africa; and *Echis carinatus* Schn., the viper of the Pyramids, called 'efa.'

The genera of the Viperinæ (Boulenger) are:—*Vipera* Laurent; *Causus* Wagler; *Bitis* Gray; *Pseudocerastes* Boulenger; *Cerastes* Wagler; *Echis* Merrem; *Atheris* Cope; *Atractaspis* Smith.

Geographical Distribution.

Asia.—ELAPINÆ: *Naja tripudians*, *N. samarensis*, *N. bungarus*; *Bungarus fasciatus*, *B. candidus*, *B. ceylonicus*; *Hemibungarus*, *Callophis*, *Doliophis*.

HYDROPHIINÆ: *Enhydrina valakadien*, *Hydrus platurus*, *Enhydris curtus*, *Hydrophis obscurus*, and many others.

VIPERINÆ: *Vipera berus*, *V. renardi*, *V. raddii*, *V. lebetina*, *V. russellii*, *Pseudocerastes persicus*; *Cerastes cornutus*; *Echis carinatus*.

CROTALINÆ: *Ancistrodon halys*, *A. himalayanus*, *A. hypnale*, and others, *Lachesis flavoviridis*, *L. sumatranus*, *L. borneensis*, etc.

Africa. ELAPINÆ: *Naja haje*, *N. flava*, *N. melanoleuca*, *N. nigricollis*, *N. anchietæ*, *N. goldii*; *Sepedon hæmachates*; *Boulengerina stormsi*; *Elapechis guentheri*, etc., *Aspidelaps scutatus*, *Walterinnesia ægyptia*, *Dendraspis viridis*, etc.

VIPERINÆ: *Causus rhombeatus*, etc., *Vipera ammodytes*, etc., *Bitis arietans*, *B. cornuta*, *B. gabonica*, *B. caudalis*, *B. atropos*, *B. nasicornis*, *B. peringueyi*, *B. inornata*, *Cerastes cornutus*, *Echis carinata*, *Atheris chlorechis*, *Atractaspis congica*, etc.

Australia and Oceania. ELAPINÆ: *Ogmodon vitianus*, *Glyphodon tristis*; *Pseudelaps muelleri*, etc., *Diemenia psammophis*, etc., *Pseudechis porphyriacus*, etc.; *Denisonia superba*, etc., *Micropechis elapoides*, *Hoplocephalus variegatus*, etc., *Tropidechis carinata*; *Notechis scutatus*, *Brachyaspis curta*, *Elapognathus minor*; *Acanthophis antarcticus*, *Rhynchelaps australis*, *Furina calonota*, etc.

HYDROPHIINÆ: *Hydrus*, *Thalassophis*, *Hydrelaps*, *Hydrophis*, *Distira*, *Enhydris*, *Enhydrina*, *Aipysurus*, *Platurus*.

America. ELAPINÆ: *Elaps*, many species, *Micropechis elapoides*; *Ancistrodon piscivorus*, *A. bilineatus*, *A. contortrix*, *Lachesis mutus*, *L. lanceolatus*, and many others, *Sistrurus miliarius*, *S. catenatus*, *S. ravus*; *Crotalus adamanteus*, *C. horridus*, *C. confluentus*, *C. atrox*, *C. oregonus*, *C. cerastes*, *C. mitchelli*, *C. terrificus*, and others.

The Act of Striking.

The poison is secreted by glands, which are either modified upper labial glands or a pair of glands occupying the sides of the head behind the eyes, and which are the homologues of the parotid gland of other animals. (An account of the structure of the glands can be found in 'Spolia Zeylanica' 1913.) The duct usually begins as a receptacle which runs the whole length of the gland. This receptacle is of importance, as it enables the reptile to store the venom. Into this receptacle the smaller ducts of the gland open, and from it the main duct runs forward just above the line of the lip, to a point below the eye. It is now bent backwards, and ends on a small papilla on the anterior wall of the sheath of mucous membrane, which embraces the base of the fang.

Weir Mitchell describes a sphincter muscle of reddish appearance, and composed of non-striated muscle, on the course of the duct of *Crotalus*, but no such sphincter has been described in the other snakes.

The poison from the duct either runs along a groove on the anterior surface of a long tooth called the fang, or else along a canal formed by the sides of the groove meeting and coalescing by the bending of the developing dentine. It should be clearly understood that the venom duct does not directly communicate with the groove or canal in the tooth, but ends close to it, the venom being conducted into the groove by a fold of mucous membrane. The vipers have the longest fangs, measuring nearly 1 inch.

The poison-fang projects downwards and backwards in the closed mouth, being firmly attached to the alveolar process, and it is entirely due to the free mobility of the cranial bones one on the other that the fang can be placed in such a position as to be able to enter the skin of the victim.

The act of striking, as described by Weir Mitchell in *Crotalus*, is as follows: In preparing to strike, the snake first of all throws itself into its well-known characteristic attitude, with the lower part of the body coiled, the tail slightly projecting, and the head raised a few inches

The tongue now darts backwards and forwards, and the air of expiration, in passing through the narrow glottis, produces the characteristic hissing. The muscles on the convexity of the coils now contract and straighten the snake, so that the head is thrust suddenly upwards, forwards, or downwards, as required. The maximum thrust is half of the body-length, the usual one-third; but the reptile judges this for itself, and sometimes makes mistakes. The jaws are widely separated, and the head is bent back on the cervical vertebræ, and a muscle called the spheno-pterygoid, which, passing from the basal orbito-sphenoid region backwards, to be inserted into the inner dorsal surface of the pterygoid, contracts, and draws forward the pterygoid, thus pushing upwards the ecto-pterygoid (transversum), and causing the superior maxillary bone to rotate forward on its lachrymal articulation, and thus to erect the fang. This motion, when it reaches its limit, is checked by ligaments, and now the lachrymal yields a little to the force applied to the maxilla, with the result that the whole muzzle of the snake is elevated, and produces the curious appearance which it has when preparing to strike. The fang now enters the flesh of the victim, and the head of the snake is drawn violently backwards, too much action being prevented by the muscles of the spine. In the meanwhile the spheno-pterygoid, acting from the pterygoid, and together with the external pterygoid, rotates the maxilla and pulls the fang backwards, and so drives it deeply into the flesh.

The lower jaw now closes on the bitten part, and this act squeezes the fluids from all parts of the glands forward into the duct, and not merely deepens the wound, but injects the venom forcibly into it.

The snake then has to disentangle itself, and in so doing may lose its fang. But this is of no moment, for fangs are shed naturally, and there are a number of tooth-germs in different stages of development ready to take the place of the lost tooth.

Sometimes the fangs have not been properly erected, and therefore only their convex borders touch the skin of the victim, in which case the venom will flow on to the skin, but the fangs will not penetrate.

The Venom.

Collection.—The venom can be collected by making the snake strike a watchglass covered with a thin, tightly stretched piece of indiarubber sheeting, or by chloroforming the snake and squeezing the poison out of the glands into a vessel.

In order to preserve this venom, it must be quickly dried over calcium chloride or sulphuric acid in a desiccator, when it will keep for years—*e.g.*, Weir Mitchell kept his *Crotalus* venom for twenty-three years, and then found it active.

Physical Characters.—The quantity of the venom obtained depends upon many factors, such as the general condition and size of the snake, whether it has previously ejected venom, and whether it has been long in captivity—a condition in which the secretion diminishes.

An adult cobra in good condition is said by Martin to give from 0·6 c.c. to 1·1 c.c., and this should yield from 200 to 370 milligrammes of solids. Calmette gives 124 milligrammes of liquid venom, yielding 35 milligrammes of dry venom for *Naja haje* Linnæus.

The water-snake, *Enhydrina valakadien* Boie, gives only 9·4 to 2·3 milligrammes of dry venom, according to Rogers.

A *Vipera russellii* Shaw gives from 0·6 c.c. to 1·0 c.c. of liquid, which yields 150 to 250 milligrammes of solids.

According to C. J. Martin, *Notechis scutatus* Ptrs. gives 205 milligrammes of liquid, containing 73 milligrammes of solids, *Notechis pseudechis* 160 milligrammes of liquid and 91 milligrammes of solids.

According to Calmette, *Lachesis lanceolatus* Lacép. gives 320 milligrammes of liquid venom, containing 127 milligrammes of solids. *Cerastes cornutus* Forsk. from Egypt gave 123 milligrammes of liquid and 27 milligrammes of solids, and *Crotalus confluentus* Say gave 370 milligrammes of liquid and 105 milligrammes of solids; while *Crotalus durissus* L., according to Flexner and Noguchi, yields from 309 to 170 milligrammes of dry venom; and *Ancistrodon piscivorus* Lacép. from 180 to 125 milligrammes.

The different venoms vary in physical characters, as may be judged by a few descriptions.

Cobra-venom, when fresh, is a transparent, almost colourless fluid, with a syrupy consistence and a disagreeable bitter taste. When dried, it becomes yellowish-brown, and may be kept for months. It can decompose and become of a dark brown colour, possessing a disagreeable odour.

Crotalus-venom, according to Mitchell, may vary from a pale emerald-green to an orange or straw colour, and when dried resembles dried albumin. It has no taste or smell.

The poison varies, being clear and limpid or pale straw or yellow in colour, which is said to vary with the degree of pigmentation of the snake and the concentration of the venom. The specific gravity varies from 1030 to 1044 (Weir Mitchell) for *Crotalus*, 1110 for *Cobra*, and 1077 for *Vipera russellii*. Microscopically, there may be only a few epithelial cells and salivary corpuscles and bacteria, all due to contamination with fluids from the mouth.

Chemical Analysis.—The reaction of pure venom is acid.

The ultimate analysis was made by Armstrong for Sir Joseph Fayrer, and is as follows:—

Crude Dried Poison.

Carbon	43·5
Nitrogen	13·43

Alcoholic Extract.

Carbon	45·76
Nitrogen	14·30
Hydrogen	6·60
Sulphur	2·50
Ash	Traces.

These figures merely indicate the presence of proteid in some form, and, as a matter of fact, Armstrong found reactions indicating the presence of albumin; but it must be remembered that Prince Charles Lucien Bonaparte had already shown that a proteid existed in the venom of the viper, and that the toxicity was carried down with this when precipitated, and, further, that Weir Mitchell had corroborated his statements while examining Crotalus-venom.

Weir Mitchell and Reichert went further, and discovered toxalbumins of the nature of globulins (which must be considered to include the more modern proteoses) in venom. They considered these proteids, which they found to be poisonous, to be the true active principles of the venom. In this they have received support from Phisalix and Bertrand, who separated from viper-venom two toxalbumins—echidin, which acts locally; and echitoxin, which acts generally—and also from C. J. Martin and Smith, who showed that the proteoses consisted of proto- and heteroproteose, with perhaps a little deuteroproteose, and that true peptones were absent.

The reader will, therefore, not be surprised to hear that venom gives proteid reactions—*e.g.*, Millon's, the xanthoproteic and the biuret—and that precipitates appear on the addition of picric acid, copper sulphate, and alcohol, and on saturation with sodium chloride, magnesium chloride, or ammonium chloride, and, lastly, that it coagulates on heating.

With regard to heat, it is found that viperine venoms more readily lose their toxicity than colubrine—*e.g.*, 80 to 85° C. will destroy most of the former venoms, while it takes 120° C. to do the same to those of the latter with certainty.

If venom is only heated to the temperature of first coagulation, and then filtered, it will be found that the filtrate still gives a precipitate with alcohol, and is still active, though its virulence is diminished, and that this action is mostly on the nervous system.

The analysis of venom, however, does not stop with toxalbumins, for, as Ewing pointed out long ago, they contain true toxins allied to those produced by bacteria, and recently Faust has separated from the toxalbumins a very poisonous non-nitrogenous substance called *ophiotoxin*.

The knowledge of these toxins is principally due to the work of Flexner and Noguchi on the venoms of *Crotalus durissus*, *Ancistrodon piscivorus*, *A. contortrix*, and *Naja tripudians*.

The work of these investigators, coupled with that of C. J. Martin, Calmette, Lamb, Weir Mitchell, Reichert, Stewart, Rogers, and others, have shown that snake-venoms are very complex liquids containing some, but not in any one venom all, of the following active principles:—

1. *Neurotoxins.*
   (1) Acting principally on the respiratory centre.
   (2) Acting principally on the vasomotor centre.
   (3) Acting upon nerve end-plates in striated muscle, particularly on those of the phrenics.
2. *Agglutinins.*
3 *Cytolysins.*
   (*a*) Hæmolysins.
   (*b*) Leucolysins.
   (*c*) Hæmorrhagins.
   (*d*) Other cytolysins.
4. *Antihæmolysins.*
5 *Antibactericidal substances.*
6. *A fibrin ferment.*
7. *An antifibrin ferment.*
8. *A proteolytic ferment.*
   A cardiac and vascular tonic.

Of these principles, the most important are the neurotoxins, the cytolysins, and the fibrin ferment.

The analysis of the venom, according to Martin, may be effected by:

(1) Dialyzing and filtering the venom through a gelatin filter supported in the pores of a Pasteur Chamberland filter. *Fibrin ferments and hæmorrhagins do not dialyse.*

(2) Heating from 70° to 100° C., when some *neurotoxins* and some *hæmolysins* will not be affected.

(3) Hæmolysins can be separated from neurotoxins by digestion with red blood cells mixed with serum which has previously been heated to 56° C.

Neurotoxins and other cytolysins can be separated by the method of Flexner and Noguchi, which will be described later. It must be clearly understood that the venom of any one snake does not contain all these principles.

1. NEUROTOXINS. The neurotoxins are the most important active principles of the venom of many snakes, especially the colubrine snakes. They have been studied in *Ancistrodon contortrix* by Flexner and Noguchi, who tested the anchoring power of the various tissues of the body for the principles in venom in the following manner: They took a definite weight of tissue washed in tepid, sterile, normal saline solution, and after triturating it in a sterile mortar, mixed it in test-tubes with a given number of minimal lethal doses (M.L.D.) of the venom. The mixture, after being placed in a thermostat for one hour, was centrifugalized, and the supernatant fluid injected into guinea-pigs. They first took 2 grammes of the organs, and mixed them with three times M.L.D., calculating that after centrifugalizing there should be left at least two M.L.D.

The results were as follows:—

Control guinea-pig died in 45 minutes.
Brain-injection guinea-pig died in 19 hours.
Blood-injection guinea-pig died in 3 hours 50 minutes.
Adrenals-injection guinea-pig died in 2 hours 35 minutes.
Spleen-injection guinea-pig died in 2 hours 10 minutes.
Liver-injection guinea-pig died in 1 hour 30 minutes.
Kidney-injection guinea-pig died in 1 hour 55 minutes.
Muscles-injection guinea-pig died in 1 hour 30 minutes.

Next they tried two M.L.D., with the following results:—

Brain-injection guinea-pig survived.
Blood-injection guinea-pig died in 28 hours.
Liver-injection guinea-pig died in 19 hours.

From these experiments they conclude that snake-venom contains a neurotoxic principle, which is the chief poison, and which unites in multiple minimal doses with the nerve cells, but that, even if this chief toxic principle be removed, there is still left sufficient hæmolysin to cause death.

This neurotoxic substance has been shown by Rogers in the cobra and the Hydrophidæ to attack the respiratory centre in the medulla, the respirations becoming both fewer in number and less in amplitude minute by minute, until they cease if sufficiently large doses are administered, but when smaller doses are given there is at first a temporary stimulation.

Further, he shows that the neurotoxic substance can paralyze the end-plates of the phrenic nerves in the diaphragm shortly after the failure of the respiratory centre in the medulla.

The blood-pressure does not appear to be affected by the poison, and, in fact, the circulation can be kept going for a long time after cessation of breathing if artificial respiration is resorted to—a fact first shown by Brunton and Fayrer.

On the other hand, with regard to viperine snakes—*e.g.*, *Vipera russellii*, *Bitis arietans*, *Crotalus horridus*, and *Lachesis anamallensis*—Rogers concluded that the neurotoxin acted upon the vasomotor centre in the medulla—a point which was noted by Weir Mitchell and Reichert as a cause of the variation of the blood-pressure in Crotalus poisoning.

There are thus several neurotoxic elements in snake-venom, of which two great groups can at present be provisionally described:

(1) Colubrine neurotoxic element, acting upon the—(1) Respiratory centre in the medulla; (2) the end-plates of the phrenic nerve.

(2) Viperine neurotoxic element, acting upon the vasomotor centre in the medulla.

Kilvington has studied the effects of the venom of *Hoplocephalus curtus* Günther (*Brachyaspis curta* Schleg.) on nerve cells, and found that the nerve cells of the central part of the cervical enlargement showed a breaking-up of the Nissl granules into a fine dust-like deposit. The nucleus may become indistinct, but it remains in the centre of the cell. The cells are unequally attacked. Those around the central canal are most severely injured, while the motor cells are little affected. In sudden death no change is noted. He says that the character of the changes are of the same order as those described by Marinesco as toxic degeneration, and are very like those following the fatal dose of abrin. Inflammatory and vascular changes are absent.

As to the cause of this cytolysis, it would appear from the researches of Flexner and Noguchi that it is probably due to the union of an endocomplement (capable of being neutralized by calcium chloride, and therefore not lecithin) in the nerve cell with an amboceptor in the venom. This neurotoxin, according to Ehrlich's denomination, is neurotropic—*i.e.*, unites only with nerve cells—and monotropic—*i.e.*, has affinities for one tissue only.

These facts have been demonstrated by Flexner and Noguchi in cobra-venom by first treating it with erythrocytes to remove the hæmolysin, and then heating it to destroy the hæmorrhagin, thus leaving only the neurotoxic principle to act on the animal.

They found that after cerebral injection the appearance of the nervous symptoms was almost immediate, while with other methods of injection the development was more gradual.

The first effect of the neurotoxin was irritation (convulsions), and the final paralysis. By cobra-venom, death was caused by respiratory paralysis. Intracerebral injection of a viperine venom like that of *Crotalus*, however, caused but slight symptoms.

They further found that the venoms of *Ancistrodon piscivorus* Lacép. and *A. contortrix* L. occupied an intermediate position between the colubrine and viperine venoms, containing both neurotoxins and hæmolysins in considerable quantities. From these experiments it was possible to classify venoms into the three classes given above.

2. AGGLUTININS.—Agglutination of the red cells was first described by Weir Mitchell and Reichert, and that of the leucocytes by Halford and Ralf.

The reaction can be studied by adding a 0·01 per cent. to 10 per cent. solution of dried venom in normal saline to washed corpuscles suspended in normal saline.

The time required for agglutination depends upon the strength of the solution of venom, and the effect upon the corpuscles depends upon whether they come together quickly or slowly. In the former case they are not damaged, while in the latter their shape is considerably altered. Agglutinins are destroyed by heating the venom to 75°-80° C.

The agglutinins for the red cells appear to be the same substances as those for the white, and in both cases they appear to act prior to the cytolysis of the cells.

3. THE CYTOLYSINS.—(*a*) *Hæmolysins.*—Fontana many years ago noted that the blood of animals bitten by vipers was fluid, and Weir Mitchell and Reichert described the hæmoglobin dissolving out of

the agglutinated red corpuscles, which finally became invisible when treated with Crotalus-venom. Feoktistow showed that a 2 per cent. solution of the venom of *Vipera berus* destroyed red corpuscles in eighteen to twenty-four hours. Martin has demonstrated also that the venom of *Pseudechis* in 0·1 per cent. solution destroyed the red corpuscle.

Flexner and Noguchi showed that these hæmolysins must be looked upon as amboceptors, which require a complement, and this they obtain in the bactericidal principles found in the serum of the victim. Hence, when they join with the erythrocytes and the complement, they not merely produce hæmolysis, but they take away the bactericidal powers from the blood. If, as was found to be the case in *Necturus*, they are incapable of uniting with the complements, they are incapable of damaging the bactericidal properties of the serum; for it was found that hæmolysis was but slightly produced in the blood of *Necturus*, and then only after long periods, and at the same time the serum of *Necturus* did not lose its bactericidal effects to *Bacillus coli communis* and *B. typhosus*.

The hæmolysins have been further studied by Kyes, who showed that in some animals the venom alone could hæmolyze the washed red cells, whereas in others it could not do so until some fresh serum was added. In the first class came man, dog, rabbit, guinea-pig, and horse, and with reference to these he came to the conclusion that the complement was contained in the red blood cell itself—*i.e.*, was an endocomplement. In a further research with Sachs, he shows that this endocomplement is attached to the stroma of the red cells. Further, they conclude that it is the lecithin of the stroma which acts as the complement, and support this by experiments showing that lecithin prepared from the yolk of an egg can act as a complement for the venom, and dissolve cells which are not affected by the venom alone. They look upon the fatty acid radical of the lecithin as being probably the active agent.

In the second class—viz., those animals whose erythrocytes are not affected by venom alone without the presence of serum—come the ox, sheep, and the goat; but Kyes found it very easy to produce solution by the addition of foreign sera—*e.g.*, ox blood by venom and guinea-pig serum; sheep blood by venom and guinea-pig serum—which clearly showed that the venom was an amboceptor, and agreed with the results of Flexner and Noguchi.

Further, he showed that by heating the serum to 56° C. for half an hour this action was destroyed, but if heated to 65° C. for half an hour hæmolysis took place. In other words, serum contained two possible complements: (1) free in the serum, and destroyed by heat; (2) only in heated serum. Kyes and Sachs consider (1) to be complements in the restricted sense of the term, and that there are differences in their workings from that of the lecithin complement. More recently, however, they have doubted this, and begun to believe that the serum merely frees the lecithin, which acts as the true complement.

In (2) the lecithin, being free, is able to combine with the amboceptor and cause the hæmolysis. They further show that if a blood solution is heated to 62° C., it is inactivated, owing to the union at this temperature of the lecithin directly to the hæmoglobin.

They therefore came to the conclusion that the reason why there was a difference in the action of the venom on red cells was that in the first class—*e.g.*, man, etc.—the lecithin was so loosely bound to the cell that it was available as a complement for the venom amboceptor, whereas in the other cases it was more closely bound, and therefore was not available.

Kyes then went a step further, and mixed 40 c.c. of a 1 per cent. solution of cobra-venom in a 0·75 per cent. salt solution, with 20 c.c. of 20 per cent. solution of lecithin in chloroform, and then centrifugalized the mixture. The result was the separation of chloroform and water into two layers; from the former the cobra-venom lecithin could be precipitated by the addition of pure ether. This body possessed hæmolytic but no neurotoxic properties, which entirely remained in the water. Thus Kyes clearly supports the fact first pointed out by the late Dr. Myers that the neurotoxic and hæmolytic actions are quite separate.

This cobra-venom lecithin differs in many of its properties from cobra-venom and from lecithin—*e.g.*, it is soluble in water, which lecithin is not; it is soluble in alcohol, chloroform, and toluol, which the cobra-venom amboceptor is not.

Kyes found that the lecithin was active with the blood cells of all the species he examined, and that the absolute quantity necessary for hæmolysis was the same for the blood cells of different species. Thus lecithin corresponding to 0·003 milligramme of the dry cobra-venom was capable of hæmolyzing 1 c.c. of a 5 per cent. suspension of the erythrocytes of guinea-pig, rabbit, man, or ox.

The lecithide acts very quickly on the red cells (twenty-four times more quickly than the venom), which is due to the fact that no time is spent in developing the real toxic agent—*i.e.*, the lecithide.

The lecithide is not destroyed by heating to 100° C. for six hours, and is little affected by Calmette's serum.

Kyes went further, and studied the lecithides of—(1) *Lachesis anamallensis* Günther; (2) *L. lanceolatus* Lacép.; (3) *L. flavoviridis* Hallow; (4) *Crotalus durissus* L.; (5) *Vipera russellii* Shaw (6) *Naja bungarus* Schleg.; (7) *Bungarus candidus* L.; (8) *B. fasciatus* Schn.

All these poisons, on the addition of sufficient lecithin, destroy blood cells, and, except in the first and the third, the absolute quantity of the poison is the same as that mentioned just above.

That of *Lachesis anamallensis* Günther is, however, twenty-five times weaker, and *L. lanceolatus* Lacép. ten times weaker, this being due to the fact that the former forms only one-twenty-fifth and the latter one-tenth the usual quantity of lecithide.

Hence Kyes concludes that the hæmolytic element of all snakes is an amboceptor possessed of a haptophore group for the erythrocyte, and a toxophore group for lecithin, which contains the active element for the hæmolysis. The haptophore group, however, probably differs in different poisons, for Lamb has shown that, while cobra-venom will unite with Calmette's antitoxin, poison of *Vipera russellii* will not. *Bungarus* and *Naja bungarus* act like the cobra, and *Lachesis* and *Crotalus* do not.

Noguchi investigated lecithin, and found it to be by no means an inert substance, and, further, that certain oleic compounds and oleic acid itself would act as venom activators.

He found that the addition of oleic acid or its soluble soaps to a non-activating serum in the ratio which corresponds to the percentages of fatty acids and soaps contained in some of the easily activating sera makes it highly active to venom. In the normal serum of a dog, however, he found that there was a lecithin compound acting like free lecithin. He further found that these two classes of activators could be differentiated from one another by calcium chloride, which annulled the first group, but was powerless against the lecithide. Non activating sera do not contain this lecithin compound, and other lecithides—*e.g.*, lecith albumin—are powerless.

When serum is heated, the non-coagulated portions contain a lecithin activator, as described by Kyes, which is identical with Chabrié's albumon; but this does not exist preformed in unheated sera, and is due to the high temperature altering other proteid lecithides into albumon.

He further found ovovitellin to be one of the best lecithin proteid activators. He finally came to the conclusion that the reason why some red corpuscles (man, etc.) are acted upon by venom, while others (ox, etc.) are not, depends solely upon the amount of fatty acids, and perhaps also of soaps and fats, contained in the corpuscles, to the stroma of which they are attached. They exist plentifully in corpuscles easily affected, and in small amount in those not easily affected.

The position at the present moment is, therefore, that snake-venom produces hæmolysis by its amboceptors uniting with complements contained in the sera of the majority of mammals and birds investigated, and that these complements are fatty acids and soaps (belonging principally to the oleic series).

Further, there are endocomplements in the erythrocytes of certain species, and these are of the same nature as those in normal sera, and are attached to the stroma of the corpuscle.

Finally, the reason why heated sera become active at high temperatures after losing their activity at lower temperatures is because of the conversion of the proteid lecithides into another form of lecithide called albumon, which is an activator.

For the controversy between von Dungern, Coca, supported by Mainwaring on the one side and Kyes on the other, reference must be made to the original papers given in our list at the end of this chapter.

(*b*) *The Leucolysins.*—Weir Mitchell and Reichert had noticed in their researches that the mobility of leucocytes absolutely ceased in crotalus poisoning. Martin studied this carefully with Pseudechis venom, and says that for the first fifteen minutes he could see no change in the white cells, but they exhibited no amœboid movements. At the end of this time the nuclei in some of them were very distinct, as if fixed by acetic acid. They then became intensely granular, and soon began to swell, and their outlines to grow less distinct, until they disappeared, leaving only a small heap of granules.

Flexner and Noguchi studied this phenomenon, and found that leucocytes with large coarse granules were most quickly affected; next came the fine granular varieties; and last of all the lymphocytes. They found cobra poison much more vigorous than that of crotalus. As to the leucolysins, they proved that they were separate from the hæmolysins by treating washed red corpuscles with copperhead venom until the supernatant fluid, after centrifugalization, ceased to have any effect on red cells. This fluid was then brought into contact with leucocytes, when lysis without agglutination took place. If, however, washed leucocytes were treated first, the supernatant fluid was found to be actively hæmolytic. They therefore concluded that the hæmolysins were distinct from the leucolysins, but that the agglutinins were probably the same.

We are not aware of further researches as to the nature of the leucolysins, though obviously such researches are required.

(*c*) *Hæmorrhagin.*—Weir Mitchell and Reichert, by observing a mesentery moistened with crotalus-venom, came to the conclusion that the blood escaped from the vessel owing to damage to the wall.

Flexner and Noguchi found that by heating crotalus venom to 75° C. for thirty minutes, this hæmorrhagic power was lost, and along with it most of the toxicity, as ten or twenty M.L.D. were required to cause death with symptoms resembling cobra-venom. They conclude that this death must be due to the neurotoxic or hæmatoxic properties (hæmolysins and agglutinins) in the venom, and that, as the latter can be eliminated without any apparent loss of toxicity, it must be due to the neurotoxins.

The toxic principle lost by heating to 75° C., Flexner and Noguchi called hæmorrhagin. They studied its action in the mesentery by injecting the venom into the peritoneal cavity, or placing a minute particle of the dried poison on the exposed mesentery, and then removing specimens, which they fixed in Zenker's fluid, cut into sections, and stained with hæmatoxylin and eosin. They found that the extravasation of blood took place not by diapedesis, but through actual rents in the walls. These rents are not simple ruptures, but are apparently due to a cytolytic action upon the endothelial cells of the capillaries and the walls of the small veins.

(*d*) *Other Cytolysins*.—Flexner and Noguchi have found that the amboceptors in venom can act upon a number of the cells of the body—*e.g.*, liver, kidney, testicle, and ovary—causing lysis, the complement being probably either endocellular or in the lymph-stream. The nature of the complement is, however, quite unknown at present, but is probably different from the complement acting on the red cells, as its activity is destroyed by heating to 60° C. for some time. The histological effects of these toxins can be noted particularly in the microscopical appearances in the liver and kidney. The liver shows necrosis and fatty degeneration of its cells, and, as a reactionary process, leucocytic infiltration around the bile-passages. In the kidney, the glomeruli show intense congestion of their capillaries, often associated with ruptures of their walls and hæmorrhage into Bowman's capsule. The cells of the tubules are necrotic and detached, filling the lumen. The whole organ is congested, and there may be interstitial hæmorrhages. The spleen is but slightly affected.

4. ANTIHÆMOLYSINS.—Weir Mitchell and Stewart have shown that if crotalus-venom is added to red corpuscles in a certain degree of concentration, no hæmolysis takes place. This fact has been confirmed by Myers and Stephens for the cobra, and Lamb for *Vipera russellii*.

Noguchi believes that the action is due to venom having the power in certain cases of precipitating the outer layer of the hæmoglobin, while in other cases this does not take place.

5. ANTIBACTERICIDAL SUBSTANCES.—Weir Mitchell drew attention to the fact that bodies of animals dead from crotalus poisoning rapidly decomposed, while Ewing found that the normal germicidal power of the serum was destroyed—a fact confirmed by Martin.

Flexner and Noguchi also investigated this action, and came to the conclusion that:—

(1) All venoms, when used in suitable quantities, destroy the bactericidal properties of many normal sera.

(2) The manner of this destruction consists in the fixation of the serum complements by the venoms.

(3) Venoms have no action upon the intermediary bodies of the serum.

6. FIBRIN FERMENT.—A fibrin ferment has been shown by Martin to be present in the venoms of the viperidæ and also of some of the colubridæ. In the former it is the active agent which causes the vascular clotting in small animals, with convulsions and sudden death. This coagulative substance has been shown by Barratt to be a thrombin.

7. ANTIFIBRIN FERMENT.—An antifibrin ferment—that is to say, a substance which in minute quantities is able to prevent the coagulation of the blood—is found in cobra and allied venoms.

8. PROTEOLYTIC FERMENT.—Venom contains a body of some description, probably a ferment, which is capable of transforming proteid.

Thus, Mitchell and Reichert long ago showed that muscle-fibres at the site of the bite were quickly softened by crotalus-venom, and Flexner and Noguchi have shown that gelatin is liquefied by both crotalus- and cobra-venoms, but that coagulated proteids are not acted upon. Microscopically the muscular fibres at the site of the bite are seen to have undergone necrosis and degeneration, and later a polymorphonuclear leucocytic infiltration may be noted.

9. CARDIAC AND VASCULAR TONIC.—Sir Lauder Brunton and Sir Joseph Fayrer showed that the poisons of the cobra had a stimulant effect on the heart, and that the circulation could be kept going for a long time after complete failure of breatning if artificial respiration is kept up—a fact of considerable importance if any antidotal treatment is available.

It is not clear whether this is due to direct action on the muscles of the heart, but it appears from Rogers' experiments that the effect on the bloodvessels is due to local action on the arterioles. This effect is produced by the cobra and *Vipera russellii* venom.

Entry of the Venom into the Body.

The poison, the characters of which have been described, is introduced into the body of man or that of an animal usually by the snake biting the skin and injecting the poison either subcutaneously or into a vessel. In the former case it will soon reach the bloodstream, and be distributed to the different parts of the body.

The effect of entry into a bloodvessel is to produce immediately the signs of the poisoning, whereas in the subcutaneous tissue it may take some time, and even be modified, especially in the viperine type.

The quantity injected by a cobra, according to Acton and Knowles, during the first strike, is 0·172 gramme (*i.e.*, $\frac{10}{16}$ of total venom in gland); during the second 0·1215; after which it steadily diminishes until it is not fatal to man (probably) about the seventh or eighth strike. Echis injects $\frac{10}{11}$ of total venom during first strike.

If the venom falls on the conjunctiva it is readily absorbed, and symptoms of poisoning will ensue, or an acute inflammation be set up.

Taken by the mouth, the venom of the colubridæ is harmless, provided there are no cracks or abrasions, and is destroyed by the saliva and pancreatic juice. Viperine venom, on the other hand, causes gastritis, gastro-intestinal hæmorrhage, and even death, without the appearance of the usual symptoms, a fact known to the natives of Ceylon with regard to the venom of *Vipera russellii*.

Minimum Lethal Dose (M.L.D.).

The minimum lethal dose varies with the species of snake, the condition of the snake, and with the species of the victim.

Tables are given by Calmette, and Martin and Lamb, showing the amount for different snakes and animals. Thus, the quantity of cobra-venom required to kill a kilogramme of a dog is 0·0008 gramme, and of a rabbit 0·0005; and that of *Bungarus candidus* for a rabbit is 0·0008 gramme, and that of *Enhydrina valakadien* for a rabbit is 0·00006 gramme, while the same for a cat is 0·0002. Putting it in another way, 1 gramme of cobra-venom will kill 1,250 kilogrammes in weight of a dog, 2,000 of rabbit, 2,500 of guinea-pig, 1,500 of rat, and 8,333 of mouse, and 20,000 grammes of horse.

Calmette calculates that, taking a man of average size, the minimum lethal dose might be halfway between the dog and the horse—*i.e.*, would be 0·015 gramme of cobra-venom—and 1 gramme will kill 10,000 kilogrammes of man, or 165 persons of the weight of 60 kilogrammes; but, of course, this is only a very approximate guess. Lamb calculates the M.L.D. for man to be 0·015 gramme of cobra-venom, and Fraser puts the same at 0·031 gramme, while other authors give cobra M.L.D. for man 0·010 gramme and echis M.L.D. the same figure.

Lamb gives a number of minimum lethal doses for snakes calculated per kilogramme of rabbit and injected intravenously, which are:—

Bungarus candidus	0·00004 gramme.
Enhydrina valakadien .	0·00005 ,,
Vipera russellii	0·0001 ,,
Naja tripudians and N. bungarus	0·00035 ,,
Bungarus fasciatus	0·0007 ,,

Effects of the Venom.

The effects of the venom have been carefully studied on warm and cold blooded animals by many observers for a long series of years, but there is a distinct difference in the action of different kinds of venom, and therefore it is as well to discuss the effect of each separately.

In doing this it will be noted that it is difficult to obtain undoubted cases of bites by definitely known snakes in man, and even when these are obtained the urgent necessity for treatment causes the symptoms to be little noted. Therefore it is necessary to detail first the experiments on animals, and then the symptoms found in man.

Colubrine Venom—*Naja tripudians* Merrem.—The experiments of numerous observers show that the effects of this venom on animals are:—

1. Paralysis of voluntary movement.
2. Salivation.
3. Marked effect on the respiration, which ceases before the heart.

In smaller quantities the paralysis becomes more marked, and in cases of longer duration several features are added:—

1. Local inflammation where the bite was inflicted.
2. Lachrymation.

3. Mucous discharges from the nose, respiratory organs, and stomach.

4. Very occasionally the mucous discharges are stained with blood.

Beyond obvious pain, the local effects are engorgement of the vessels with blood, and effusion into the tissues. If the animal recovers, there may be suppuration and sloughing of the affected part. The effects on the nervous system seem to be due to the action of the poison on the brain and spinal cord, and *pari passu* on the motor nerve endings. The most evident paralysis is that of the tongue, larynx, and pharynx, as evinced by the inability to retain the saliva within the mouth, to move the tongue, or to swallow. This is due to the action of the poison on the medulla.

There is also, as indicated above, clear evidence of action upon the respiratory centre, which has been carefully studied by Wall and others, who show that in large doses there is a progressive slowing, and in smaller doses first acceleration and then slowing of the respirations. There appears to be but little effect upon the heart and circulation or temperature.

The effect on the blood in causing hæmolysis was first demonstrated by Cunningham, who considered it the main feature. Not merely are the corpuscles dissolved, but the coagulability is reduced, and hence the blood-staining of the tissues and the urine in experiments on animals, provided that artificial respiration is kept up.

The effects of the venom on man are local pain in the neighbourhood of the bite, which appears as two small punctures about ¾ inch apart, usually exuding a blood-stained fluid. The pain increases in severity, and spreads up the limb on to the body. In a short time the victim feels intoxicated, and presently loses control of his legs, which become paralyzed, as may other muscles, including those of the jaw. There is often profuse salivation, and inability to speak or swallow. The pulse and respirations increase for a time, and then the breathing becomes slower, and death occurs from failure of the respiration, while the heart continues to beat for a short time after the respirations have ceased.

If recovery takes place, the urgent symptoms abate, some slight fever and local swelling occurs, while a large amount of urine is passed.

When examined post mortem, it will be found that the rigor mortis is well marked, while the blood is fluid in man, but coagulated in animals. If the corpuscles are examined soon after death, no change will be noted, but later they alter, and blood-crystals, indicating hæmolysis, may form. The parotids may be swollen. The brain is normal, but the pia mater is gorged with blood. The muscles are often of a dirty red colour. The lungs in human beings are generally congested, and the bronchi and smaller tubes filled with thin frothy fluid and intensely congested. Particles of food or remedies are to be found in the air-tubes because of the paralysis of the larynx. The right heart is distended with blood. The liver is congested and dark. The kidneys may be normal or intensely congested. The intestines show nothing in particular. The bladder is contracted

Microscopically, fatty degeneration of the liver and kidney, and necrosis of hepatic and renal epithelium, are to be seen, as well as round-celled infiltration along bile-ducts, which is probably due to excretion of poison.

Turning now to the colubrine snakes, which resemble the cobra, there are observations upon *Naja haje*, *N. bungarus*, *Bungarus candidus*, *B. fasciatus*, and the *Hydrophidæ*.

Naja haje Linnæus.—Calmette records that Dr. Deschamps observed a case of this bite in Senegal in which the snake bit the patient in the forehead. Almost immediately great weakness, accompanied by nausea and pains in the head and neck, set in. Locally two raised areas were seen, around which the tissue was œdematous. Cold sweats occurred. The œdema spread to the face, dyspnœa appeared, and the pulse became small and intermittent, paralysis set in, and the patient became comatose, but recovered on treatment with antivenene.

Naja bungarus Schlegel.—*N. bungarus*, the hamadryad, is by far the biggest of the Indian poisonous snakes. Rogers finds its venom very like that of the cobra, producing paralysis and death from failure of respiration, while the heart continues to beat for a time.

There is no intravascular clotting, and the hæmolytic action is very slight, but the phrenic nerve-plates are paralyzed. If small doses are given, the respirations are increased.

We are not acquainted with the symptoms exhibited by an undoubted case of this bite in a human being.

Bungarus candidus Linnæus.—As to *B. candidus* L., the commonest of all Indian snakes, there is not much to say, except that all researches (Fayrer, Wall, and Rogers) indicate that its venom is almost exactly the same as that of the cobra, but is slightly more virulent.

Cases of this bite are common. In brief, the symptoms are:—a sense of tightness across the chest, with paralysis, particularly of the muscles of the face, deglutition, and phonation. The conjunctivæ are suffused, the pupils dilated, the pulse and respirations quickened; the temperature is normal, and the local signs are not marked.

Coma and convulsions precede death, which is due to failure of respiration. Congestion of the meninges and brain and liquid blood are the principal signs found post mortem.

Bungarus ceylonicus (Günther).—*B. ceylonicus*, the Ceylon krait or carawalla, has been reported by Green to have killed a man in twelve hours. The man was bitten on the left foot at 4 a.m., and felt quite well till 5.30 a.m., when he felt drowsiness, which increased till 10 a.m., when he could hardly swallow and was very sick. Paralysis affected his legs, and he became cold. Artificial respiration was now resorted to, but at 2 p.m. he became very feverish and insensible, and died at 4 p.m.

Bungarus fasciatus Schneider.—The effects of the poison of *B. fasciatus* have been carefully studied by Wall, Lamb, and Rogers.

In acute cases death takes place quickly from failure of respiration; the blood is coagulated, and there is paralysis, and sometimes convulsions.

Chronic cases, on the other hand, last for days, during which there is loss of weight and emaciation, and perhaps some paralysis.

Microscopical examination of the cortex of the brain, medulla, and spinal cord shows diffuse chromatolysis, affecting a very considerable portion of the ganglion cells, being most marked in the cortex, next in the cord, least in the medulla. The cells show a rather deeply stained plasma, in which are scattered dust-like granules, the remnants of the Nissl bodies; many cells show vacuolation of the plasma, and some are reduced to mere outlines (ghost cells).

Rogers' experiments tend to show that even in injecting large doses the blood may not clot, and that the animal may be killed, as in cobra-venom, by direct action of the poison on the respiratory centre, and also on the nerve-endings of the phrenics, so that the venom appears to be a mixture of a viperine with a colubrine poison.

The only authentic case of human poisoning by *B. fasciatus* is mentioned by Fayrer, in which there was tingling sensation and later pain at the seat of the punctures, with some swelling, all of which disappeared in less than twenty-four hours.

Australian Snakes.—The symptoms produced by the bite of the Elapinæ in Australia are local swelling and pain, followed in from fifteen minutes to two hours by constitutional symptoms. The patient becomes unable to stand, signs of prostration, accompanied by vomiting, appear. The circulation begins to fail, the heart's action becomes weak, the extremities cold, and the skin blanched, while the respiration, after a preliminary excitation, becomes slowed. Coma now intervenes, the sensations being diminished and the pupils dilated, and death results from failure of the respiration, preceded sometimes by convulsions. The heart continues to beat after the circulation has ceased.

Elaps fulvius, the harlequin snake, which is found in the eastern parts of the Southern United States, causes great local pain, followed in one hour by drowsiness, unconsciousness, and collapse, lasting until death, or for a day or so if the patient recovers. Death usually ensues in about twenty-four hours after a bite, and in persons tending to recovery the danger of death is not escaped until three to four days have passed away, as the symptoms tend to recur periodically.

Spitting Snakes.—The known spitting snakes—*i.e.*, snakes which can project their venom to a distance—are *Sepedon hæmochates*, *Naja flava*, and *N. nigricollis*, *N. tripudians*, *Echis carinata*, with perhaps the addition of *Naja melanoleuca* and *Vipera russellii*; and it is possible that further observations will show that all the Colubridæ and Viperidæ have this power to a greater or lesser extent. Of course the action is not spitting in the correct sense of the word, but merely projection of venom, which causes conjunctivitis if it enters the eyes, and a saltish taste if it enters the mouth.

The Hydrophidæ.—Rogers experimented with *Enhydrina valakadien* Boie, *Distera cyanocincta* Daud., and *Hydrophis cantoris* Gthr., and came to the conclusion that their venom only differed from that of the cobra in the following points:—

1. They were more toxic.
2. They were much less hæmolytic, and hence caused no blood-stained effusion at the site of the injection.
3. They did not affect the coagulability of the blood; therefore the poison is almost purely neurotoxic.

There is at first an excitation of the nervous system, leading to a feeling of activity and vivacity, which, however, soon passes off. The earliest signs of distress begin with difficulty of articulation and feeling of stiffness in the body and of suffocation. The stiffness in the muscles increases, and occasional spasms occur, while signs of gastric irritation, with vomiting, appear. Convulsions and death may ensue after a day or so. The local signs may be slight.

Viperine Venom.—*Vipera russellii* Shaw, the *tic polonga* of Ceylon, is a good example of this type of venom. Wall's experiments show that a dog bitten by one of these vipers will become convulsed, and die within five minutes. The cause of this sudden death has been shown by Rogers to be intravascular clotting, which is best marked in the portal vein, and then only in small animals. Post mortem, there are hæmorrhages into the area of the bite, and into kidney and intestine.

In addition to these acute cases, there are also chronic cases, in which the local symptoms are more or less extensive subcutaneous hæmorrhages, around which there is much œdema. This hæmorrhage may be absorbed, or the area may slough, or an abscess, or even a spreading gangrene, may ensue.

The general symptoms are rapid emaciation, profound anæmia and lethargy, and in some cases hæmaturia and a discharge of blood from the bowel.

Rogers has carefully investigated these symptoms, and has pointed out that there is a remarkable fall of blood-pressure due to vaso-dilatation of the portal system, caused by action of the poison on the central, and not the peripheral vasomotor apparatus, the heart muscle being unaffected. Lamb and Hanna showed that in chronic cases there is deficiency in the blood coagulability.

In man there are the two small punctured wounds caused by the fangs, around which the skin is swollen and livid and painful. The swelling and discoloration spreads, and in the course of twenty-four hours the patient becomes at first excited, with thready pulse and hurried respirations, and later stuporous. The skin is clammy and covered with a cold sweat, while the swelling and discoloration spreads considerably, reaching the trunk. In due course convulsions set in, and death ensues from failure of the circulation. The post-mortem reveals congestion of the meninges and lungs with fluid blood, and nothing else of importance.

Bitis arietans.—The puff-adder poison was found by Rogers to work in much the same manner as that of *Vipera russellii*, but not to be so poisonous.

Echis carinata.—This is a very poisonous snake, and the effects of its bite resemble that of the cobra.

Wall records a case in which there was much local swelling, passage of blood in the urine, fæces, and vomit, elevation of temperature, and death from exhaustion, due to loss of blood, on the ninth day. Martin and Lamb record another case in which there was much swelling of the bitten part, due to exudation of liquid blood. Pain and tenderness were felt along the nerves, together with anæsthesia, extreme restlessness, with cold and clammy extremities, but no hæmorrhages. Loss of consciousness, with delirium, set in only a short time before death, which took place at the twenty-fifth hour.

Fayrer gives a good account of a chronic case, in which there was depression and faintness, coldness of the extremities, with swelling of the affected part, and marked hæmorrhages from eyes, gums, throat, nose, vagina, and under the nails.

The Crotalidæ are typically represented by *Crotalus horridus* of America, which has been carefully studied by Weir Mitchell and Reichert, and by *Lachesis*, which latter has been studied by Rogers in India.

Crotalus horridus.—The local effects are: —œdema, swelling, darkening of the parts with infiltration of incoagulable blood, breaking down of the tissues, putrefaction, and sloughing. There is no clotting of the blood, which, on the other hand, is fluid and incoagulable. There is a marked fall of blood-pressure, and respiration gradually ceases, due to the failure of the circulation, but there is no direct effect on the respiratory centre, and the phrenics are not paralyzed. The heart goes on beating after respiration ceases, but is slightly weakened. Post-mortem examination shows hæmorrhages into the peri- and endo-cardium, and into the peritoneum and pleura, but not in the brain or the medulla, while the whole portal system is much congested.

Rogers placed a loop of small intestine in an oncometer, and found that fall of blood-pressure was associated with a vaso-dilatation of the portal system, in which the blood was not clotted. This vaso-dilatation he considers may possibly be due to the action of the venom on the vasomotor centre in the medulla, and thinks that he is supported in his theory by the appearance of Traube-Hering curves in his blood-pressure tracings. Pearce notes acute glomerular lesions due to the endothelialytic body.

Weir Mitchell and others have carefully collected the symptoms following this bite. In most instances the bite is painful, and the part becomes swollen and discoloured, while both the pain and the swelling increase steadily. The swelling is due to the effusion of blood. Very seldom is there any lymphangitis or enlargement of the lymphatic glands. Vesication, sloughing, and gangrene may result if life is prolonged and the dose considerable. If, on the other hand, the amount of poison injected is inconsiderable, the swelling declines, and the pain disappears very quickly. Constitutional symptoms are said by some people to begin directly after the bite, but this is hardly likely, as man is a relatively large animal. Under exceptional circumstances it is recorded that the symptoms did not begin till about thirty minutes after the bite, but usually the length of time is only a few minutes. The person feels extremely faint, or complains that his lower limbs are not able to support him. There is no primary stimulating effect like that mentioned in other venoms. The patient staggers or falls, cold sweats bathe the surface of the skin, and nausea and vomiting occur. The pulse is rapid and feeble, the expression anxious, and, according to Mitchell, in a few cases the mind may be slightly disturbed, but this may be largely due to fear. If the patient does not die at this stage, the local symptoms mentioned above become very pronounced, and signs of general blood-poisoning show themselves, and often lead to death.

The post-mortem reveals that the brain is normal, but congested and somewhat œdematous; the trachea and bronchi are congested, and full of red frothy mucus; while the lungs are healthy, but somewhat congested. The peritoneum may contain a little fluid, and the mucosa of the stomach and small intestines may be intensely congested and infiltrated with serum. In some cases the blood is coagulated, in some it is fluid. The local swelling is due to serous exudation. The chief features of the post-mortem are vaso-dilatation of the portal system and fluidity of the blood.

Lachesis.—This snake shows the same symptoms as *Crotalus*, but it has some effect upon the respiratory centre, causing quickening of respiration before the slowing begins. The phrenics are not paralyzed. Moreover, it is possible that the first quick fall of blood-pressure observed is due to action of the poison on the heart, but the subsequent steady fall is due to the action on the vasomotor centres, as in *Crotalus*.

Kitajima says that the region of the bite becomes dark purple in colour and swells; that the pain is severe and burning; and that the lymph glands become enlarged and tender. The face is pale, the pulse feeble and rapid. Respiration is normal; a slight fever is not infrequent. Coldness of the extremities, with dyspnœa and cold sweats, come on just before death. Blood has been observed in the urine and fæces.

Excretion of the Poison.

It is believed that the poison leaves the body principally by the kidney, and to a less extent by the mucosa of the stomach, the salivary and mammary glands.

With regard to the kidney, there is some direct proof of the excretion, because the urine of a dog poisoned by *Enhydrina valakadien*, when injected hypodermically into a pigeon, caused death in twenty-two hours.

It is also stated that 1 drachm of the saliva of a dog poisoned by a cobra was capable of causing death in two hours.

With regard to excretion by the mammary glands, an infant is said to have died after sucking the breast of a woman bitten by a poisonous snake.

Immunity.

Having considered the chemical composition and physiological action of the venom, the next point to be discussed is immunity to its action.

Ancient and modern peoples have equally held the belief that a person who has been bitten by a poisonous snake and survived obtains some sort of immunity; generally the belief has been that this immunity is capable of protecting the individual against all kinds of snakes.

Ancient fables credited the Psylli of Africa, the Marsi of Italy, and Gouni of India, with immunity, on the ground that they had snake's blood in their veins.

The pig was long thought to be naturally immune; but this is a mistake, for the relatively slight effect of snake-venom is due to the presence of the thick layer of but slightly vascular fat which surrounds the animal's body. The mongoose (*Herpestes ichneumon*) is believed to be naturally immune to cobra-bite.

Acquired immunity is said to occur among natives, especially snake-charmers, and Europeans who have been bitten several times by snakes. The Eisowy of Western Barbary are said to have acquired such an immunity, and to allow themselves to be bitten by snakes proved afterwards to be poisonous by killing a fowl. The natives of Bushmanland, Namaqualand, and Damaraland are said to drink the venom of snakes as a protection. In Ceylon a cobra is said to have bitten a snake-charmer, and shortly afterwards a bystander. The snake-charmer escaped without symptoms, the bystander died.

The first scientific attempt to produce an artificial immunity was made by Sewall in 1887, when by repeated small injections he raised the resistance of pigeons so high that they were able to resist ten times the minimum lethal dose of the venom of a *Crotalus*. Kanthack also produced a partial immunity to cobra-venom in 1891. Kaufmann, a little later, obtained a similar result with the French viper.

In 1892 Calmette showed that by repeated inoculation of venom heated to 80° C. a certain amount of resistance was produced in animals. In 1894 he made researches on the venom of the cobra, and about the same time Phisalix and Bertrand investigated that of the viper, and showed that animals vaccinated with venom developed a true immunity, and those inoculated against the cobra-venom were able to resist mortal doses of *Vipera, Bungarus, Cerastes, Naja haje,* and *Pseudechis* venoms. Later they showed that the serum of an animal vaccinated by snake-venom contained antitoxins capable of producing an immunity in new animals.

Calmette obtained his serum from horses, but with great difficulty, as many of the animals died in the course of treatment from endocarditis and acute nephritis, while in others abscesses formed.

He found that in a fresh horse 0·025 gramme of cobra-venom was sufficient to kill the animal in twelve to twenty-four hours, but on vaccinating the animals for sixteen months, it was found that a horse could stand without reaction the injection of 2 grammes of cobra-venom—*i.e.*, eighty times the M.L.D.

From such a horse it was found possible to withdraw as much as 20 litres of blood in three bleedings spread over ten days, the serum being considered to be ready for use when 1 c.c. mixed with 0·001 gramme of cobra-venom produced no sign of intoxication when injected subcutaneously into a rabbit, and when, after injecting 2 c.c. of the serum into a rabbit of 2 kilogrammes weight, two hours later 1 milligramme of venom could be injected without results. This serum was said to preserve intact its antitoxic value in all climates The venom used for these injections was principally that of the cobra, with a slight admixture of other venoms.

In 1895-96 Fraser of Edinburgh confirmed Calmette's results, and believed that if an animal was so successfully vaccinated that it could resist the minimum lethal dose of one venom, it would also be able to resist that of other venoms. He believed that venom introduced into the stomach conferred immunity.

In 1897 C. J. Martin showed that Calmette's serum did not preserve animals against the venom of *Notechis scutatus*.

From 1901 onwards Lamb in India studied carefully the effects of snake-venoms, and came to the conclusion that Calmette's serum is active against cobra-venom, but is not useful against that of *Vipera russellii*, *Bungarus fasciatus*, or of *Echis carinatus*.

In 1902 Tidswell showed that serum prepared from the venom of *Notechis scutatus* did not neutralize the venoms of the cobra, *Bungarus fasciatus*, or *Vipera russellii*, and, further, had no effect on the venoms of the brown and black snakes and death-adder of Australia.

In the same year Lamb pointed out that there was a precipitin in venom-immune sera, and this point being further investigated by Hunter, the deduction was made that these precipitins were specific, and due to the coagulable proteids.

The following pure sera have been prepared:—

1. *Lamb's Pure Naja tripudians* Merrem *Serum.*—This serum is strongly antitoxic for cobra-venom, and in large doses for *Enhydrina valakadien* Boie, but has no effect upon *Bungarus candidus* L., *Brachyaspis curta* Schleg., *Echis carinatus* Schn., *Lachesis gramineus* Shaw, *Vipera russellii* Shaw.

It delays death in *Bungarus fasciatus* Schn., *Naja bungarus* Schleg., *Crotalus durissus* L.

2. *Lamb's Pure Vipera russellii* Shaw *Serum.*—This serum

neutralizes the venom of *Vipera russellii* and *Crotalus durissus*, but has no action upon—Colubridæ: *Naja tripudians* Merrem, *N. bungarus* Schleg., *Bungarus candidus* L., *B. fasciatus* Schn., *Enhydrina valakadien* Boie; Viperidæ: *Echis carinatus* Schn., *Lachesis gramineus* Shaw.

3. *Tidswell's Pure Notechis scutatus* Ptrs. *Serum.*—This serum has a strong antitoxic effect upon the venom of *Notechis scutatus*, but has no effect upon that of—Colubridæ: *Naja tripudians* Merrem, *N. bungarus* Schleg., *Bungarus candidus* L., *B. fasciatus* Schn., *Enhydrina valakadien* Boie; Viperidæ: *Vipera russellii* Shaw, *Echis carinatus* Schn., *Lachesis gramineus* Shaw, *Crotalus durissus* L.

4. *Noguchi's Pure Crotalus Serum.*—It has a strong effect upon *Crotalus* venom, and a slight effect upon *Ancistrodon piscivorus* Lacép., and none on the cobra.

5. *Noguchi's Pure Ancistrodon piscivorus* Lacép. *Serum.*—This has a marked effect upon moccasin-venom, and medium effect upon *Crotalus*, and none on cobra-venom.

6. *Brazil's Pure Crotalus horridus* L. *Serum.*—This serum is equally efficient for the venoms of *Crotalus horridus* or *C. durissus*, but is useless for cobra-venom.

The Caracas Commission reports that this serum is more efficacious against the venom of *Crotalus* than that of Calmette, which fails to neutralize the hæmorrhagins.

7. *Kitajima's Pure Lachesis flavoviridis* Hallow *Serum.*—This serum is specific for *Lachesis* venom, against which Calmette's serum is useless.

It is clear that the antisera mentioned above are very nearly specific, for they neutralize principally the venom of the species employed, and sometimes, in larger doses, that of some allied species.

It is obvious that this is of great importance in considering the serum treatment of snake-bite.

8. *Polyvalent Sera.*—Polyvalent sera prepared for more than two venoms are not very efficacious.

Diagnosis.

It might be thought that the diagnosis of snake-bite would be obvious, and that nothing need be written on the subject, but this is not always so, because snake-bite often takes place in the dark, and the nature of the snake is unknown.

The diagnosis may be divided into two heads:—(1) Has a snake bitten the person? (2) Was the snake a poisonous one?

The first thing to do is to tie a proximal ligature on the limb, and then to examine the area of the supposed bite. If there are absolutely no fang-marks and no venom on the skin, then obviously there is no danger; but fang-marks on the skin, or venom on mucous membranes (which, of course, may have cracks), or on skin with scratches, may be dangerous.

If there are no fang-marks, and the snake is forthcoming, examine it to see whether it is poisonous or not, especially to see whether there are fangs, and if non-poisonous, the patient's mind can be relieved at once.

Prognosis.

It appears that only a relatively small percentage of persons bitten by snakes (supposed to be poisonous) die. C. J. Martin and Lamb place it about 30 per cent., but much depends upon the quantity of venom injected and the rapidity with which symptoms develop. The recoveries from full doses of echis-venom in untreated cases is about 40 per cent., and of cobra-venom only 3 to 4 per cent. Personally, we believe that in most cases if treatment has been prompt, and the symptoms appear slowly, the outlook is by no means hopeless.

Treatment.

Snake-poisoning consists in the hypodermic or intravascular injection of a series of poisonous principles which act chiefly upon the nervous system and the blood.

The virulence of the poisoning depends upon the ratio of the quantity of the poison injected to the size of the animal. The same quantity of poison will therefore have a more serious effect upon a child than upon an adult. The less the quantity of poison which gets into the general circulation, the less the symptoms; hence the first indication for treatment is to prevent the passage of the poison, as far as possible, into the circulation.

The second indication for treatment is to neutralize the poison which has got into the system, and the third indication is to treat special symptoms as they appear.

1. **Prevent the Poison getting into the General Circulation.**—In order to prevent the poison getting into the general circulation, three points must be attended to:

(1) Stoppage of the flow of blood and lymph from the affected area.
(2) Free opening of the poisoned area.
(3) The neutralization of the poison locally.

(1) *Stoppage of the Flow of Blood and Lymph from the Affected Area.*—A person is usually bitten in the arm or leg, and in such a case the old treatment advised by Celsus should be carried out by applying a tight ligature round the affected limb on the proximal side of the wound, so as to compress the blood and lymphatic vessels. In order to do this successfully, the ligature must be applied to the arm or the thigh—*i.e.*, where there is one bone—and not the forearm or leg.

Such a ligature cannot be left in position indefinitely, otherwise gangrene will result; and after some attempts at neutralization of the poison have been made, it must be loosened for a couple of seconds and reapplied, and this must be repeated. It must be kept on for at least twenty or thirty minutes.

The advantages of the ligature or tourniquet have been known since ancient times, but C. J. Martin has shown that its principal action with colubrine poison is not merely to delay the absorption of the poison, but also to give time for any already absorbed to be excreted. In the viperine poisons, which coagulate the blood by fibrin ferment, it is most beneficial; for the blood, in coagulating locally, retains the poison, which therefore but slowly passes into the general circulation, and may, as Martin and Lamb suggest, unite with the cells near the bite.

There is therefore no doubt that the correct immediate treatment in a bite due to any kind of poisonous snake on a limb is the application of a proximal tourniquet.

(2) *Free Opening into the Poisoned Area.* -It will be obvious that the two minute punctures caused by the fangs are not sufficiently large openings into the area of the bite for the application of antidotes.

Therefore the next step is to cut, not merely round the apertures of the fangs, but also to extend the incision along the course of the veins and lymphatics, and in some cases to remove the piece of skin marked out. In this way the area of inoculation is freely opened.

(3) *Neutralization of the Poison Locally.*—The next indication is to diminish the toxicity of the poison as much as possible, and to do this the best remedy we at present possess is *permanganate of potash*, though recent laboratory experiments have thrown some doubt upon its efficacy.

This should be used in strong solution, and not as a solid, as the liquid penetrates better into the interstices of the wound, which should be well washed with it. For carrying out this treatment a most useful little case has been devised containing a little lancet for making the wound, and permanganate crystals for making a solution. This little case only costs a few pence, and can be carried without any inconvenience in the waistcoat pocket, and therefore should be carried by everyone in countries where poisonous snakes abound, especially when on business or pleasure in jungles or grassy places. Should there be no water available to make a solution, then the crystals can be rubbed into the wound.

If the bite is on the head or trunk, the incision should be made as above, and the resulting wound thoroughly soaked with permanganate of potash solution (3 per cent.). The subcutaneous tissue must be freely opened, otherwise the permanganate may be prevented from doing its work properly.

The after-treatment should be boric fomentations, frequently repeated at first; but if there is no marked swelling of the part, these may be gradually, not quickly, diminished in number, and finally a mild antiseptic dressing should be applied until the wound heals.

2. Neutralization of the Poison in the System.—We have already endeavoured to impress on the reader the following facts:—

(1) The specificity of snake-venom.

(2) The inutility of an antiserum prepared for one venom against another venom.

It now remains to consider these subjects from a practical point of view.

The serum most readily obtained is Calmette's, in 20 c.c. and 50 c.c. phials standardized against cobra and *Vipera russellii* venoms, and prepared by the immunization of horses against these venoms, as well as those of *Bungarus* (krait) and *Enhydrina* (sea-snake). Reliable sera are also prepared by the Indian Pasteur Institute of Kasauli for the venoms of the cobra and Russell's viper.

All these sera, unfortunately, deteriorate quickly unless kept in a dark and cool place, and, further, must be used in large doses, for even when fresh, 1 c.c. will only neutralize 1 milligramme of cobra-venom. A healthy cobra when it bites may inject from 250 to 350 milligrammes of venom, of which the minimum lethal dose may be estimated at 15 to 17·5 milligrammes for a person weighing 60 to 70 kilogrammes; therefore at least 350 c.c. of the antivenene must be injected intravenously, or ten to twenty times that amount must be injected subcutaneously—*i.e.*, from 3,500 to 7,000 c.c.

The antivenene, of course, will succeed in much smaller doses if a small quantity of venom has been injected, and will fail if the quantity be large. Therefore the obvious indication is to begin with 100 c.c. of antivenene, injected hypodermically, or far better intravenously, and to repeat this several times if necessary. The technique for the intravenous injection is as follows:—

An all-glass syringe should be carefully sterilized by boiling, and the skin over the vein must be cleansed with 1 in 40 carbolic and with absolute alcohol; a band should be tied round the arm, so that the vein shows up clearly, and the needle should be inserted with the aperture pointing proximally—*i.e.*, towards the heart—and should be felt free in the vein. The ligature should then be removed and the serum slowly injected. On removal of the needle, an antiseptic pad and bandage should be applied.

If, on the other hand, the species of snake which inflicted the wound is known, and the particular serum for that animal's venom happens to be available in good condition, then it should be used intravenously.

3. **Treatment of Special Symptoms**—(1) *Failure of the Respiration.*—The experiments of Fayrer, Brunton, and Rogers seem to indicate that in cases of poisoning due to cobra and sea-snake venoms artificial respiration should be resorted to when natural respiration is failing and medical aid or remedies are being sent for.

(2) *Failure of Circulation.*—In poisoning due to viper-venoms, which produce, according to Rogers, a paralysis of the central vaso-motor centre, he recommends that:—

(*a*) A binder should be applied to the abdomen and bandages to the legs, so that as much blood as possible may be available for maintaining the circulation of the brain and medulla.

(*b*) That hypodermic injections of adrenalin be used to constrict the peripheral vessels and to stimulate the vasomotor centre.

In both colubrine and viperine poisons it is obvious that the circulation should also be maintained by the applications of warmth, by stimulants, either alcoholic or ammoniacal, or by strychnine hypodermically.

Summary.—1. Apply proximal ligature.

2. Freely open the cellular tissue in the vicinity of the bite.

3. Wash the wound well with a strong solution of permanganate of potash (3 per cent.), or apply crystals.

4. Inject 100 c.c. of fresh antivenene intravenously.

5. Artificial respiration, if necessary.

6. Keep up the circulation by binders to abdomen, bandages to legs, stimulants, and hypodermic injections of strychnine.

Other Methods of Treatment.

Other methods of treatment which may be briefly mentioned are:—

Snake-Stones.—The cure which is strongly believed in by the native is the snake-stone. These stones are smooth, highly polished, very light, black bodies, said to consist of calcined animal bone soaked several times with blood, and calcined after each soaking. It is easy to understand that these stones are very hygroscopic, and when applied to a wound, cling tightly, and suck up fluids, and perhaps some poison. There are supposed to be three kinds of stones:—(1) Those composed of burnt bone; (2) those composed of chalk; (3) those composed of burnt vegetal substance. Of these three only the first is considered of value.

The method of use is as follows:—Puncture the wounds of the snake-bite slightly, and apply the stone, which adheres for about two minutes, and should then drop off into a vessel of water, after which it should be dried by a cloth, and applied again to the wound, when it will adhere for about a minute. It should be applied a third time. During application the limb should be rubbed towards the stone. The stones are used principally in India and Ceylon, but they are also known in Mexico as 'piedra ponsona.' It is hardly necessary to say that from the days of Redi it has been shown how useless these stones are.

Exorcism of the poison by shouting charmed verses is used in India. Numerous plants, seeds, earth moistened with urine, etc., have been extolled as cures.

Ammonia.—Of all the old remedies ammonia has lived the longest, and it is almost incredible that Fontana settled the question as to its lack of utility by his experiments on vipers more than 130 years ago. Whether given by the mouth, injected subcutaneously, or into a vein, it is useless, except as a stimulant, when it is certainly of no more use than alcohol. Fayrer has shown that if liquor ammoniæ is mixed in more than equal parts with venom, it does not destroy the poison.

Oils.—It is extraordinary how the remedies of the Middle Ages are clung to, and oil is still used, though known to be useless since the days of Morgagni.

Strychnine.—Many years ago Duncan recommended strychnine as a remedy for East Indian snake-bites. Recently Müller of Victoria, Australia, has strongly recommended the hypodermic injection of this drug. He says that never less than $\frac{1}{10}$ grain is to be used, and this must be increased in urgent cases to $\frac{1}{8}$ or $\frac{1}{4}$, and repeated every fifteen or twenty minutes, until the symptoms of snake-poisoning are removed. If a fang has perforated a vein, he recommends intravenous injection instead of subcutaneous The patient must be watched for twenty-four hours after the disappearance of the last symptoms, in order to combat a sudden relapse. Colonel Duke, in 1895, highly recommends this remedy.

Arsenic.—Arsenic is principally famous as the Tanjore pill, which was said to contain white arsenic and many other substances, but is quite useless.

Iodine.—Brainard's remedy was the injection of a solution of 10 grains of iodine and 30 grains of iodide of potassium, dissolved in 1 ounce of water, and probably owed its reputation to its caustic action.

Bromine was at one time considered a specific.

Caustics.—Fontana strongly advised caustics, which he considered to be useful, but long experience has shown their inutility.

Stimulants.—Brandy and whisky have been repeatedly vaunted, and so have sinapisms, warmth to the precordial region, and electricity along the spine, but all these are useless.

Energetic Movements.—Energetic movements, such as walking the patient about, flogging him, pinching him, have been advised, but are contra-indicated, as tending to exhaustion and to hasten the end.

Prophylaxis.

In the tropics Europeans and better-class natives seldom suffer from snake-bite, because they do not sleep on the ground, in the open or in small huts, like the lower-class native. Among the latter, however, any prophylaxis is difficult in regions such as India, because they reverence the cobra, and encourage it to take up its abode in their huts.

Gardens should be kept free from jungle or long grass, and gratings should be placed on the drains from bath-rooms, as snakes have often been found in these rooms.

Good strong boots and the puttee pattern of legging should be worn when going shooting or into the jungle. A lantern should be used when walking after dark, and the small permanganate case already mentioned should be carried in the waistcoat pocket in case of accidents.

LACERTILIA.

FAMILY HELODERMIDÆ Gray, 1838.

Synonym.—*Helodermatida* Fitz, 1843.

In the Helodermidæ there are two celebrated lizards—*Heloderma horridum* Wiegmann and *H. suspectum* Cope—which were placed by Sumichrast in the family Varanidæ, and though this may be disputed, still, it is probable that they are allied closely to that family.

GENUS HELODERMA Wiegmann, 1831

Heloderma horridum Wiegmann, 1834.

Synonym.—*Trachyderma horridum* Wiegm., 1829.

This lizard lives exclusively in Mexico in the hot zone which extends from the western slope of the Cordilleras to the Pacific. It inhabits the hot, dry districts of Jamiltepec, Juchitan, and Tehuantepec, where it lives in holes dug at the roots of trees or under vegetable débris. It is called 'escorpion' by the Creoles, and 'tala-chini' by the Zapotec Indians; and in 1651 Fernandez says it was called 'acastetepon' by the Mexicans.

When irritated, there escapes from its mouth a white, glutinous fluid, which is secreted by the large salivary glands. Its bite is much dreaded by the natives, who say that ill-effects are produced thereby and by eating its flesh. It may reach to a length of nearly five feet when old. We are not aware of observations on the bite or venom of this reptile.

Heloderma suspectum Cope, 1869.

Cope gave the lizard the name *suspectum*, because he suspected that its bite would be found to be poisonous. This lizard is found in the United States—in Arizona, Texas, Utah, New Mexico, and Southern California—where it is called the 'gila monster.' The poison apparatus consists of glands under the lower jaw and teeth in that jaw.

The poison gland in this species lies on either side of the lower jaw, and from its mesial aspect four ducts pass upwards, each towards its opening on the outer surface of the mandible, through which it passes obliquely upwards and inwards, to end at the base of a tooth near the termination of a groove.

The upper teeth are also grooved, but Schufeldt failed to find any gland wherewith they could be supplied with poison.

There appears to be no doubt as to the poisonous nature of the secretion from the glands above mentioned, for Bonberger records that a bite in the leg of a guinea-pig caused convulsions and death in three minutes.

Venom.—The venom was obtained by Mitchell and Reichert by making the lizard bite a saucer. It was found to be alkaline, with a weak smell, and to kill frogs, pigeons, and rabbits.

The effects of gila poison have been most carefully investigated by Weir Mitchell and Reichert, and by Van Denburgh and Wight.

The latter consider that it differs in no important respect from snake-venoms, causing death by acting rapidly upon the respiratory centre in the medulla, and causing paralysis of respiration. Its other actions are to first stimulate and then paralyze the heart by poisoning its muscular fibres. On inoculation, there is an immediate great fall of blood-pressure, but whether this is due to action on the vasomotor centre or not is not clearly known. There is a secondary gradual fall due to cardiac failure. The motor nerves and cells are not affected, but the sensory apparatus is at first rendered more irritable and then paralyzed. Coagulation of the blood is at first accelerated and then retarded, so that it may become incoagulable. Hæmolysis may occur. Local signs are almost nil, as a rule a little œdema and slight extravasation being present.

Symptoms.—Very severe pains radiating from the part, rapid swelling, faintness, profuse perspiration, may be noted

Treatment.—A proximal ligature should be applied if on a limb, and permanganate of potash, 1 3 in 100, should be used to bathe the wound, which, finally, should be dressed aseptically.

FAMILY LANTHANOTIDÆ Steindachner, 1877.

This family was formed for Lanthanotus Steindachner, 1877, which is the type genus. It is closely related to Helodermidæ.

Lanthanotus borneensis Steindachner, 1877.

This lizard, which is closely allied to *Heloderma*, is suspected of being poisonous, but there are as yet no proofs of this, especially as the teeth are not grooved, and there is doubt as to the presence of poison glands. Its habitat is Borneo, but it requires reinvestigation, as but few specimens are known.

MAMMALIA Linnæus.

The mammal suspected of causing poisoning is *Ornithorhynchus paradoxus*, belonging to the Monotremata.

MONOTREMATA Bonaparte, 1837.

Ornithorhynchus paradoxus Blumenbach, 1800.

As is well known, the males of this animal, which is only found in Australia, have large spurs projecting backwards from their hind-limbs. These spurs are hollow, and into them open the ducts of poison glands. The venom is an albuminous fluid containing albumoses.

Injected subcutaneously, it only causes local swelling, and the animal recovers in a few days. Injected intravenously, it causes fall in the blood-pressure and death from respiratory failure. The heart appears to be unaffected, but the blood in the venous system is found coagulated after death, which takes place in twenty-five to thirty minutes. The venom has no hæmolytic or proteolytic action.

The difference between the slight effect of the subcutaneous and the serious effect of the intravenous injection is thought to be due to the fact that the poison is but slowly absorbed.

In a man who was stung on the hand the symptoms were very severe pain, swelling in the hand, which rapidly spread up the arm, difficulty in opening the mouth, cold sweats, with severe sickness. Recovery took place in a few days as far as the general symptoms were concerned, but it was several weeks before the hand quite recovered.

The treatment has generally been ammonia, but the symptoms and the experiments point to a venom closely related to viperine poison, and we should recommend the proximal ligature and permanganate of potash—in fact, the treatment advocated for snake-bite.

O. paradoxus is often called *O. anatinus* Shaw, 1799.

CHAPTER XVII

PLASMODROMATA AND SARCODINA

Preliminary—Animal parasites—Nomenclature—Classification—Protozoa—Classification—Plasmodromata—Sarcodina—Gymnamœbida—Loeschia—Vahlkamfia—Dientamœba—Craigia—Thecamœbida—Chlamydophrys—References.

PRELIMINARY.

In tropical medicine the parasitic causes of disease are extremely important, and it is well to be clear as to the meaning of the term 'parasite.' A parasite is defined to be a living organism, animal or vegetal, which takes up its abode temporarily or permanently on or within other living organisms (called the hosts) for the purpose of obtaining food. Parasites may be divided into animal parasites and vegetal parasites, and it is with the former that we are concerned in this chapter.

ANIMAL PARASITES.

Animal parasites (zooparasites), in the process of obtaining their food, may cause disease by their mechanical action and chemical products, or by introducing into the host pathogenic micro-organisms.

As examples of the latter may be mentioned the transmission of the animal organism which causes malaria by certain members of a family of the mosquitoes, or that of the vegetal organism which is the cause of plague by certain fleas. Intestinal worms probably cause many of the symptoms of the disease with which they are associated by the introduction into the body of poisons through their bites, or, according to Sambon and other observers, by their active migrations before attaining maturity and reaching their selective anatomical habitat.

A well-known example of the irritation caused by the introduction of chemical poisons is the ordinary mosquito-bite already described, while *Trichinella spiralis* Owen, 1835, produces severe disturbance during its wanderings through the body.

Mechanically the jigger (*Dermatophilus penetrans* Guérin, 1838) causes much irritation to the foot, and *Loa loa* (Guiyot, 1778) to the eye.

Animals may be only '*temporary parasites*'—*i.e.*, they may only temporarily affect the host, as, for example, mosquitoes—or they may be '*stationary parasites*,' such as the malarial organism which lives in the red cells of the blood. These latter may be subdivided into 'periodical parasites,' which only spend a portion of their life-history within a host, and 'permanent,' which are parasitic throughout the whole life-cycle. As an example of the former may be mentioned the larvæ of certain flies which are parasitic, while the fly itself is not, and of the latter *Oxyuris vermicularis* (Linnæus, 1767) is a good example.

Animal parasites may be classified into *ectoparasites* or *epizoa*, affecting the skin and exterior of the host; and *endoparasites* or *entozoa*, affecting the internal organs or cavities of the host.

Until recent years the greatest confusion existed as to the nature of parasites. With our present knowledge it appears that parasites, however altered in structure some of them may have become during their parasitic existence, have been originally derived from free-living forms. It will, however, be noted that there are great differences in the structure and appearance between some of the permanent parasites and their nearest free-living affinities. This difference has been brought about mainly by environment.

The permanent parasite, particularly if an entozoon, has food prepared for it by its host in an easily assimilated form; hence there is no necessity for a complicated digestive apparatus, which in certain cases has entirely disappeared.

Further, certain parasites, having reached an organ which supplies them with suitable food, do not require organs of locomotion, for they have only to remain where they are, and the tissues of the host will subserve their purpose. Some of them have no necessity, as a rule, for locomotion for sexual purposes, because hermaphroditism is common, and even in cases where this is not found parasites often live in couples (male and female). Being enclosed in the body of the host, there is no necessity for sense organs; therefore these are much reduced, or are absent.

On the other hand, the parasite requires something to enable it to fix itself firmly to the tissues of the host; hence suckers and hooks are often found, and also clasping and clinging organs.

The chance of a parasite, locked up inside a host, successfully reproducing its species is small; hence reproduction assumes important features associated with the production of large numbers of new forms, which are often protected by shells or other coverings.

Reproduction may be asexual, especially in the protozoa, or sexual. Sexual reproduction in parasites is generally complicated, ending in the production of large quantities of eggs or spores; and very often the spores of the protozoa or the corresponding larval forms of the metazoa may travel through one or more intermediary hosts before they infect another definitive host—that is, one in which the sexual life-history is gone through.

With regard to the sexual process, it may be noted that often the male is smaller than the female, and in fewer numbers, but there are exceptions.

Usually parasites keep strictly to certain hosts called 'normal hosts,' but at times they are found in unusual hosts—for example, *Echinorhynchus gigas* (Goeze, 1782), which is usually found in pigs, may infect man. Such a parasite is called a 'chance parasite,' while objects mistaken for parasites are known as 'pseudo-parasites.'

The above are examples of simple parasitism; but there are parasites which are parasitic upon other parasites—a condition called 'hyperparasitism.' These hyperparasites may be secondary, tertiary, or quaternary, and their importance in disease has been emphasized by Sambon, who has shown that it may be one of the causes of the disappearance of malaria from a district, for the black spores found by Ross in mosquitoes infected with malaria are now known to be hyperparasites of the genus *Nosema*.

For further remarks see the article on Metazoan Parasites.

Nomenclature.—Medical men in the tropics are at present almost daily discovering new, or what are thought to be new, parasites, and are generally desirous of giving them definite names, but before doing so it behoves the discoverer to know and obey the international code laid down by zoologists, for which purpose they should study Stiles's pamphlet in the bulletins of the United States Public Health and Marine Hospitals Service.

Four rules may be mentioned here:—

1. **Language Rule.**—The name given to the parasite must be in Latin, and not in any vernacular.

2. **Rule of Priority.** The valid name for a genus or species is the oldest available name. Therefore, in describing a species or genus, give not merely the name of the authority who invented the term, but the date also.

3. **Rule of Homonyms.**—When two distinct genera or species of animals receive the same name, that applied earliest alone must stand.

4. **Rule of Appropriateness.**—No name is allowed to be changed simply because it is inappropriate.

With regard to disease there is no fixed rule, but we feel sure that if medical men would attempt to evolve a fixed method of nomenclature, much confusion would be avoided.

When an animal parasite causes a series of symptoms in a man or an animal, it is usual to name the affection by that of the animal causing the disease, together with the suffix 'iasis.' Thus, *Loeschia histolytica* (Schaudinn, 1903) causes loeschial dysentery and liver abscess, etc., which may be classed together under the term 'Loeschiasis'; or *Paragonimus ringeri* (Cobbold, 1890) causes a varied number of symptoms, which can all be classed together as 'Paragonimiasis.'

The drawback to this nomenclature is that, parasites being very often changed from genus to genus, such terms are not permanent. For instance, the same pathological condition may be indicated by various authorities with the terms 'Amœbiasis,' 'Entamœbiasis,' 'Loeschiasis.' We therefore prefer, wherever possible, to use common names for diseases—*e.g.*, 'Kala-azar.'

Classification.—The animals which cause and convey the diseases of man may be classified into the following subkingdoms: Subkingdom I., Protozoa; Subkingdom II., Metazoa.

SUBDIVISION A. PROTOZOAN PARASITES.

SUBKINGDOM I. PROTOZOA Goldfuss, 1817.

Definition.—Protozoa are unicellular animals, solitary or united into colonies, free-living or parasitic, with asexual reproduction (schizogony) by binary fission, budding or fragmentation and sexual reproduction (sporogony), or merely rejuvenescence by conjugation.

Remarks.—The border-line between unicellular animals and unicellular plants is very vague, and hence at present it is uncertain whether some forms should be classed with the bacteria and considered to be plants, or with the protozoa and considered to be animals. Therefore it is not unusual to call both 'protists.'

Phylogenesis.—There can be little doubt that the primitive form of protozoon must have been an animal with some of the characteristics of the amœba, and would most likely be free-living, most probably in water. This simple form, taken into the alimentary canal of higher animals, possibly benefited by the ease with which food was obtained and by the protection afforded by the new position, and thus became modified to suit its environment. The most important modification would be some protection for the earliest stages of its life-history, which would enable it to live in the outside world until taken up by a suitable host, and associated with this would be the necessity to produce large numbers of such protected spores, as the chance of one finding a suitable host must be relatively small. Such a type would be represented by the *Loeschia coli* Loesch, which is a parasite of man. Such a parasite may cause no harm to its host, which is fairly indifferent to its existence. On the other hand, a parasite may not find sufficient nutriment in the alimentary canal, and be compelled to seek better food, and perhaps more protection, by entering the glands of Lieberkühn, or even the submucosa of the bowel. Such a parasite might cause disease in its host, and would be illustrated by the *Loeschia histolytica* Schaudinn of man.

Such a process, however, took place not merely in man, but in many other kinds of animals, among which may be mentioned insects, in the alimentary canal of many of which protozoan parasites are found. In these insects the sexual process occurs, and therefore they are the definitive hosts, and may also be considered the primary hosts.

If these primary hosts become predatory, biting and sucking the blood of other animals—*e.g.*, vertebrates—then, during this process, they might pass the spores of their parasites into the blood of the vertebrata, and if these are not killed off (for some animals are repellent) by chemical substances, or destroyed by leucocytes, they might develop in the blood of some vertebrate (called tolerant), which thus becomes the secondary host.

It is, of course, possible that some of these blood protozoa may have been derived from parasites originally intestinal in the vertebrate, which found their way not merely into the mucosa of the bowel, but later into the blood-stream, in which they would be fairly well protected, and from which they would at first escape by becoming encysted in the intestinal wall, and then, bursting into the bowel, make their way to the exterior with the fæcal matter and so infect a new host. When blood-sucking animals became evolved, a new cycle would be open for them—viz., from the vertebrate through the blood-sucker back to the vertebrate—and thus the old method by way of the alimentary canal would be lost.

The origin of the protozoan blood-parasites of man may therefore be twofold: (*a*) from man's intestine into the blood; (*b*) from an invertebrate's alimentary canal into the blood of man.

The result of one or other of these methods is well illustrated by the malarial parasite, which passes through its sexual cycle in an *Anopheline* mosquito, which is its definitive and according to the view adopted, its primary or secondary host. When the infected *Anopheline* bites a man, the parasite enters into the blood-stream, in the red cells of which it develops and undergoes its asexual cycle. Man is therefore the intermediary, and either the primary or secondary, host of the malarial parasite, as mentioned above.

The blood-stream of man contains two different elements—(1) liquor sanguinis; (2) cells (*a*) red, (*b*) white. Therefore the parasite has two possibilities before it—either to live in the liquor or in a cell, or partially in one and partially in the other; and this last is what generally happens—*i.e.*, the parasite lives so much of its cycle in a cell and so much in the blood-stream. It would, however, appear that there is a great phylogenetic tendency for protozoan parasites to leave the liquor sanguinis and to reside in red cells (the malarial parasite) or in white cells or in endothelial cells (the Leishman-Donovan parasite).

Infection of the Embryo. Protozoan blood parasites apparently can be arranged in two categories as regards the infection of the fœtus, for some, like the malarial parasite (which is generally considered to be incapable), do not traverse the placenta, while others, like the *Spirochætes* and *Treponemata*, can do so. With regard to the infection of invertebrate eggs the matter is quite different, for many of these parasites infect the eggs, thus carrying the germs of disease into a new generation of blood-suckers.

It would appear as though the intracellular stage enabled the parasite to grow (*e.g.*, consider Schaudinn's history of the development of *Hæmoproteus noctuæ* in the little owl) and to multiply (*e.g.*, note the development and multiplication of the malarial parasite).

In the evolution of such hæmatozoan types some authorities (Woodcock) hold that the flagellate forms living in the blood-stream are to be considered the most primitive, and that the more truly cellular the parasite becomes the more it has evolved. Hence the *Hæmoflagellata*, or parasites freely moving in the liquor sanguinis, are with difficulty separated from the *Hæmosporidia*, or parasites which mostly live in blood cells. For many reasons some of these two groups of parasites were united together into one order of the flagellates by Hartmann.

Morphology.—Protozoan parasites vary in size from the large *Sarcocystidæ* in muscle to most minute forms in the blood (*Hæmoprotozoa*). In fact, it is possible that some forms may exist which we have not yet recognized, because their minute size prevents their being visible to the human eye, even when aided by the highest powers of the microscope.

The parasites themselves consist of protoplasm, which in some instances shows a modification into ectoplasm and endoplasm, the former being clear and hyaline and the latter dark and granular. In the protoplasm are to be found—(1) one or more nuclei, (2) chromidiosomes and chromidia, (3) metachromatic granules, (4) volutine granules, (5) metaplastic granules, (6) centrosomes, (7) archoplasm, (8) rhizoplast, (9) vacuoli.

(1) The nucleus in its simplest form is merely a collection of smaller or larger particles of chromatin (chromidiosomes or chromidia). A very simple form is that termed *Protokaryon*, in which one large chromidial mass (the Karyosome) lies in a delicate achromatic network of linin inside a vacuole filled with nuclear sap, called *enchylema*. Some chromidia may or may not be situated peripherally as well as more centrally. There is no definite membrane. The next advance is the vesicular nucleus, which consists of a definite nuclear membrane separating it from the cytoplasm. Inside this membrane there is an achromatic framework made of linin; a nuclear fluid or enchylema, lumps of a substance called *plastin* giving rise to the *nucleolus*, so common in the Metozoa and so rare in the Protozoa, and in association with chromatin to the *karyosome*, which in this instance is called the *endosome*, or Binnenkörper. The granular nucleus is a further evolution, and is produced by a more scattered condition of the chromatin.

The nucleus is therefore a complex body composed of chromatic and achromatic substances. It may be single, or divided into two principal masses—trophonucleus or nutrition-nucleus and kinetonucleus or motion-nucleus, or into macronucleus and micronucleus. The latter are quite different from the tropho- and kinetonuclei, for the macronucleus is trophic and kinetic, while the micronucleus is purely reproductive. The former is typically seen in the trypanosomidæ and the latter in the heterokaryota.

(2) Chromidiosomes are the smallest particles of chromatin which, when massed together, give rise to the chromidia which may be intranuclear or extranuclear. (3) The metachromatic granules or chromatoid grains represent stages in the anabolism or katabolism of chromatin. (4) Volutine granules stain like chromatin. They are composed of nucleic acid in combination, and represent reserve food material for the nucleus. (5) Metaplastic granules are products of cytoplastic anabolism or katabolism. (6) Centrosome is a

minute grain or pair of granules (diplosome) lying typically outside the nucleus close to the membrane. (7) The archoplasm is the clear protoplasm which sometimes surrounds the centrosome. (8) The rhizoplast is the portion of the flagellum (when present) which penetrates into the cytoplasm. The flagellar apparatus is described under the heading 'Mastigophora' in the next chapter. (9) The vacuoli may be either contractile vacuoles which are considered to be respiratory and excretory in function, or the food vacuoles, which begin with a globule of water taken in with the food. Into this vacuole an acid is secreted from the cytoplasm and digests the food, which is then absorbed. Then the vacuole with the undigested food travels to the periphery, and the waste product is extruded.

Protozoa generally have some power of movement by pseudopodia, cilia, or flagella, but under unfavourable circumstances they may lose this power, and, becoming quiescent, surround themselves with an envelope and become encysted. Unfavourable circumstances are lack of food, desiccation, irritating chemical substances, and unusual surroundings.

Life-History.—Reproduction in the protozoa takes place asexually or sexually. As long as conditions are favourable—*i.e.*, there is abundance of food—protozoa reproduce asexually by one of the following methods: (1) binary fission; (2) gemmation; and (3) sporeformation.

1. *Binary Fission.*—In binary fission there is first division of the nucleus, which sometimes takes place by amitosis, followed by that of the cytoplasm. Then the parasite divides into two more or less equal halves (Fig. 42). The other methods of nuclear division are by chromidial fragmentation or by mitosis, of which there are three types—(*a*) Promitosis, (*b*) Mesomitosis, (*c*) Metamitosis. In chromidial fragmentation the nucleus breaks up into minute chromidia, which eventually collect into two new nuclei. In Promitosis a prokaryon type of nucleus divides by the centrosome splitting into two, and giving rise to the central thread (centrodesmose) of the spindle. Then the karyosome divides by constriction, and the achromatic spindle is formed from the framework of the nucleus, and lies between the two separating karyosomes, with the centrodesmose in the middle. Then the chromosomes appear formed from the peripheral chromatin as well as from that of the karyosome.

There are two types of Promitosis—the simpler, in which no equatorial plate is formed, and the chromosomes are merely scattered along the spindle, and finally gather at opposite poles to form the daughter nuclei; and the more advanced, with an equatorial plate of chromosomes which may divide by either an equating or a reducing division. In Promitosis the nuclear membrane is negligible, while the whole process is confined to the nuclear area. In mesomitosis, which takes place in a nucleus in which the karyosome is reduced and in which there are more chromatic particles in the body of the nucleus, perfect karyomitotic figures are formed, but the whole process takes place inside the nuclear membrane. In metamitosis the polar caps of archoplasm situate in the cytoplasm assist in the mitosis.

2. *Gemmation.*—In gemmation the nucleus divides usually by mitosis into two or more nuclei, which either travel to the periphery, and become surrounded by small masses of protoplasm, which separate from the parent parasite—ectogenous gemmation—or remain in the cytoplasm, a portion of which becomes differentiated around each nucleus—endogenous gemmation.

The explanation of the two methods is that in ectogenous gemmation the buds are separated from the mother cell externally, while in endogenous gemmation the localized budding area sinks into the body substance of the mother cell, with the result that the buds are contained in a brood sac. This localized endogenous area is called a pansporoblast, though in some the entire organism forms a pansporoblast, which is considered to be phylogenetically derived from the localized condition—*i.e.*, the whole cell represents only the pansporoblast.

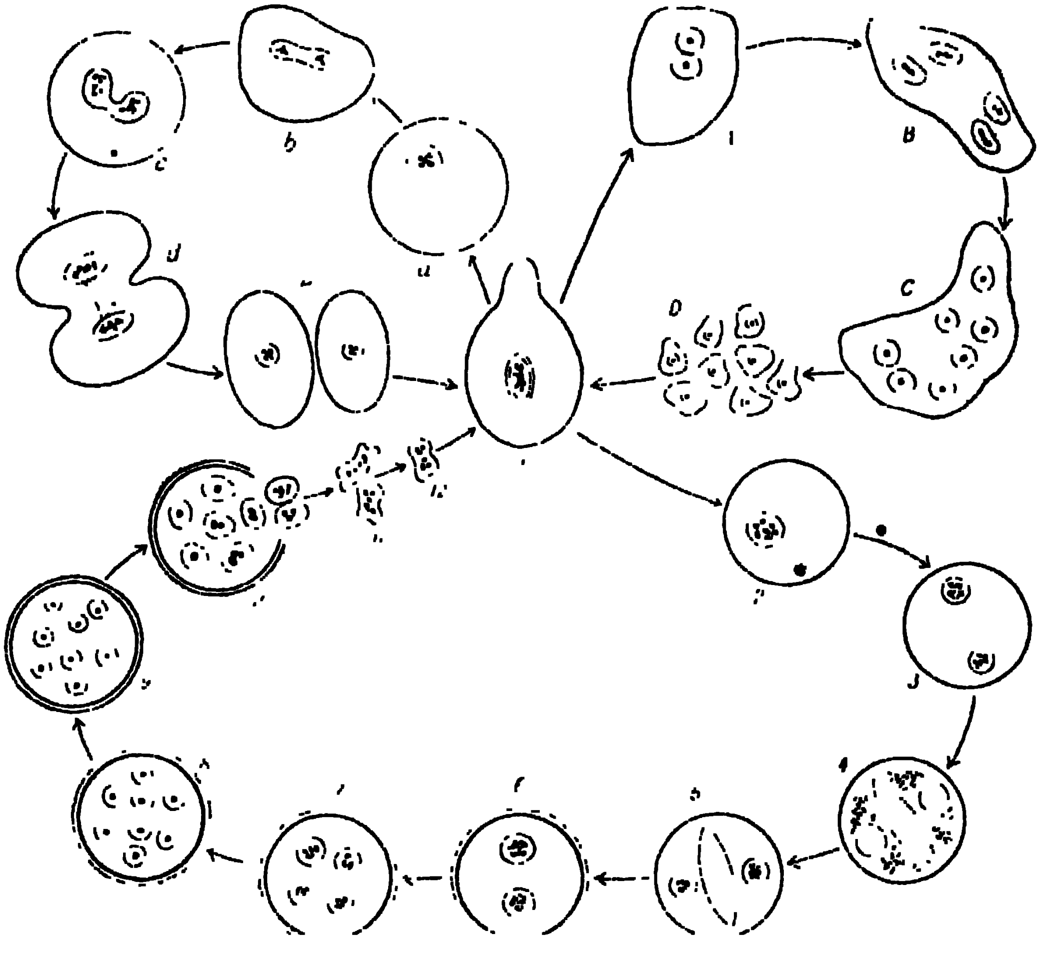

FIG. 42.—DIAGRAM OF THE LIFE-CYCLES OF *Loeschia coli* LOESCH, *emendavit* SCHAUDINN, 1903, SHOWING HARTMANN AND WHITMORE'S VIEWS AS TO ZYGOSIS.

1, *Loeschia coli*; *a-c*, stages in the process of binary fission by promitosis; A-D, schizogony by repeated division; 2-12, sexual reproduction or sporogony; 11 are the gametes, 12 the zygote, but these stages are not definitely known.

Plasmotomy.—Plasmotomy is the term applied to the intermediate division of the cytoplasm of multinuclear parasites into two or more masses, which afterwards may or may not reproduce by spore-formation.

3. *Spore-Formation.*—Instead of being considered a process of internal gemmation, the formation of pansporoblasts may be looked upon as a process of spore-formation proceeding while the organism grows, as is typically seen in the Neosporidia.

The typical asexual spore-formation or schizogony is, however, met with in the Telosporidia, in which the early stages absorb nutriment and increase in size, being therefore called trophozoites. When fully grown they form a quiescent body, the schizont, whose nucleus and cytoplasm divide into a number of small forms called asexual spores or merozoites, generally, however, leaving a little undivided cytoplasm laden with effete matter,

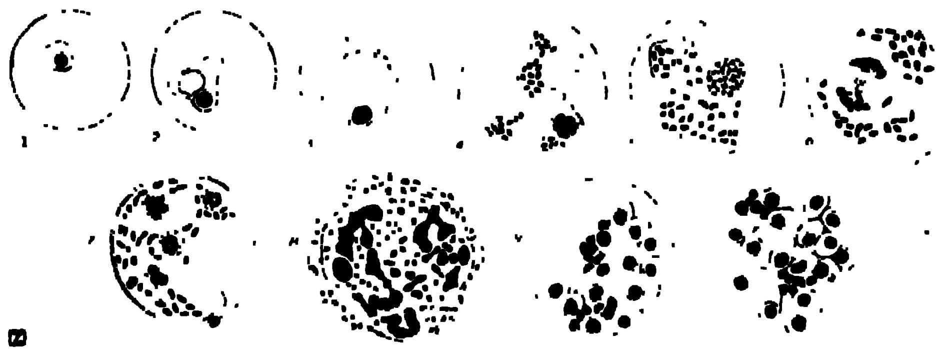

FIG. 43.—SCHIZOGONY OF *Plasmodium vivax* GRASSI AND FELETTI.
(After Schaudinn.)

1, Young trophozoite; 2, ring form; 3, ring form showing hæmozoin; 4, parasite with pseudopodia, 5, old trophozoite, 6, schizont showing commencement of first division; 7, schizont with four nuclei; 8, schizont with several nuclei (the corpuscle shows Schüffner's dots); 9, schizont divided into merozoites, 10, merozoites and hæmozoin free.

These merozoites are the forms by which the parasite multiplies in the given host, and are not the means by which new hosts are infected. They therefore enter new cells in the host in which they are formed, and, growing into a trophozoite, complete an asexual life-cycle, which is called the cycle of schizogony, or simply schizogony (Fig. 43).

A time arrives in the infection of every host when the food material for the given parasite is diminished by the numbers of forms produced by asexual reproduction, or when the tissues of the host react against the parasite by chemical substances, or phagocytosis, or by both methods combined.

When these adverse circumstances become sufficiently severe, changes take place in the parasite which produce forms capable of leaving the given host and existing outside it, either in a different species of animal or simply in the exterior, until an entry is made into a new host of the same species as before, when schizogony begins again.

The changes which the parasite has to undergo in spreading from one host to another are generally associated with sexual reproduction, and the whole cycle from a given host of a certain species to another host of the same species is called the cycle of sporogony, or, more simply, sporogony (Figs. 44, 45, and 46).

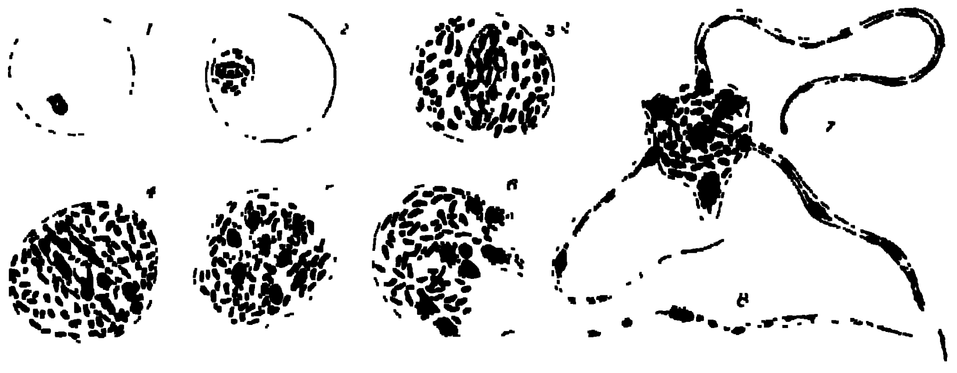

FIG. 44.—SPOROGONY OF *Plasmodium vivax* GRASSI AND FELETTI. DEVELOPMENT OF THE MICROGAMETE. (After Schaudinn.)

1, Young microgametocyte; 2, 3, older forms; 4, fully grown microgametocyte, as seen in the blood of man; 5, division of the nucleus (reduction) in the stomach of an anopheline; 6, nuclei have travelled to the periphery, which has grown out to form the commencement of a microgamete; 7, microgametocyte with three microgametes; 8, a free microgamete.

In adverse or changed circumstances, therefore, the merozoites develop into more resisting forms, which are called gametocytes, in which, by reduction of the nuclear material, the male and female elements in the nucleus are separated; the two elements may exist in the same cell or in separate cells, but usually the male element of one cell fuses (zygosis) with the female element of another cell, and forms a new individual with a new nucleus or synkaryon.

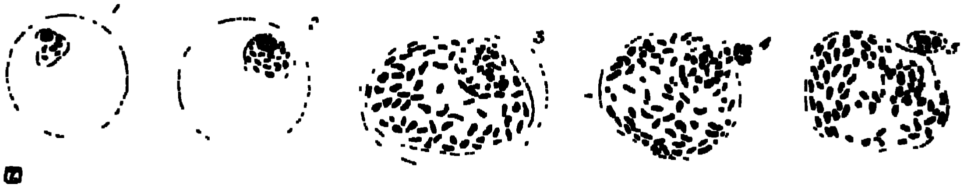

FIG. 45.—SPOROGONY OF *Plasmodium vivax* GRASSI AND FELETTI. DEVELOPMENT OF THE MACROGAMETE. (After Schaudinn.)

1-2, Young macrogametocytes; 3, fully developed macrogametocyte in the blood of man; 4, reduction and formation of a polar body in the stomach of an anopheline mosquito; 5, macrogamete and one polar body.

This new individual proceeds to reproduce itself rapidly by either binary fission or spore-formation. In the latter case, in order to prevent confusion, the terms employed are different from those used in asexual reproduction. The parasite is called a sporont, the spores sporozoites. The sexual reproduction takes place in the definitive host, which may be different from the intermediary host in which the asexual reproduction is found.

Parthenogenesis and Etheogenesis.—Reproduction is said to take place from a female type of parasite (parthenogenesis) or more rarely from a male type of parasite (etheogenesis), without any completion of the sexual process (Fig. 47).

An example of parthenogenesis is found in the malarial parasite, in which the female gametocyte is capable of resisting both the action of the chemicals of the body and drugs, and is therefore capable of lying dormant for some time. When given an opportunity for development, its nucleus and protoplasm divide into two portions, one of which degenerates and disappears, while the other forms merozoites and starts the cycle of schizogony anew. Another is described by Prowazek in *Herpetomonas muscæ-domesticæ*, but neither example has been definitely proved; and, indeed, of late grave doubts have arisen as to its truth. Nevertheless, we feel that it is necessary to keep some remarks upon the subject, as we feel that the last word has not yet been said, as we have seen once bodies very like those described by Schaudinn.

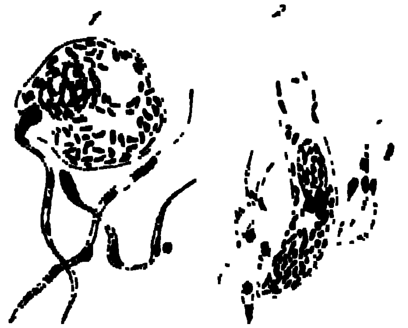

FIG. 46.—SPOROGONY OF *Plasmodium vivax* GRASSI AND FELETTI: ZYGOSIS. (After Schaudinn.)

1, Zygosis of one microgamete with the macrogamete; 2, oökinete and degenerate microgametes

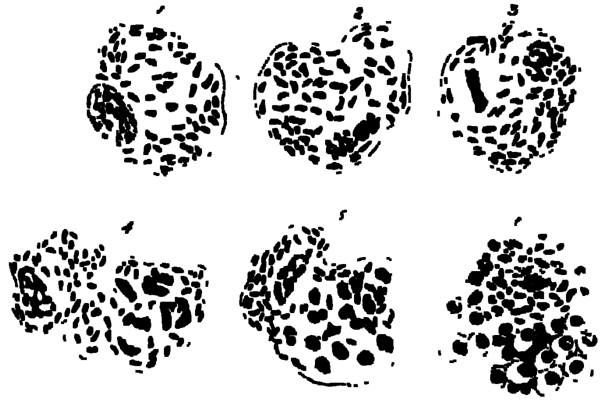

FIG. 47.—PARTHENOGENESIS OF *Plasmodium vivax* GRASSI AND FELETTI. (After Schaudinn.)

1, Macrogametocyte, 2, division of the nucleus; 3-6, formation of merozoites from one portion of the nucleus, and separation of the other portion with the hæmozoin.

Etheogenesis, a term introduced by Prowazek, is the much rarer change in the male parasite whereby asexual reproduction begins again. He described it in *Herpetomonas muscæ-domesticæ*, but Flu says that an error was made, and that the objects believed to be male elements were really stages in the life-cycle of a Microsporidian —*Octosporea muscæ-domesticæ*.

Pathogenicity.—The pathogenicity of the Protozoa is of the highest importance, as they are the causes of a large number of endemic and epidemic diseases in man and animals, as will be described in the following pages. They produce toxins; but these have not been well studied, with the exception of the Sarcosporidiotoxin, which is only toxic for rabbits and not for other animals. The toxins produced by the malarial parasites have been referred to on p. 203.

Classification.—The classification of the subkingdom Protozoa is by no means satisfactory at present, but for remarks upon this subject we refer the reader to Poche's article thereon written in the *Archiv für Protistenkunde*, vol. 30, in 1913.

The old classification was into four classes: (1) sarcodina; (2) mastigophora; (3) sporozoa; (4) infusoria.

The sarcodina move and capture food by pseudopodia; the mastigophora by flagella; the sporozoa are parasites without motile organs; and the infusoria move by means of cilia. When this classification was brought into use, practically nothing was known about the life-history of the protozoa, a more complete knowledge of which is still required.

Schaudinn's work with regard to the life-history of flagellates having failed to be confirmed, and Hartmann's binucleate theory having fallen into disuse, we have returned to Doflein's classification as set forth below.

Among the blood parasites of man and other animals there are found some wavy, thread like organisms (*Spirochætes* and *Treponemata*), with which must be classed some free-living forms whose position, even in the animal kingdom, has been disputed.

Most authorities believe that these forms are protozoa with a low type of nucleus, but so different are they from the ordinary phyla of protozoa that, following Doflein's and Fantham's suggestions, we shall place them in a separate section making them an Appendix to the Mastigophora, though Calkins thinks it better to leave them in their old position at present.

Further, the old group of the Sporozoa Leuckart, 1879, contains two such different groups of animals in its subdivisions into Telosporidia and Neosporidia that it is justifiable to do away with this combination, and to raise the two divisions to the rank of separate phyla.

Finally, the two nuclei of the infusoria are so totally different in function from the nucleus or nuclei of the rest of the protozoa that the Subkingdom is capable of being divided into two divisions:— the Heterokaryota or infusoria; and the Plasmodromata, under which heading come the other phyla.

In the present work the following classification is adopted:—

DIVISION A. PLASMODROMATA Doflein, 1901.

Phylum I.—*Sarcodina* Hertwig and Lesser, 1874.
Phylum II.—*Mastigophora* Diesing, 1866.
Phylum III.—*Telosporidia* Schaudinn, 1900.
Phylum IV.—*Neosporidia* Schaudinn, 1900.

DIVISION B. HETEROKARYOTA Hickson, 1903.

Phylum V.—*Ciliata* Perty, 1852.
Phylum VI.—*Acinetaria* Lankester, 1885.

Species.—Before commencing the systematic description of the Protozoa it may perhaps be as well to remind the reader that in the higher animals the distinctness of a species depends upon the fertility of its members *inter se*, but not usually with members of other species.

In protozoology and bacteriology many mere varieties have been called species, but such variants *lack any morphologically specific character*, and are merely separated from one another by *physiological characters*, which, as we have seen in the section on evolution of disease, can be made to alter by change of environment.

It is convenient and useful for purposes of identification and reference to give them names as though they were true species, and this does no harm so long as the reader does not expect to find morphologically specific differences in these forms, which can only be separated biologically and physiologically.

DIVISION A: PLASMODROMATA DOFLEIN, 1901.

Synonym.—*Cytomorpha* Hatschek, 1888.

Definition.—Protozoa in which the nucleus is not separated into reproductive (micronucleus) and non reproductive (macronucleus) portions.

Classification. The Plasmodromata may be divided into phyla according to the following scheme:—

(*a*) *With motile organs in adult stage*:—
  I. Move and capture food by pseudopodia—*Sarcodina*.
  II. Move and capture food by flagella—*Mastigophora*.
(*b*) *Without motile organs in adult stage*
  I. Spore formation distinct from and takes place after the trophic phase—*Telosporidia*.
  II. Spore formation and trophic stage proceed simultaneously—*Neosporidia*.

PHYLUM: SARCODINA Hertwig and Lesser, 1874.

Definition.—Plasmodromata which move and capture their food by means of pseudopodia.

Classification.—The Sarcodina may be classified as follows:—

(*a*) Without axial filaments in the lobose, filose, or reticulose pseudopodia—*Rhizopoda*.
(*b*) With central axial filaments in fine ray-like pseudopodia—*Heliozoa* Haeckel, 1866; *Radiolaria* Haeckel, 1861.

Remarks.—Only the Rhizopoda concern us at present.

CLASS: RHIZOPODA VON SIEBOLD, 1845.

Definition.—Sarcodina, parasitic or free-living, without axial filaments in their lobose, filose, or reticulose pseudopodia.

Classification.—This class may be divided into subclasses as follows:—

(*a*) With blunt loose pseudopodia which do not anastomose—*Amœbæ*.
(*b*) With fine branching and anastomosing pseudopodia—*Foraminifera*.

Remarks.—Only the Amœbæ concern us.

SUBCLASS: AMŒBÆ Ehrenberg, 1830.

Synonyms.—*Amœbina* Auctores (a misprint); *Chaidea* Poche, 1913; *Amœbidæ* Brown, 1859.

Definition.—Rhizopoda, parasitic or free-living, with blunt, loose pseudopodia which do not anastomose.

Classification.—The subclass Amœbæ may be divided into two orders as follows:—

(*a*) Without a shell—*Gymnamœbida*.
(*b*) With a shell—*Thecamœbida*.

ORDER I. GYMNAMŒBIDA Delage Hérouard, 1896.

Synonym. *Lobosa* Carpenter, 1861; *Amœbidæ* Broun, 1859; *Chaidæ* Poche, 1913.

Definition.—Amœbæ without a shell, but with a tendency of the peripheral plasm to harden into a membrane-like zone.

Type Genus.—*Amœba* Bory de St. Vincent, 1822.

Remarks.—The genera of this order are in a wild state of confusion. Calkins in 1912 gave a large number of genera—Amœba, Vahlkamfia, Naegleria, Craigia, Trimastigamœba, Entamœba, Paramœba, Trichospherium, Hyalodiscus, Chromaletta, Pelomyxa, Dactylosphera, Nucleophaga. In the same year Alexeieff created the genera Naegleria and Hartmannia for Amœbæ of the limax type, and also Proctamœba for Amœbæ parasitic in vertebrates, but the two last names have not come into general use. Doubtless many more exist.

Classification.—Those found in man up to the present may be classified into:—

1. *Loeschia* Chatton and Lalung-Bonnaire, 1912.
2. *Vahlkamfia* Chatton and Lalung-Bonnaire, 1912.
3. *Craigia* Calkins, 1912.
4. *Dientamœba* Jepps and Dobell, 1918.

They may be differentiated as follows:—

A. *Without uniflagellate stage*:—
  I. Typically uninucleate:—
    Ecto- and endoplasm distinct when moving. Nucleus with or without visible karyosome and centriole. Contractile vacuoles generally absent. Division by mesomitosis—*Loeschia*.

Ectoplasm only seen in outbursts. Nucleus with finely divided chromatin forming a membrane-like contour and with definite karyosome. Division by promitosis—*Vahlkamfia*.

II. **Typically binucleate, the two nuclei having the same size and structure.**

Ecto- and endoplasm distinct—*Dientamæba*.

B. ***With uniflagellate stage*** :—

Ectoplasm visible on movement. Endoplasm with or without a body like a *Nebenkörper*—***Craigia*.**

THE GENUS AMŒBA.

The old original genus Amœba seems to have been first described by Rösel von Rosenhof in 1775, under the heading the ***Small Proteus***, and to this organism Linnæus gave the name ***Volvox chaos***, which Pallas in 1766 turned into *Volvox proteus*. In 1822 Baron Bory de Saint Vincent, in the 'Dictionnaire Classique d'Histoire Naturelle,' vol. i., pp. 260-262, established the genus Amiba, calling *Volvox proteus* by the name *Amiba divergens*, which Ehrenberg in 1831 altered to *Amœba princeps* and Leidy in 1878 to *Amœba proteus*.

This original genus is now divided into the following genera:—

A. *Usually free living* :—

I. Without a flagellate stage in the life-cycle:—

(*a*) Usually uninucleate.

1. Large forms reaching to 1 millimetre in diameter, free living, with well differentiated ecto- and endoplasm and well developed pseudopodia. One or many large nuclei with doubly refracting membrane and chromatin concentrated into a single large karyosome or as granules diffused through nucleus. One or more contractile vacuoles—Genus 1, *Amœba* Bory de St. Vincent, 1822.

2. **Minute forms, free living or commensal, ectoplasm not well differentiated from endoplasm, moving as a finger-formed single pseudopodium or with irregular ectoplasmic bursts to form a general or local ectoplasm.** Nucleus single or double, with finely divided chromatin, forming a membrane-like structure and a definite karyosome. One contractile vacuole present as a rule—Genus 2, *Vahlkamfia* Chatton and Lalung-Bonnaire, 1911; ***emendavit*** **Calkins, 1912.**

(*b*) **Usually binucleate. Genus 3, *Dientamæba* Jeffs and Dobell, 1918.**

II. With a flagellate stage in the life-cycle:—
(*a*) Flagellate forms divide—Genus 4, *Paramœba* Schaudinn, 1896.
(*b*) Flagellate forms do not divide:—
1. Uniflagellate—Genus 5, *Craigia* Calkins, 1912.
2. Biflagellate—Genus 6, *Naegleria* Alexeieff, 1912; *emendavit* Calkins, 1912.
3. Triflagellate—Genus 7, *Trimastigamœba* Whitmore, 1911.

B. *Parasitic, commensal, or pathogenic* :—
I. Contractile vacuoles numerous; cysts give rise to gametes—Genus 8, *Entamœba* Leidy, 1879.
II. Contractile vacuoles absent; cysts not known to give rise to gametes—Genus 9, *Loeschia* Chatton and Lalung-Bonnaire, 1912.

The principal species of the genus Amœba are the type *A. proteus* (Pallas, 1766), *A. vespertilio* Penard, 1902, *A. verrucosa* Ehrenberg, 1838, and *A. terricola* Greeff, 1892, but the last two may be the same species.

The type species of Naegleria is *N. punctata* Dangeard, 1910, found in pond water and infusions.

Trimastigamœba has only one species, *T. philippinensis* Whitmore, found in tap water in Manila.

Entamœba has as its type species *E. blattæ* Bütschli, 1878, described in detail by Mercier in 1909 and 1910, who says that the gamete-forming cysts give rise to minute uninucleate gametes, which conjugate outside the cyst, while the copula develops directly into the trophozoite. This is very different from what is known concerning the life-history of Loeschia.

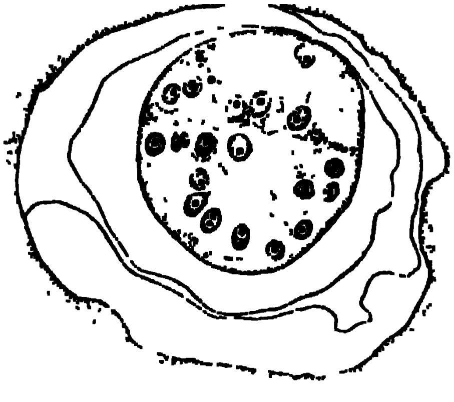

FIG. 48.—Cyst of *Amœba proteus* (Pallas, 1766). (After Carter.)

As the type genus is Amœba, and its type species *Amœba proteus* (Pallas, 1766), it is interesting to know its life-cycle, which is but little understood at present.

Miss Carter has, however, studied encystment, while simple division is fully established and schizogony is doubtful.

The precystic stage is characterized by the Amœba becoming sluggish, clearing its body of debris, and exuding a slimy mucus, which causes surrounding detritus to adhere to it, and so to form an outer protecting covering, inside which two membranous cyst walls, separated by fluid, are formed. The cysts measure 70 to 140 microns in diameter, and are found in England from late December to the middle of March. They are spherical and without means of attachment.

Inside the cyst the nucleus breaks down and the chromatin and plastin are distributed throughout the cytoplasm, in which they form secondary nuclei of the protokaryon type, and finally some 75 to 100 young nucleated amœbæ, which apparently do not become flagellate, and so far as is known do not form gametes, but this and the further development require investigation.

Metcalf has, however, observed zygosis in minute gametes of *Amœba proteus*.

Genus Loeschia Chatton and Lalung-Bonnaire, 1912.

Synonyms.—*Amœba* Ehrenberg, 1830, *pro parte*; *Entamœba* Casagrandi and Barbagallo, 1897; *nec Endamœba* Leidy, 1879.

Definition.—Gymnamœbida, with a vesicular nucleus containing a small karyosome (as a rule) and abundant peripheral chromatin, and dividing by mesomitosis, and with cysts containing four to eight nuclei, which form young amœbæ which are not known to be gametes.

Nomenclature.—The name Amœba was applied by St. Vincent in 1822 and by Ehrenberg in 1830 to free living forms, of which the type is *Amœba proteus*, which Poche thinks is the *Volvox chaos* of Linnæus; and the term *Endamœba* was given by Leidy in 1879 to the parasitic *E. blattæ* Bütschli, but this name cannot be applied to the human parasites, because Mercier's researches have shown that it may be different, and therefore it is necessary to use Chatton and Lalung-Bonnaire's term.

Remarks.—The genus is composed of amœba-like forms varying in size from 5 to 80 microns, and possessing distinct ectoplasm and endoplasm, which, however, may be only visible during motion. The ectoplasm is clear and hyaline, while the endoplasm may be either clear or finely granular. The nucleus usually has a karyosome and centriole. Reproduction is by simple division, schizogony, and cyst formation.

The species live in the alimentary canal of man and animals, but may enter other tissues and organs, and may be pathogenic or non-pathogenic.

It is still doubtful whether artificial cultivation has been performed successfully.

Type Species.—The type species is *Loeschia coli* Loesch, 1875, found in man, but used in the sense of the term as defined by Schaudinn in 1903, and not as defined by Loesch in 1875.

Classification.—Chatton and Lalung-Bonnaire suggested the formation of two subgenera—viz., Loeschia, characterized by cysts with eight nuclei, and Viereckia, distinguished by cysts with four nuclei, but this has not been adopted so far.

As there are a very large number of species described, we will give a list classified according to the part of the body in which they were discovered, but Schaudinn's statement made in 1903 should be remembered, '*The knowledge of the development is the first postulate of protozoon research*;' and because this knowledge is lacking so much confusion exists.

I. *Intestinal*:—

1. *L. coli* Loesch, 1875.
2. *L. histolytica* Schaudinn, 1903.
3. *L. tetragena* Viereck, 1907.
4. *L. tropicalis* Lesage, 1908.
5. *L. minuta* Elmassian, 1909.
6. *L. nipponica* Koidzumi, 1909.
7. *L. undulans* Castellani, 1905.
8. *L. williamsi* Prowazek, 1911.
9. *L. hartmanni* Prowazek, 1912.
10. *L. butschli* Prowazek, 1912.
11. *L. brasiliensis* Baurepaire-Aragao, 1912.
12. *L. dysenteriæ europaeæ* Popper, 1917.
13. *L. nana* Wenyon and O'Connor, 1917. (This is considered under Vahlkamfia (see p. 323.)
14. *L. minutissima* Brug, 1917.

The researches of Hartmann, Whitmore, Wenyon, Craig, Calkins, and James, have demonstrated that only two of these are good species, viz.:—

Loeschia coli Loesch, 1875.
Loeschia histolytica Schaudinn, 1903.

II. *Hepatic and renal*:—

L. mortinatalium Smith and Weidman, 1910.

This species was found originally in the liver and kidneys of a fœtus born dead.

III. *Buccal*:—

1. *L. gingivalis* Gros, 1849.
2. *L. buccalis* Sternberg, 1862.
3. *L. dentalis* Grassi, 1879.
4. *L. dentalis* Braun, 1883.
5. *L. buccalis* Prowazek, 1904.
6. *L. maxillaris* Kartulis, 1901.

There is only one good species, viz.:—

Loeschia gingivalis Gros, 1849.

IV. *Genito-urinary*:—

L. urogenitalis Baelz, 1883, which may be the same as *Amœba urinæ granulata* Ward, Coles and Friel, which the latter suggests comes from an organism like a protococcus taken into the alimentary canal. Chalmers and O'Farrell consider it to be *L. histolytica* in all probability.

V. *Pulmonary*:—

L. pulmonalis Artault, 1898.

This may be the same organism as *L. mortinatalium* Smith and Weidman, 1910, and both may be *L. histolytica*, as Chalmers and Atkey have reasons for believing that *L. pulmonalis* is very like *L. histolytica*.

VI. *In Abscesses :—*
  L. kartulisi Doflein, 1901.
VII. *In serous exudations :—*
  L. miurai Ijima, 1898.

All the above, except the last, are probably either *L. coli* or *L. histolytica*, while the last may be the Leydenia stage of *Chlamydophrys enchelys* Ehrenberg, which is often classified in the Foraminifera.

If this is accepted, we have only three species to consider—viz.:—

L. coli Loesch, 1875, *emendavit* Schaudinn, 1903.
L. histolytica Schaudinn, 1903.
L. gingivalis Gros, 1849.

And these may, with difficulty, be distinguished as follows:—

(*a*) *Size small—average* 12-20 *microns :—*
  Endoplasm often contains red blood-corpuscles, cysts with one nucleus—1. *Gingivalis*.
(*b*) *Size larger—average* 25-35 *microns :—*
  1. Endoplasm does not normally contain red blood-corpuscles. Cysts usually contain eight nuclei, but may have sixteen—2. *Coli*.
  2. Endoplasm normally contains red blood-corpuscles. Cysts contain one to four nuclei and characteristic chromidial bodies—3. *Histolytica*.

AMŒBÆ IN ANIMALS.—A full list of Amœbæ according to hosts was given by Hassall in 1913 (see references), and therefore we omit the full list given in previous editions, only a short list being given on p. 321 but we may say that in vertebrates and invertebrates a very large number of species have been described, but many of these will probably be found to be the same.

Type Species.—The type species in *Loeschia coli* (Loesch, 1875) Schaudinn, 1903, which we will now describe.

Loeschia coli Loesch 1875, *emendavit* Schaudinn, 1903.

Synonyms.—*Amœba coli* Loesch, 1875; *Entamœba coli* Loesch, 1875.

Probable Synonyms.—*Entamœba tropicalis* Lesage, 1908; *E. nipponica* Koidzumi, 1909; *E. williamsi* Prowazek, 1911; *E. muris* Grassi; and perhaps others (*vide supra*).

Definition.—*Loeschia* with cysts containing eight nuclei, cytoplasm almost always without red blood-corpuscles, ectoplasm invisible except when a pseudopodium is being protruded. Nucleus subcentral, vesicular, with cyclic changes not well marked. Karyosome often with two granules.

Nomenclature.—The correct name is *Loeschia hominis* Casagrandi and Barbagallo, 1897. The name *L. coli* was originally applied by Loesch to the pathogenic amœba which caused dysentery, but the nomenclature was reversed by Schaudinn (as Dobell has pointed out) in 1903, and it is most difficult to alter it at the present time.

History.—In 1859 Lambl published a note referring to the presence of an amœba, associated with other protozoa, in the motions of a case of dysentery, and this was followed by an account by Loesch in 1875 in which he states that he considers these amœbæ to be the cause of dysentery. Grassi, in 1879, was the first observer to demonstrate the presence of amœbæ in the motions of healthy people, and alone or with Calandruccio described encystment, while Calandruccio infected himself *per os* with the cysts. They both noted its non-pathogenicity. Lewis and Cunningham in 1881 saw them in the motions of persons suffering from cholera. In 1894 Celli and Fiocca described and named six species of amœba occurring in man, but it is doubtful what these really are; probably some of them belong to *L. coli*. Grassi's findings were confirmed by Koch and Kartulis, but Kruse and Pasquale in a classical investigation demonstrated that there were two kinds of amœbæ, one harmless and the other the cause of dysentery. It was not, however, until Casagrandi and Barbagallo investigated and defined *L. coli*, which is harmless, that it was possible for Jürgens to make his researches, which, extended by Schaudinn, ended in defining a second amœba named *L. histolytica*, which was considered to be the cause of amœbic dysentery. It has been studied in detail in 1912 by Hartmann and Whitmore with important results, and in an important memoir by James in 1914.

It seems to us that Wenyon's researches into *L. muris* are so important with regard to the opposing opinions of Schaudinn and Werner on the one hand, and Hartmann and Whitmore on the other, that we give this in detail.

Loeschia muris Grassi, 1881.

The life-history of this amœba has been carefully studied by Wenyon in 1907. *L. muris* lives in the cæcum of mice and rats, either freely amongst the contents, or upon the epithelial surface, or in the glands to their ends. It measures up to 30 to 40 microns in diameter.

The food appears to be anything at hand—bacteria, flagellates and their cysts, yeast cells, and cast-off epithelial cells.

The Trophozoite.—The narrow ectoplasm is only distinctly visible in the formation of the pseudopodia, while the granular endoplasm contains the food vacuoles and the nucleus, which latter is distinctly visible as a clear vesicle with a distinct nucleolus.

When stained, the nucleus is seen to have a definite fairly thick membrane, with chromatinic lumps at one or two points. The nucleolus or karyosome is chromatinic, and between it and the nuclear membrane is the linin network with scanty granules of chromatin scattered over it. This is the type of nucleus found in *L. coli*.

Multiplication takes place by binary division and by encystment. In the former a nuclear spindle is formed without chromosomes or an equatorial plate, as the chromatin gathers at the poles, and the nucleus after elongation becomes indented and then divided in the middle, and after some length of time the cytoplasm divides.

The precystic stage is distinguished by having its endoplasm cleared of all large inclusions, and is surrounded by a soft gelatinous wall, through which the remains of food materials can be cast out.

Cystic Stage.—A cyst is spherical or slightly oval, 12 to 14 microns in diameter, and contains a cytoplasm free from food particles, and may or may not contain a refractile body, while the nucleus is large and contains much chromatin. This nucleus divides, by simple division, forming two daughter nuclei, and this binucleate stage, which is of long duration, is characterized by the throwing out of chromatin from the nuclei.

Autogamy.—Each nucleus now gives off reduction bodies which are dissolved in the cytoplasm. These two nuclei are slightly different: in one it is evenly distributed, while in the other it is concentrated at one end; the former migrates towards the latter, and both become alike and throw out chromatin. The nuclei were not seen to fuse, but they elongate greatly, spindles are formed, and they divide, giving rise to four nuclei—*i.e.*, two pairs at opposite poles of the cysts, composed of one nucleus from each of the original forms extending to the opposite pole of the cysts.

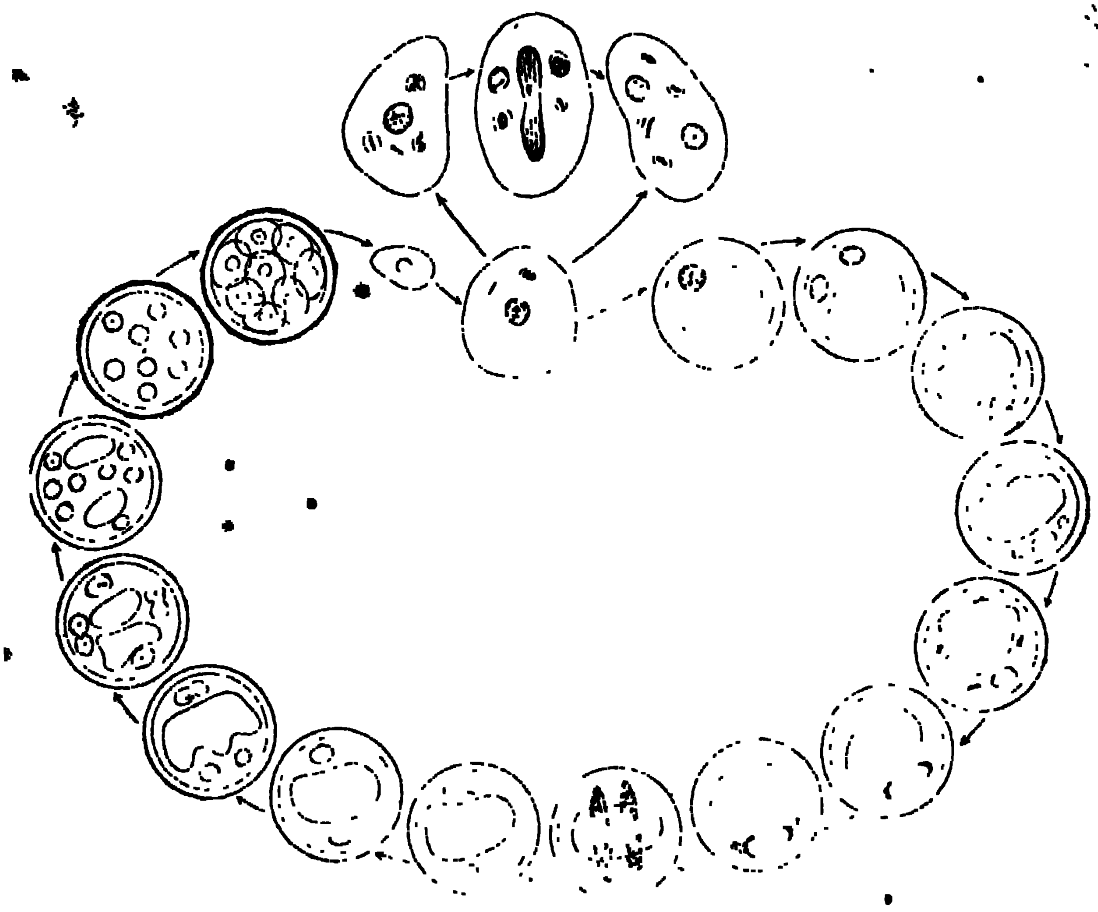

FIG. 49.—DIAGRAM OF THE LIFE-CYCLES OF *L. muris* GRASSI (CONSTRUCTED FROM WENYON'S DRAWINGS).

Each pair then fused to form one nucleus, and then almost immediately divided to form four nuclei, and these again to form eight nuclei.

During this process the soft gelatinous cyst wall of the precystic stage is converted in a tough resistant envelope, inside which an inner membrane is formed (compare *Amœba proteus*). The outer cyst wall becomes tough and irregular in the fæces.

Method of Infection.—The cysts now escape from the intestine in the normal fæces, in which the amœbæ are not seen, these being only found in diarrhœal motions. Cysts were used to infect by feeding a mouse, which was apparently free from infection, and in about three to four weeks cysts appeared for the first time in the fæces.

Wenyon did not see the cysts burst and the amœbæ escape.

Wenyon says: 'When we take into account the striking similarity of these two amœbæ (*L. muris* and *L. coli*), both in the free condition and in their encysting process, it is difficult to avoid the conclusion that they are identical'

In 1917 Wenyon and O'Connor published exceedingly valuable researches on the diagnosis of *L. coli* and on the house-fly as a carrier of the cysts.

We therefore see that while a great deal is known as to the structure, life-history, and method of infection, there is still much to be observed. Are Schaudinn and Wenyon correct in their description of autogamy, or does *L. coli* really form gametes like *Entamœba blattæ*? Is there any true schizogony?

After this rather long history, we will not enter fully into the structure of *L. coli*, but will only present a very condensed account.

Morphology. In diameter it measures as a rule 20 to 40 μ, although forms as small as 10 μ and even 5 μ have been described. The cytoplasm is vacuolated and contains bacteria, and extremely rarely one red corpuscle. The ectoplasm is not visible until a pseudopodium is about to be protruded. The vesicular nucleus resembles that of the tetragena stage of *L. histolytica*, an account of which is given below, but the cyclic changes are not so well defined. The karyosome when present is small, and is composed of two chromidia united by a chromatic substance. At the commencement of a cycle this karyosome is a round compact mass of chromatin connected with the periphery by a linin network with few chromatinic granules. This karyosome breaks up, its chromatin increasing in amount, the linin network becomes thicker, and there are more chromatin granules at its nodes, and this goes on until all the chromatin is collected as blocks under the nuclear membrane and only a small granule is left in the centre, and then the cycle begins again by the growth of the granule into a large karyosome.

Life-History. The life-cycle comprises two phases: a binary division by promitosis takes place (and not by amitosis, as described by Schaudinn). The process of schizogony is described to take place by repeated division into two, forming two, four, and eight nuclei (*vide* Fig. 42, p. 292), which form eight little Loeschiæ which begin the asexual cycle again, but this is very doubtful. Encystment takes place, followed by division of the nucleus into two, four, and finally eight nuclei. During this stage a large vacuole exists in the cytoplasm, which disappears in the eight-nuclei stage. Contrary to Schaudinn, Hartmann and Whitmore believe that no zygosis takes place in the cyst, but that eight little amœbæ are formed which, on escaping from the cyst, they think may conjugate in pairs and form the synkaryon or zygote from which the vegetative forms arise after the manner described by Mercier in 1909 for *E. blattæ*. Sometimes the cysts have more than eight nuclei—*e.g.*, ten or twelve—which must be considered to be abnormal.

Bionomics.—*L. coli* lives in the lumen of the intestine, and feeds upon the contents of the bowel.

Diagnosis.—Amœbæ moving slowly with pale non-refractile pseudopodia, with a thin rim of ectoplasm and with an endoplasm containing all sorts of organisms and no red cells, and with a large distinct nucleus, are *L. coli*, and this diagnosis should be confirmed by the discovery of the cyst because—

1. The typical characters are liable to considerable changes, and the amœba may be very like *L. histolytica*, as will be emphasized below.
2. Wenyon and O'Connor's researches confirm that *L. coli* will not, as a rule at all events, ingest red blood-corpuscles.

With regard to the cysts, they measure from 13–38 microns, but the average is over 25 microns; the typical cyst has eight nuclei and the very large cysts sixteen. At times chromidial bodies may be present, making them look like *L. histolytica* cysts, from which they are to be distinguished by the number of nuclei, which in the motions is generally eight.

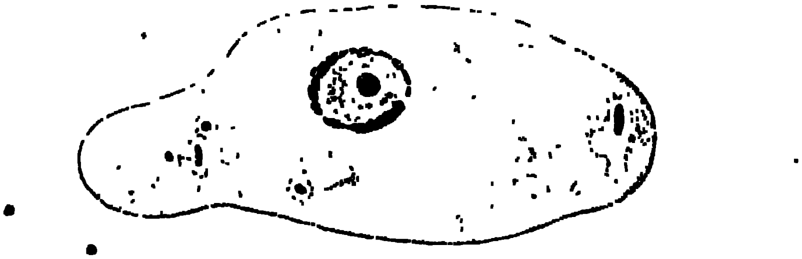

FIG. 50.—*Loeschia coli* SCHAUDINN, VEGETATIVE FORM, STAINED. (× 1050 DIAMETERS.)
(After James.)

Carriage by House-Flies. Wenyon and O'Connor, working in Egypt, have shown that *L. coli* and *L. histolytica* cysts can be ingested by house-flies (Musca, Fannia, Calliphora, and Lucilia) which have fed on fæces containing such cysts. These cysts can live in the gut of the fly so long as any fæcal matter remains there, but die after all the fæcal matter has been expelled, which takes place some twenty-four hours after the fæcal feed. The cysts may be seen in the droppings of the fly as early as five minutes and as late as twenty-four hours after the fæcal feed.

As to the conveyance of cysts on the exterior of the fly, the observations of Kuenen and Swellengrebel and Nicol show that flies do not move far until they have cleaned themselves, so that but little fæcal matter is left, and as this dries the cysts perish.

Method of Infection. The experiments of Calandruccio and of Wenyon and O'Connor have proved that infection takes place *per os*, and is due to the cysts; and that, further, these are introduced most probably by food contaminated by the cyst-laden fæcal matter of house-flies.

Distribution.—*L. coli* is found in both the tropics and the Temperate Zone. In the former it is especially common in the fæces of natives.

Pathogenicity.—*L. coli* is a non-pathogenic commensal found in man, and possibly in rats and mice, and perhaps in other animals. Views as to its pathogenicity have probably arisen through mistaking the tetragena phase of *L. histolytica* for *L. coli*. An Amœba resembling *L. coli* is found in monkeys in which an Amœba resembling *L. histolytica*, and called *L. nuttalli*, is also found.

Loeschia histolytica Schaudinn, 1903.

Synonyms.—*Amœba coli* Loesch, 1875; *Entamœba histolytica* Schaudinn, 1903; *Entamœba tetragena* Viereck, 1907; *E. africana* Hartmann and Prowazek, 1907; *E. minuta* Elmassian, 1909; and *Amœba dysenteriæ* Councilman and Lafleur, 1891. Among the many doubtful species of Amœbæ found in man there must be many names which are synonyms of *L. histolytica*, but comparisons are very difficult, as descriptions are often incomplete—*e.g.*, *Amœba urogenitalis* Baelz, and *Amœba pulmonalis* Artault.

Nomenclature.—The correct name is *Loeschia coli* (Loesch, 1875), as will be explained below.

Definition.—*Loeschia* with cytoplasm often containing red corpuscles and with four nucleate cysts.

Historical.—*Early Observations.*—Loesch discovered the amœba which he named *Amœba coli* in motions from a case of dysentery, and considered it to be pathogenic. It was by this name that Quinke and Roos in 1893 called the organisms found by them in dysentery. As already stated, Councilman and Lafleur called an amœba found in cases of dysentery *Amœba dysenteriæ*, and it is certain that this was Loesch's *Amœba coli*. An amœba somewhat similar to the 'tetragena stage' of *L. histolytica* was seen by Kruse and Pasquale in 1893.

We thus see that the correct name for the dysenteric amœba is *Loeschia coli*, as Dobell has pointed out, and that the correct name for the harmless amœba is *L. hominis*, because Casagrandi and Barbagallo called it *Entamœba hominis* in 1897, when it really had no name. Unfortunately Schaudinn did not utilize this name, and in his revision applied the term 'coli' to the non-pathogenic form, and invented the name *histolytica* for the pathogenic amœba, which is difficult to change at the present time, as there is no certainty that there is at present finality in this nomenclature.

Differentiation.—In 1902 Jürgens for the first time clearly differentiated the pathogenic amœba, and in the following year (1903) Schaudinn studied and compared the morphology and the life-cycles of his *L. coli* and his *L. histolytica*, and thus established their characters, and gave the following account:—

Morphology.—Its average measurement is 25 to 50 μ in diameter, and therefore the average is greater than that of *L. coli*. It consists of clear hyaline ectoplasm and granular endoplasm, in which can be seen red blood-corpuscles, vacuoles, bacteria, and other matters, but the nucleus is not clearly visible unless coloured by some preparation. When resting it is oval or spherical, but during movement it alters its appearance repeatedly, throwing out pseudopodia and creeping about. The nucleus is small, about 5 μ in diameter, and is poor in chromatin, and placed excentrically sometimes close to the periphery. The limiting membrane is difficult to define, and the amount of chromatin is relatively very small. A small karyosome can sometimes be seen in the centre of the nucleus.

Life-History.—It reproduces in three ways: (1) binary fission; (2) gemmation; and (3) sporogony.

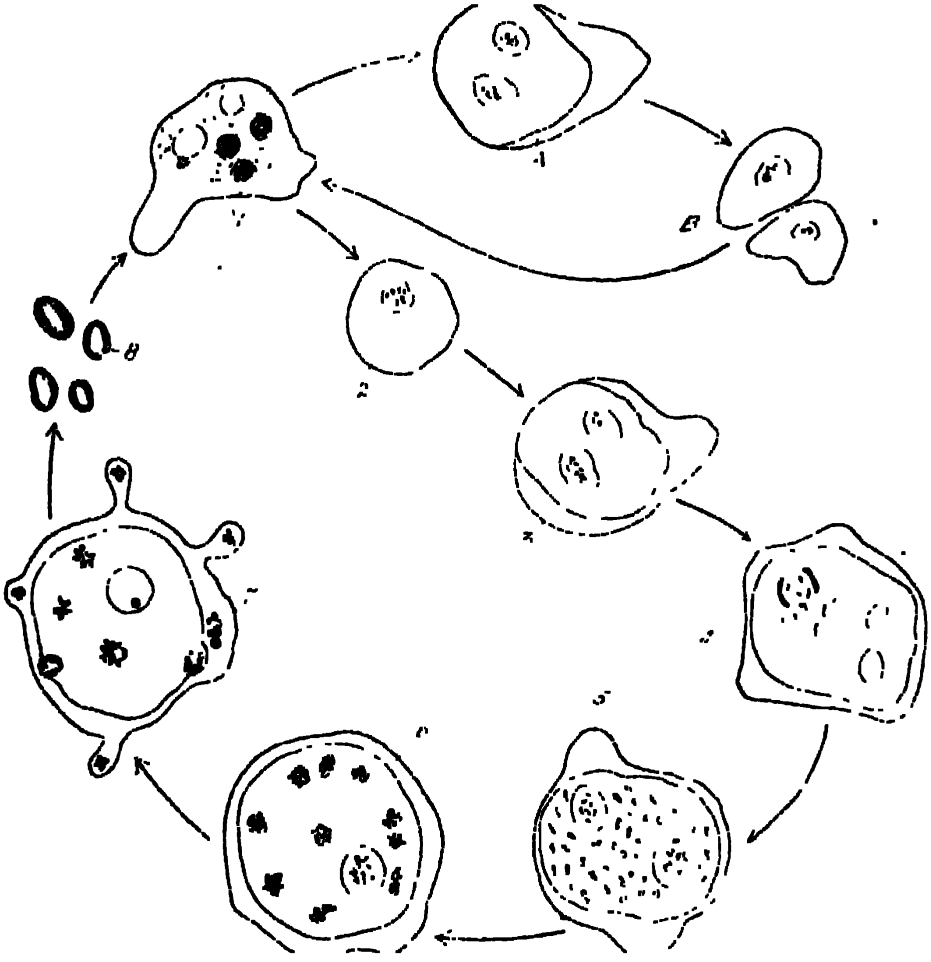

FIG. 51.—DIAGRAM OF THE LIFE-CYCLES OF *Loeschia histolytica* ACCORDING TO SCHAUDINN'S VIEWS.

(Constructed from Craig's drawings in the *Journal of Infectious Diseases*.)

A, B, Binary fission; 1-8, spore-formation.

1. *Binary Fission.*—This method was only discovered by Schaudinn on examining fresh specimens of the infected alimentary canal.

The nucleus divides by amitosis into two, and then the cytoplasm splits into two equal daughter cells.

2. *Gemmation.*—Gemmation, found more commonly than binary fission by Schaudinn, consists of the division of the nucleus by amitosis into two or more daughter nuclei, which, together with small portions of the cytoplasm, separate off from the mother cell, the daughter cell being smaller than the mother cell.

3. *Spore-Formation.*—In spore-formation, which only takes place under favourable circumstances, such as when [illegible] is taking place after an

attack of dysentery, the chromatin in and around the nucleus becomes diffused into the cytoplasm, and finally collects near the periphery, and the remains of the nucleus disappear, being either pushed out or absorbed. The ectoplasm forms small knobs, containing several chromidia in each. These knobs and their chromidia become separated off as rounded bodies, which, becoming surrounded with a yellowish-brown envelope, form the spores for the infection of a new host, as has been shown by Schaudinn's feeding experiments on cats, which developed typical dysentery with the amœbæ in the motions, in the lumen, and in the wall of the alimentary canal. These experiments further proved that it was only by the spores that infection would be spread. The remaining portion of the amœba dies after the formation of the spores.

Recent Work.—Modern researches tend to confirm Schaudinn's morphological description as well as his binary fission, but not the amitotic form of division, while the bud formation (Fig. 52) has been proved by James and others to be artificial, and the spores are regarded as not belonging to an Amœba, but to some other organism in the fæces.

In 1905 Craig in the Philippine Islands confirmed Schaudinn's morphological characters, and called attention to the rapid movements of *L. histolytica* and to the greenish tint which it often assumes in motions containing much blood.

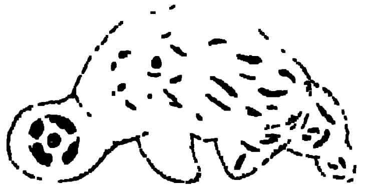

FIG. 52.—ARTIFICIAL BUDDING IN *Loeschia histolytica* SCHAUDINN, IN MOIST CHAMBER PREPARATIONS. (After James.)

In 1907 Viereck stated that there were more than one pathogenic amœba in man. The second one, which he named *Entamœba tetragena*, looked like *L. coli*, but had only four-nucleate cysts, and this, he thinks, is the type seen by Quincke and Roos and by Kruse and Pasquale. In the same year Hartmann and von Prowazek found an entamœba in patients coming from Africa, which could be differentiated by its nuclear structure from *L. coli* and *L. histolytica*, and this they named *E. africana*; but later Hartmann, finding quadrinucleate cysts, concluded that it was the same as *E. tetragena*, which is an accepted fact.

In 1908 Craig, drawing attention to variations in *L. histolytica* and in *L. coli*, emphasized the difficulty in differentiation between these organisms, and in the same year Werner confirmed the existence of *L. histolytica* and of *E. tetragena*.

In 1909 Hartmann states that Schaudinn knew about *E. tetragena*, and that of the three, *L. coli*, *L. histolytica*, and *E. tetragena*, *L. histolytica* is the smallest, and has ectoplasm differentiated from endoplasm even at rest. Its nucleus is excentric, can be distorted, and does not possess a double contoured achromatic membrane, while its lack of chromatin is characteristic, there being only a little karyosome and a condensed layer of chromatin at the margin of the nucleus, while nuclear cyclical changes are rare. In the same year Noc wrote a paper mainly of an epidemiological nature, but also dealing with this amœba, and Elmassian described

E. minuta, which is to-day generally considered to be a stage of *L. histolytica*.

In 1911 there appeared a valuable paper by Walker, in which he distinguished only *L. coli* and *L. histolytica*, but the latter was considered to have 'a tetragena stage,' a fact accepted to-day. He said that *L. histolytica* was hyaline, feebly refrangent, with active motility, feebly staining cytoplasm, and an indistinct nucleus, with a relative paucity of chromatin, which was present as a barely perceptible layer on the inner surface of the nuclear membrane, with or without a few fragments scattered in the nuclear network (histolytica stage), or as a more extensive but loose peripheral granular layer and a loose central karyosome (tetragena stage). All cysts were quadrinucleate.

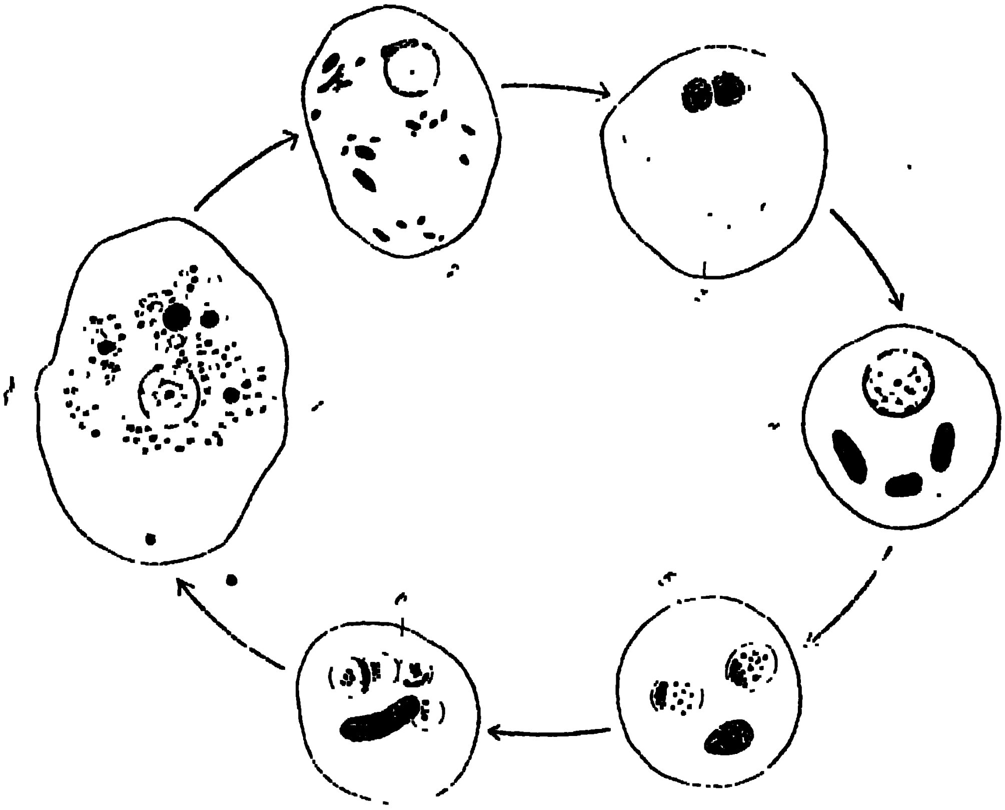

FIG. 53.—DIAGRAM OF THE LIFE-CYCLES OF *Loeschia histolytica* SCHAUDINN.

(Constructed from Hartmann's drawings in the *Archiv für Schiffs- und Tropen-Hygiene*.)

1. Fully grown parasite; 2-6, stages in encystment and nuclear division.

In the same year Whitmore and Akashi published contributions.

In 1912 Hartmann came to the conclusion that there really was only one pathogenic amœba in man, and that this was *E. tetragena*, the morphology and development of which he studied.

This was the view which we adopted in our second edition, and Hartmann's observations may be gathered from the following account:—

Morphology.—It is usually about 25 to 40 μ in diameter, but may be as small as 20 μ, 10 μ, or even 5 μ. When at rest it is spherical, but varies in shape when in motion. The ectoplasm is usually well defined, and in pseudopodia is seen to consist of hyaline highly refractive protoplasm, but this differentiation is sometimes difficult to define. The endoplasm is greyish in colour, and usually contains red blood-corpuscles as well as other matters. The vesicular nucleus is clearly visible, and has a well-defined membrane on which chromatic granules are distributed. In the centre there is a karyosome surrounded by a clear area, and containing a centrosome. A cycle of changes is constantly proceeding in the nucleus: first chromidia break away from the karyosome and pass outwards into the nucleus, and this proceeds until little but the centrosome is left, when it ceases, and chromatin begins to accumulate again around the centrosome, until the karyosome is re-formed, when the cycle begins again.

Life History.—Asexual reproduction is by promitosis. Sporogony is rare, and when it occurs tends to cyst formation, before which the amœbæ become small, and their chromidia form three to six masses. The cyst sometimes contains a large vacuole. Nuclear division takes place until four nuclei are formed. The further life-history is unknown.

In 1912 Calkins gave his account of the Genera and Species of Amœbæ, Hassall his valuable bibliography, Crawley his list of Parasitic Amœbæ, Craig his relationship of Parasitic Amœbæ to Disease, Darling his identification of Pathogenic Panama Amœbæ, and von Prowazek the structure of the nucleus of parasitic Amœbæ, while James contributed two papers on the clinical identification of the Entamœbæ and on infection with *E. tetragena*. In the latter of these papers it is stated that the *histolytica phase* is found in *infections with acute symptoms*, while the *tetragena phase* is found in more *chronic infections*. Craig formulates a life-history for *L. histolytica* as follows:—

1. *Vegetative Stage:* Histolytica-phase in acute dysentery; tetragena-phase in chronic dysentery.
2. *Precystic Stage:* Amœbæ decrease in size (minuta-phase), and the nucleus is intermediate in type between the other two phases.
3. *Cystic Stage:* Cysts 7-20 microns quadrinucleate.

In 1913 Whitmore gives an account of his own and the work of Viereck, Hartmann, and Huber. In 1914 there appeared a most important paper by James detailing historical matter, morphology, and classification and technique, with regard to the Entamœbæ of man. In 1917 Craig gave an excellent summary of the Amœbæ parasitic in man.

We thus see that although *L. coli* and *L. histolytica* are distinct, it is difficult to effect a diagnosis in the *trophozoite phase*, and that histolytica, tetragena, and perhaps minuta, are phases of one and the same organism.

In the same year there appeared papers by Wenyon and O'Connor on the 'Human Intestinal Protozoa in the Near East,' detailing the characters of *E. histolytica*, and by Chalmers and O'Farrall with regard to its presence in the urinary tract, which brings in the synonym *Amœba urogenitalis* Baelz, 1883.

Wenyon and O'Connor consider that no infection can be ascribed to *L. histolytica* unless some amœbæ with included red corpuscles are present or unless typical cysts are present in the stool. An amœba with refractile ectoplasm, and indistinct nucleus and active movement, is most likely to be *L. histolytica*, but these characters alone will not distinguish the organism.

For the diagnosis of Amœbæ they lay down the following rules:--

1. Amœbæ containing red blood-corpuscles are *L. histolytica*, whether the stool is dysenteric or not; and, further, they indicate an active dysentery. These cases urgently require emetine treatment.
2. Amœbæ, none of which contain red blood-corpuscles, occurring in a dysenteric motion are indicative of *L. coli* or of *L. histolytica* in a carrier, while the cause of the dysentery is not an amœba; and these cases should be watched for a few days, without treatment, with a view to finding the cysts.
3. Amœbæ, none of which contain red blood-corpuscles, occurring in non-dysenteric motions may be *L. coli* or *L. histolytica*, and diagnosis has to be made by finding the quadrinucleate cysts, perhaps, after several days' observation.

In 1918 Dobell showed, by experimental infection of tadpoles, that *L. histolytica* and *L. ranarum* were distinct species, and with Jepps drew attention to the existence of diverse races of *L. histolytica*, which could be distinguished by the dimensions of the cysts.

The above does not complete the history, but is as full as space permits, and we will now turn to the morphology.

Morphology.--*Vegetative Stage. Young Trophozoite Phase*.--This phase may also be termed the *histolytica phase*, as defined above.

It occurs when active dysenteric processes are proceeding in the bowel, and is represented as a rule in the fresh condition by large amœbæ measuring from 30-90 microns in diameter, but exceptionally being present in small size. As a rule its motility is very marked, often starting with such a rapid action as to be worthy of the name explosive. The pseudopodia are broad, and may be solely ectoplastic, or be composed of endoplasm as well. The ectoplasm may be clearly distinguishable from the endoplasm even when the amœba is at rest, but often there is no such distinction.

The cytoplasm may have a well-defined light green colour, or more usually this colour is wanting. It may contain a number of vacuoles, or it may not. It often possesses a number of ingested red blood cells, but at times these are wanting. It may be vacuolated, or it may be granular.

The nucleus in the fresh specimen is usually difficult to see. It is excentric, poor in chromatin, and easily altered by internal pressure. It possesses a very delicate membrane, with a few peripherally arranged grains of chromatin.

In stained specimens there is rarely any differentiation of the ectoplasm from the endoplasm. The cytoplasm may contain vacuoles, erythrocytes, and perhaps the phagocyted nuclei of other cells. The nucleus, unless distorted, is roundish, possesses a delicate nuclear membrane, under which a thin band or a few grains of chromatin may lie. The centre of the nucleus is occupied by a karyosome, which may contain a very minute centriole. The space between the karyosome and the nuclear membrane sometimes shows a delicate, poorly staining network, at the nodes of which lie fine granules of chromatin. The cyclical changes described by Hartmann for the next stage are not visible.

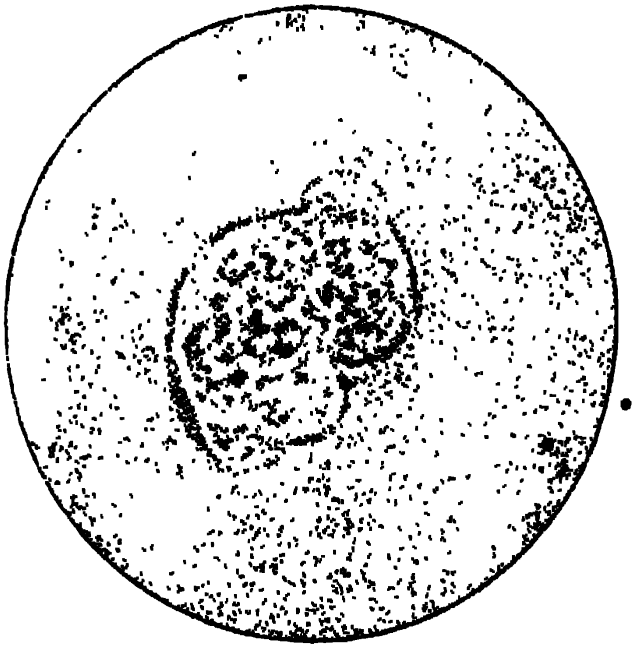

FIG. 51.—PHOTOMICROGRAPH OF THE LIVING AND RAPIDLY MOVING *Loschia histolytica* SCHAUDINN, IN THE YOUNG TROPHOZOITE STAGE OF ACUTE DYSENTERY. (× 1,500 DIAMETERS.)

(From the *Journal of Tropical Medicine.*)

James has pointed out that when stained by Hastings' and Giemsa's method the nucleus takes on a light blue colour, and contains a delicate network of blue threads, and a number of fine red coloured threads and bars scattered irregularly over this network, composed of a substance which he calls '*erythrochromatin*,' to distinguish it from the true chromatin.

Old Trophozoite Phase.—This is the phase so carefully described by Hartmann under the heading *E. tetragena*, and often called the *tetragena phase*. It resembles the *histolytica phase* in many particulars, but differs therefrom in the fact that the nucleus is usually clearly visible as a well-rounded globular vesicle plainly set off from the cytoplasm by a stout double contoured membrane and showing in the middle a small karyosome, surrounded by a clear structureless zone, between which and the nuclear membrane there is a linin network on which granules of chromatin are distributed.

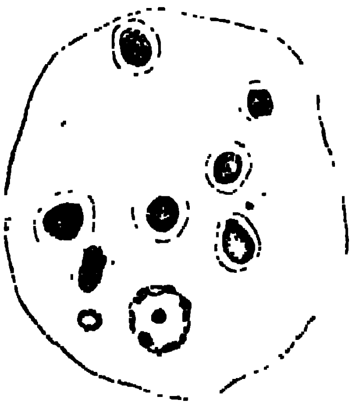

FIG. 55. *Loeschia histolytica* SCHAUDINN, YOUNG TROPHOZOITE, FIXED AND STAINED SHOWING NUCLEUS AND PHAGOCYTED RED BLOOD CELLS. (× 1,050 DIAMETERS.)

(After J.)

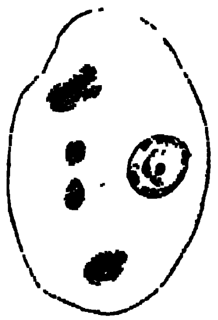

FIG. 56. *Loeschia histolytica* SCHAUDINN, OLD TROPHOZOITE OR TETRAGENA PHASE, STAINED PREPARATION (× 1,050 DIAM-

This nucleus undergoes cyclical changes, but in a given preparation, as a rule, all the amœbæ show the same appearance. The cyclical changes are:—

1. Large blocks of chromatin under the nuclear membrane, a very definite karyosome containing a centriole (Fig. 57, *a*, and 58, *a*).
2. Many small granules of chromatin scattered under the membrane and at the margin of the karyosome (Fig. 57, *b*).

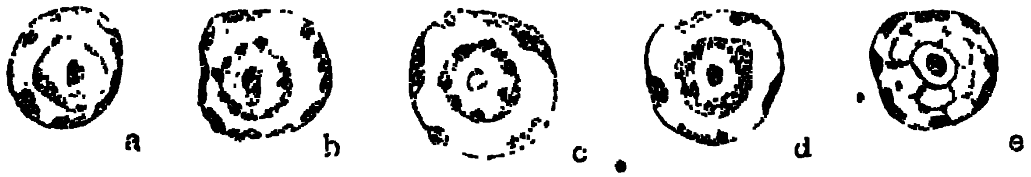

FIG. 57.—NUCLEUS OF *Loeschia histolytica* SCHAUDINN, OLD TROPHOZOITE PHASE. STAINED PREPARATIONS. (× 1,050 DIAMETERS.)

(After James.)

Note the cyclical changes described in the text.

3. Chromatin more concentrated under the nuclear membrane and at the karyosome margin, while a clear zone is appearing around the centriole (Fig. 57, *c*).
4. Chromatin under the membrane and at the karyosome margin (Fig. 57, *d*).

5. Chromatin has left the karyosome margin and passed over the linin network towards the nuclear membrane (Fig. 57, *e*).

6. The centriole swells and re-forms the karyosome, and so the cycle begins again or the amœba divides (Fig. 58, *b*).

Life-History.—*L. histolytica* may reproduce by binary fission during the vegetative stage, or it may encyst.

The first is the method by which it increases its numbers in a given host, and the second is for the purpose of passing from one host to another.

There is no sure evidence of schizogony.

Simple Division.—The centriole divides into two parts, each of which travels to opposite sides of the karyosome and are connected by a thread, the *centrodesmose*. The further stages require study.

Encystment—*Precystic Phase.*—All the amœbæ present in a given case reduce in size (*L. minuta*), but their numbers are augmented. The amœbæ become sluggish and have a clear ectoplasm, but the nucleus is not easy to see, and chromidia may or may not be present in the cytoplasm. The nucleus is spherical, with a thick regular membrane and with chromatin granules near the periphery. The karyosome shows no centriole.

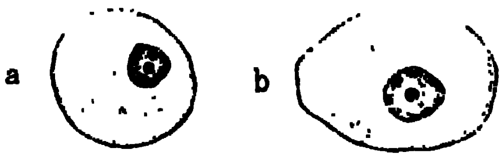

FIG. 58.—*Loeschia histolytica* SCHAUDINN OLD TROPHOZOITE PHASE SHOWING THE FIRST AND LAST STAGES OF THE CYCLICAL NUCLEAR CHANGES. (× 1,050 DIAMETERS.) (After James.)

Cystic Phase.—Different strains produce cysts of different sizes—*e.g.*, small cysts 7-10, medium 9-12, large 12-18 microns in diameter. Chromidia are formed in the cytoplasm, and may be derived from the nucleus, and may function as food material. The cytoplasm becomes granular and the nucleus swollen and elongated. An intranuclear spindle is formed between two centrioles situate at each end. The chromatin forms rows of granules extending from pole to pole. The nucleus divides and the daughter nuclei enter the resting stage, in which they remain for a long time. Each of these subsequently again divide, giving rise to the typical quadrinucleate cysts. Penfold, Woodcock, and Drew have brought evidence to show that, as a rule, the amœba escapes undivided from the cyst. No one has so far seen any flagellate forms or any gametes.

Infection.—Darling in 1913 showed that only the cysts were infective, and that they are ingested with food, and must not have been passed out of the original host longer than two or three days.

Wenyon and O'Connor in 1916 have proved that, as in the case of *L. coli*, house-flies can ingest the cysts, which are subsequently passed on to human food, and so the infection carried from man to man.

These researches clearly prove that the method of infection is by cysts passed in fæcal matter entering the flies, and so reaching human food, as direct fæcal contamination is not so likely, though, of course, it may also be a method of infection.

Further, these cysts are spread abroad by the fæcal matter of *human carriers—i.e.*, persons who have recovered from amœbic dysentery, and even those who have never suffered in this manner. These carriers are the *human reservoir* of the parasite.

Diagnosis.—Amœbæ present in human fæces and containing red blood-corpuscles are, as a rule, *L. histolytica*. Amœbæ without red corpuscles require differentiation by the cysts, which must be sought during several days. Quadrinucleate cysts belong to *L. histolytica*, others are doubtful or definitely negative.

Cultivation.—Since the days of Auerbach in 1856 attempts have been made to cultivate pathogenic amœbæ in pure or contaminated cultures. With regard to *L. histolytica* all such attempts were failures until Cutler apparently succeeded, in 1918, on Dean and Monat's egg medium, to which a few drops of blood had been added, and on blood-clot medium. The media were inoculated with blood and mucus from motions passed not longer than three hours, and were incubated at 28°-30° C. In culture the amœbæ varied from 8-30 microns in size, with homogeneous but often vacuolated cytoplasm containing ingested red blood cells and moving typically like *L. histolytica*. Uninucleate and binucleate forms were seen. Cysts were obtained by ceasing to subculture for two to three days and then placing the culture for two hours in an ice-chest.

Cysts from the culture produced typical dysenteric lesions in cats by feeding and by inoculation high into the rectum by means of a catheter.

Strains.—*Vide* historical section (p. 313).

Pathogenicity.—*L. histolytica* is the cause of amœbiasis in man and animals, causing amœbic dysentery and amœbic abscesses in the liver and other parts of the body.

Loeschia gingivalis Gros, 1849.

Synonyms.—*Amœba gingivalis* Gros, 1849; *A. buccalis* Sternberg, 1862; *A. dentalis* Grassi, 1879; *A. dentalis* Braun, 1883; *Entamœba buccalis* Prowazek, 1904; *A. maxillaris* Kartulis, 1906.

Definition.—Loeschia with cysts containing only one nucleus, cytoplasm often containing red blood-corpuscles, ectoplasm only visible during motion as a clear highly refractive layer. Nucleus as a rule not visible. Reproduction only by simple fission.

History.—This amœba, which occurs in the mouth in healthy and diseased conditions, was first described by Gros in 1849, and was afterwards studied by Sternberg, Grassi, Prowazek, and mentioned by Braun, and is probably the same as Kartulis' organism.

Morphology.—Its size varies from 7-35 microns, the average being 12-20 microns.

The ectoplasm is only well defined during movement, which is quite active, and takes place by short blunt or long tapering pseudopodia. The endoplasm is granular, containing non-contractile food vacuoles and often red blood-corpuscles. The nucleus as a rule is not distinct.

Life-History. Reproduction apparently only takes place by simple fission, while cyst formation, which has been observed, is believed to be purely protective, as they contain only one nucleus. The cysts may measure from 8 10 or more microns.

Animal Experiments. All attempts to produce dysentery in animals by means of this amœba have so far been failures.

Pathogenicity. It has been accused, without sufficient proof, of being the cause of pyorrhœa alveolaris.

Doubtful Species.

The species to be now described are not considered as 'good' by many authorities, but we give a brief account of them for the sake of completeness.

Loeschia tropicalis Lesage, 1908.

Lesage, from his studies of tropical dysentery, has come to the conclusion that, just as there is a *Loeschia coli* Loesch parasitic, but non-pathogenic, in the intestine of man in warm and temperate countries, so there is another amœba parasitic, but non pathogenic, in the intestine of man in the tropics. This parasite he names *L. tropicalis*.

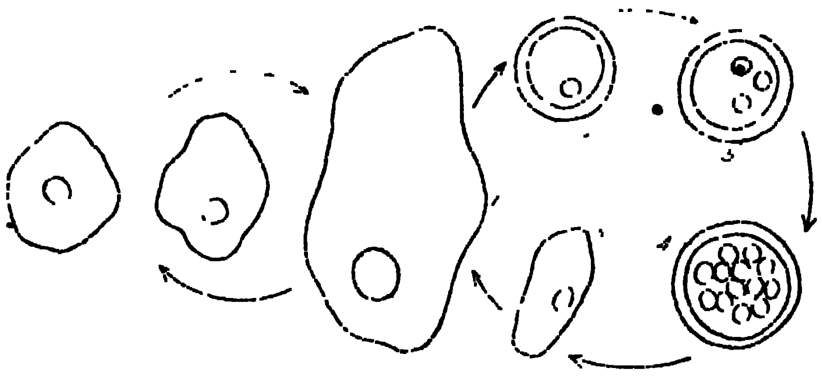

FIG. [illegible].—*Loeschia tropicalis* LESAGE, 1908: DIAGRAM OF THE LIFE-CYCLES CONSTRUCTED FROM LESAGE'S DRAWINGS.

(Constructed from Lesage's drawings in the *Bulletin de la Société de Pathology Exotique*, showing binary fission and spore formation.)

It resembles *L. coli* by having a nucleus which contains much chromatin and by becoming encysted, but it differs from the same in having a clearly visible ectoplasm, by the small size of its cysts, and by the fact that the nucleus of the cysts breaks up into a number of nuclei, which are from three to several (he draws thirteen in one cyst). This entamœba can be cultivated along with bacteria, but is non p[illegible]nic to animals.

[illegible] considers this to be the same amœba which was studied and cultivated by Musgrave and Clegg, and thinks that the production of dysenteric symptoms in their experiments was due to contamination with the minute spores of *Loeschia histolytica*. Walker in 1908 describes as a new species, *E. hominis*, which may perhaps be the same as *L. tropicalis*.

Pathogenicity. It is a harmless commensal in the alimentary canal of man.

Culture. It can be cultivated in symbiosis with bacteria.

Loeschia undulans Castellani, 1905.

Synonym.—*Entamœba undulans* Castellani, 1905.

This amœba was found in fæces from persons suffering from diarrhœa in Ceylon, together with other intestinal protozoa—*e.g.*, Cercomonata and Trichomonata. A somewhat similar amœba has been found by Gauducheau in dogs.

It varies in size, being from 12 to 30 μ in diameter, but there may be much smaller individuals. It has no flagella, but possesses an undulating membrane, and long straight pseudopodia, which are rapidly emitted and retracted, only one pseudopodium being protruded at a time. There is no marked differentiation into ectoplasm and endoplasm, and a non-contractile vacuole is usually to be seen. The cytoplasm, which is finely granular, often contains bacteria. Castellani is inclined to consider this parasite as a developmental stage of *Cercomonas hominis*, as was his original opinion. Perroncito long ago described an amœboid stage of *Cercomonas hominis*. Wenyon considers it to be a stage of a Cercomonas.

FIG. 90.—*Loeschia undulans* CASTELLANI, 1905.

Loeschia phagocytoides Gauducheau, 1908.

Synonym.—*Entamœba phagocytoides* Gauducheau, 1908.

Loeschia phagocytoides was discovered by Gauducheau in Indo-China in a case of dysentery. It is very small—only 2 to 15 μ in diameter—very actively motile, and possessing a well developed ectoplasm. It can be easily cultivated on ordinary agar-agar inoculated with *Bacillus typhosus* or other bacteria, which it readily engulfs and digests. Some individuals show in their ectoplasm peculiar spirochæte-like bodies.

Loeschia minuta Elmassian, 1909.

Synonym.—*Entamœba minuta* Elmassian, 1909.

This amœba, found by Elmassian in a case of chronic dysentery in South America, resembles *L. tetragena*, but is much smaller, rarely exceeding 14 μ in diameter. There is no differentiation between the ecto- and endo-plasm. The nucleus is invisible in fresh preparations, and when stained is rich in chromatin. Encysted forms contain four nuclei.

Loeschia nipponica Koidzumi, 1909.

Synonym.—*Entamœba nipponica* Koidzumi, 1909.

This entamœba was found by Koidzumi in the motions of cases of dysentery and in healthy people in Japan. In the former case it is associated with *L. histolytica*, which it resembles in size (15 to 30 μ) and in the marked difference between the ecto- and endo-plasm. The pseudopodia are never spinose; the endoplasm is vacuolated, and more granular than in *L. histolytica*. The nucleus is well defined (5 to 7 μ), and rich in chromatin. This amœba reproduces by fission, schizogony, and sporogony.

Loeschia hartmanni Prowazek, 1912.

Found in man in Savaii. It is 4 to 13 μ in diameter; nucleus vesicular, 2 to 3·3 μ; cysts small, quadrinucleate, characterized by a thin, bacteria-like arrangement of chromidia.

Loeschia williamsi Prowazek, 1911.

This Loeschia is considered to be identical with *L. coli* Loesch.

Loeschia brasiliensis H. Baurepaire Aragao, 1912.

Resembles *L. coli*. Cysts 7 to 15 μ in diameter, with eight nuclei and a double contour membrane. The cysts are characterized by the presence of a certain amount of siderophile substance which divides the cysts into two portions of nearly equal size.

Loeschia butschlii Prowazek, 1912.

Synonym. *Entamœba butschlii* Prowazek 1912.

Found in a boy in the Caroline Islands. It varies in size from 10 to 24 μ; coarse alveolar cytoplasm; nucleus vesicular; round karyosome and centriole; cysts roundish said to differ from those of *L. coli*.

Loeschia mortinatalium Smith and Weidman, 1910.

Synonym.- *Endamœba mortinatalium* Smith and Weidman, 1910, and perhaps *Amœba pulmonalis* Artault, 1898.

Definition. Loeschia of large size, 22-38 × 20-25 microns, with nucleus 10 microns in diameter, with well-defined membrane, large karyosome, and occasionally a centriole.

Remarks.- Somewhere about 1800 Ribbert found amœbæ in the kidneys and parotid glands of infants. In 1898 Artault observed amœbæ with a nucleus and a vacuole in a lung cavity. Brumpt has seen similar amœbæ and R. Blanchard has found some in the lungs of sheep, which may or may not be the same as the *Entamœba ovis* Swellengrebel, 1914, found in the gut of sheep.* This latter measures 12-14 × 11-12 microns. Its cysts are 8 microns in diameter, uninucleate, with a glycogen vacuole. In 1904 Jesionek and Kiolemenoglou found amœbæ in the kidneys, liver, and lungs of an eight months syphilitic fœtus. In 1910 Smith and Weidman found an amœba in the kidneys, liver, and lungs of stillborn full-term fœtus, and in 1914 they found their *L. mortinatalium* again in the lungs of a two-months old child which was syphilitic and died of pneumonia. Athey and Chalmers have observed amœbæ in the sputum and in the lungs of a case of pneumonia in the Anglo-Egyptian Sudan unassociated with any known history of dysentery, which they thought were possibly *L. histolytica*. Time must show what these amœbæ really are.

Loeschia minutissima Brug, 1917.

Synonym. *E. minutissima* Brug, 1917.

A very small amœba, 4·11 - 4·8 microns. Usually 6·5-7 × 5-6 microns.

Loeschia tenuis Kuenen and Swellengrebel, 1917.

This amœba, which was described as *Entamœba tenuis*, measures 6-9 microns in diameter, with cysts 6-8 microns, and one to four nucleated, is very like *E. nana* of Wenyon and O'Connor and the *E. minuta* of Woodcock and Penfold, which latter, however, is said to be the same as *E. histolytica*.

Loeschiæ in Animals.—Though somewhat beyond the bounds of the present work, we may mention that amœbæ, believed to belong to the genus Loeschia, but requiring restudy in the light of recent researches, occur in several vertebrates—*e.g.*, *L. nuttalli* Castellani, 1908, found in liver abscesses and dysentery in monkeys in Ceylon; *L. cobayæ* in guinea-pigs, *L. enterica* in cats, etc., *L. muris* Grassi in mice, considered by Wenyon to be *L. coli*, *L. fecalis* in several animals, *L. intestinalis* in horses, etc., *L. galloparvæ* in turkeys, *L. ranarum* Grassi in frogs, and many more.

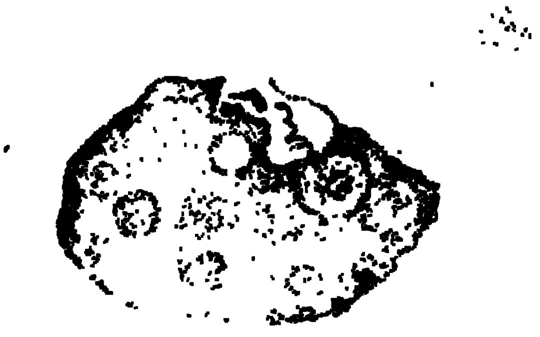

FIG. 61.—*Loeschia nuttalli* CASTELLANI, 1908 CONTAINING RED BLOOD CELLS.

Genus Vahlkamfia Chatton and Lalung-Bonnaire, 1912.

Definition. *Gymnamœbida*, with vesicular nucleus (protokaryon) having one large karyosome with or without a centrosome, with little peripheral chromatin, with division by promitosis. Cysts typically uninuclear.

Remarks.—Practically all cultivable amœbæ isolated from human stools and potable water by various observers belong to this genus. Cropper has grown a peculiar amœba belonging to this genus in citrate solution.

Type.—*Vahlkamfia limax* Dujardin, 1841, *emendavit* Vahlkamf, 1904.

Vahlkamfia punctata Dangeard, 1910.

This amœba was found in Indo-China in the motions of a case of diarrhœa. The ectoplasm is rarely visible, and the endoplasm is very basophile, while the method of division is by promitosis. The cysts are 8 to 12 μ in diameter, with a thin wall showing a double contour ornamented with punctations, and always uninucleate.

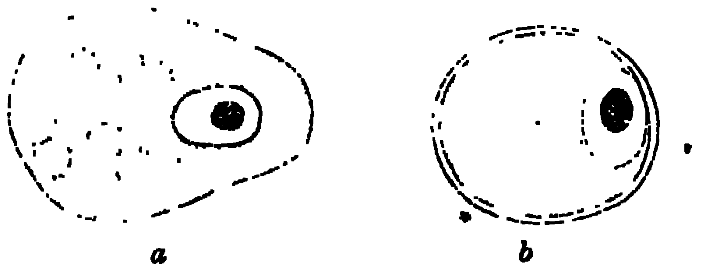

FIG. 62.—AMŒBA AND CYST FOUND IN HUMAN FÆCES AND POSSESSING THE LIMAX TYPE OF NUCLEUS. (*a*) TROPHOZOITE, (*b*) CYST. (× 1,950 DIAMETERS.)

(After James, from the *Annals of Tropical Medicine and Parasitology*.)

Vahlkamfia lobospinosa Craig, 1912.

Synonym.—*Amœba lobospinosa* Craig, 1912; *V. withmorei* Hartmann, 1912.

This amœba was cultivated from a dysenteric stool from a patient in Manila in 1905, and first described by Musgrave and Clegg. In 1912 it was studied by Craig and called *Amœba lobospinosa*, also by Williams and Calkins, by James, by Liston, and by Wells.

James, in the Canal Zone, obtained this amœba for a considerable period from the fæces of a patient which were guarded against contamination, and hence it must be admitted that it can live for a time in the intestine of man, but it is probably non-pathogenic.

On the other hand, in all the other reported cases it has occurred as an aerial contamination of the fæces or pus in which it has been found. It was first cultivated by Musgrave and Clegg.

OTHER SPECIES.

In 1917 Kuenen and Swellengrebel divided the species of *Limax amœba* into three types, the *Limax*, the *Endolimax*, and the *Pseudolimax*; but taking *V. limax* Dujardin, 1841, *emendavit* Vahlkampf, 1904, as the type species, and allowing that *V. lacustris* Naegler, 1909, is the same species, the following are known:

A. *Small forms, 3-15 microns*:—
Cysts 1·5 microns in diameter—*V. limax* Dujardin, 1841, *emendavit* Vahlkampf, 1904.
Cysts over 7 microns in diameter.
(*a*) Karyosome surrounded by a peripheral row of chromatin granules—*V. lacertæ* Hartmann, 1907.
(*b*) Karyosome not so surrounded—*V. froschi* Hartmann and Prowazek, 1907.

B. *Medium-sized forms, 15-30 microns*.—
(*a*) Trophozoite binucleate—*V. diploidea* Hartmann and Naegler, 1908.
(*b*) Trophozoite uninucleate:
1. Contractile vacuole present—*V. tachypodia* Glaeser, 1912.
2. Contractile vacuole absent—*V. polypodia* Schutze, 1875.

C. *Large forms reaching to 50 microns*:—
(*a*) Trophozoite binucleate—*V. binucleata* Gruber, 1884.
(*b*) Trophozoite uninucleate:—
1. Ectoplasm like a lamella—*V. lamellipoda* Glaeser, 1912.
2. Ectoplasm not so distinct:—
(1) Nuclear division promitotic—*V. albida* Naegler, 1909.
(2) Nuclear division mesomitotic—*V. guttula* Dujardin, 1912.

V. binucleata may be a stage in the development of Pelomyxa, which appears to be impossible to Jepps and Dobell, while Alexeieff places it in a genus Hartmannella with a type *H. hyalima* Dangeard, which Jepps and Dobell say is quite different. It probably requires a new genus creating for itself. *V. diploidea* was obtained by Hartmann and Naegler in cultures from lizard fæces, and has been found by Jepps and Dobell in human fæces which had been kept for some time. Alexeieff proposes to place it in *Sappinia* Dangeard, 1896. *V. pædophthora* Caullery, 1910, is like *V. limax*, but is parasitic in the eggs and embryos of a crab, belonging to the genus Peltogaster.

Vahlkamfia nana Wenyon and O'Connor, 1917.

Synonym. *Entamœba nana* Wenyon and O'Connor, 1917; *Vahlkamfia nana* Brug, 1917.

Definition. -*Vahlkamfia* of small size (5-10 microns), moving slowly, with blunt ectoplasmic pseudopodia, nucleus with membrane and large central karyosome, cysts 7-8 × 8-10 (when elongated) microns with one to four nuclei, without chromidial bodies.

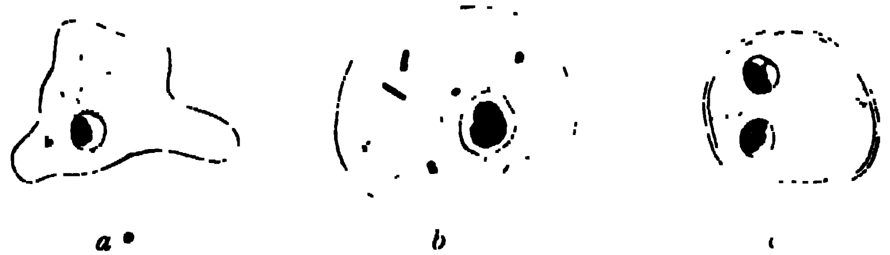

FIG. 63.—*Vahlkamfia nana* (WENYON AND O'CONNOR, 1916).
(*a*) Trophozoite, fresh conditions; (*b*) trophozoite stained preparation; (*c*) cyst with two nuclei.
(After Wenyon and O'Connor, from the publications of the Wellcome Bureau of Scientific Research.)

Remarks.- This amœba was found by Wenyon and O'Connor in Egypt, and we have seen it in the Anglo Egyptian Sudan and Southern Italy. It has been confused with *E. coli*, *E. histolytica*, and *V. limax*. *V. nana* has not been cultivated.

Time will be required to show definitely its generic position. Provisionally we have placed it under Vahlkamfia, though its cyst is binucleate.

Genus Dientamœba Jepps and Dobell, 1918.

Definition.- -*Gymnamœbida* of small size, without a known flagellate stage, and typically binucleate, with both nuclei of the same size and structure.

Type Species.- *Dientamœba fragilis* Jepps and Dobell, 1918, found in man. It is the only known species at present.

Dientamœba fragilis Jepps and Dobell, 1918.

Definition.- --*Dientamœba* with the generic characters.

Historical.- -This amœba was first detected by Jepps and Dobell in 1917 in a native of the British Isles who had never been abroad, but was suffering from slight diarrhœa, attributed to a chill. It was found in British soldiers who had been to Salonika, and in natives of New Zealand serving as soldiers. In all it has been seen in seven cases.

Morphology.—It is a very small active organism, measuring when rounded some 3·5-8-10-12 microns in diameter, and moving about by means of extremely thin, hyaline, leaf-like pseudopodia composed of sharply defined ectoplasm. The rest of the body is often rounded, and consists of granular endoplasm, and is situate posterior to the pseudopodia, thus giving a snail like appearance during active movement.

The cytoplasm is alveolar and contains bacilli and cocci. There is no contractile vacuole, but there are diffuse brown-stained patches indicative of glycogen in iodine-stained preparations. The amœba is binucleate in about 80 per cent. of the forms examined, and these nuclei are usually invisible in the living organism. In stained preparations they are 2 microns in diameter, and each contains a large central karyosome surrounded by a clear zone, which is traversed by a few very fine radiating linin threads, and which separates the karyosome from the extremely delicate nuclear membrane, on which there is no chromatin. There is sometimes a separate granule to be seen lying in the centre of the karyosome, which is the centriole of many authors.

Life-History.—No signs of division or cyst formation have been observed.

Habitat.—The intestine of man, probably in the colon.

Food.—Small bacteria and yeasts living in the intestinal contents.

Pathogenicity.—It is believed to be non-pathogenic.

Cultivation.—So far all attempts at cultivation have failed.

Binucleate Amœbæ.—We have already noted under the genus Vahlkamfia two binucleate amœbæ in addition to *V. nana*—viz., *V. diploidea* Hartmann and Naegler, 1908, with occasional uninucleate forms, and *V. binucleata* Gruber, 1884, and have shown that they probably are not *Vahlkamfia* and equally they are not *Dientamœba*. Another binucleate form may be *Amœba mira* Glaeser, 1912, about which there appears to be much doubt as to whether the name was given to a binucleate or uninucleate form. Schaudinn's *Paramœba* is a marine binucleate amœba, and forms a genus in which Janicki in 1912 placed some of Grassi's parasitic amœbæ found in Sagitta. In these amœbæ the two nuclei are dissimilar, one being a nucleus and the other a Nebenkoerper. Craigia (*vide infra*) may also possess two dissimilar bodies, one a nucleus and the other like a Nebenkoerper.

Genus Craigia Calkins, 1912.

Definition.—*Gymnamœbida*, free swimming or parasitic, with a uniflagellate swarm stage, and with or without an extranuclear Nebenkoerper-like body in the endoplasm. Ectoplasm seen on movement; size 10-25 microns.

History.—In 1896 Schaudinn described the life-history of *Paramœba eilhardi* Schaudinn, 1896, which possessed a cytoplastic extranuclear body, which he called a 'Nebenkoerper.' Reproduction was by simple fission and by cyst formation, in which the parasite broke up into a number of spores, each of which contained a piece of the nucleus and a piece of the Nebenkoerper. Each of these spores develops two flagella, and breaking out of the cyst forms the swarm stage. Finally the flagella are lost, after longitudinal division, and the spores become small amœbae.

In 1906 Craig found a parasite resembling that described by Schaudinn in the fæces of patients suffering from chronic dysentery in the Philippine Islands. He considered that they were the pathogenic agent of the symptoms from which the patients suffered, and because of their similarity to Schaudinn's organism called them *Paramœba hominis* Craig, 1906, and as such we described them in the first two editions of this work.

In 1912 Calkins considered that Craig's parasite could not be classified in the genus Paramœba, because its swarm spores have only one and not two flagella, while its extranuclear body is apparently different from that in Paramœba. He therefore gave it the name *Craigia hominis* (Craig, 1906), which Jepps and Dobell consider a non-existent organism and the genus a *nomen nudum*.

In 1915 Barlow discovered a new species, which he called *Craigia migrans* in Honduras.

Craig thinks that probably infections with this parasite are widespread, and that they may be often confounded with Cercomonads, etc.

Species.—There are four known species—viz., two parasitic in marine worms and two parasitic in man. The latter are distinguished as follows:—

A. Small accessory extranuclear body present in larger forms. Flagellate forms multiply by longitudinal division—*Hominis*.

B. Small accessory extranuclear body absent. Flagellate forms do not divide—*Migrans*.

Craigia hominis Craig, 1906.

Synonym.—*Paramœba hominis* Craig, 1906.

Definition.—Craigia in which the accessory nuclear body is present in the larger forms, and the swarm spores divide longitudinally, the accessory body and the motile organ participating in this division.

History.—It was discovered in 1906 by Craig, in the Philippine Islands, in cases of chronic diarrhœa, and in 1915 by Barlow, in Honduras, where it not only causes a form of chronic diarrhœa, but also severe ulcerative conditions of the intestine, resembling those of amœbic dysentery. Barlow fully confirmed Craig's observations.

Morphology.—In the *amœba stage* it measures from 15-25 microns, and possesses an ectoplasm which is clearly visible during motion, but not while at rest. The endoplasm is granular, and contains a nucleus which is distinct and composed almost entirely of chromatin. There is also an extranuclear body which is of an accessory nature.

Life-History.—The amœba can reproduce by binary division for some time, at the end of which it encysts, surrounding itself with a double contoured envelope, and divides into a number of small, spherical bodies, each of which contains a piece of the nucleus and a portion of the accessory body. The cyst now ruptures and the spores escape as uniflagellate swarm spores, some 3-20 microns in length. This is the *flagellate stage*. These little pear-shaped flagellates divide by longitudinal fission, in which the accessory body and the flagellum take part. Later the flagellates cease to move, lose their flagella, and become amœbæ, thus completing the cycle of the life-history.

Cultivation.—We are not aware of any attempts at artificial cultivation.

Pathogenicity.—It causes chronic diarrhœa and dysentery in man.

Craigia migrans Barlow, 1915.

Definition.—Craigia in which the accessory nuclear body is absent and in which the swarm spores do not divide longitudinally before becoming amœbæ.

History.—It was discovered by Barlow in fifty-one infections in Honduras, where it caused a severe dysenteric condition in the lower bowel and sometimes liver abscess. Barlow notes that it may be necessary to place this species in a genus distinct from Craigia.

Morphology.—The amœba measures some 12-30 microns, the average being 20 microns. The endoplasm is granular and contains a nucleus, but no accessory nuclear body.

Life-History.—The cysts measure 18 microns, and the flagellates, of which there are forty or more in a cyst, about 3.5 microns. These flagellates do not divide, but pass directly into the amœba stage.

Pathogenicity. It causes severe dysenteric lesions and liver abscess in man.

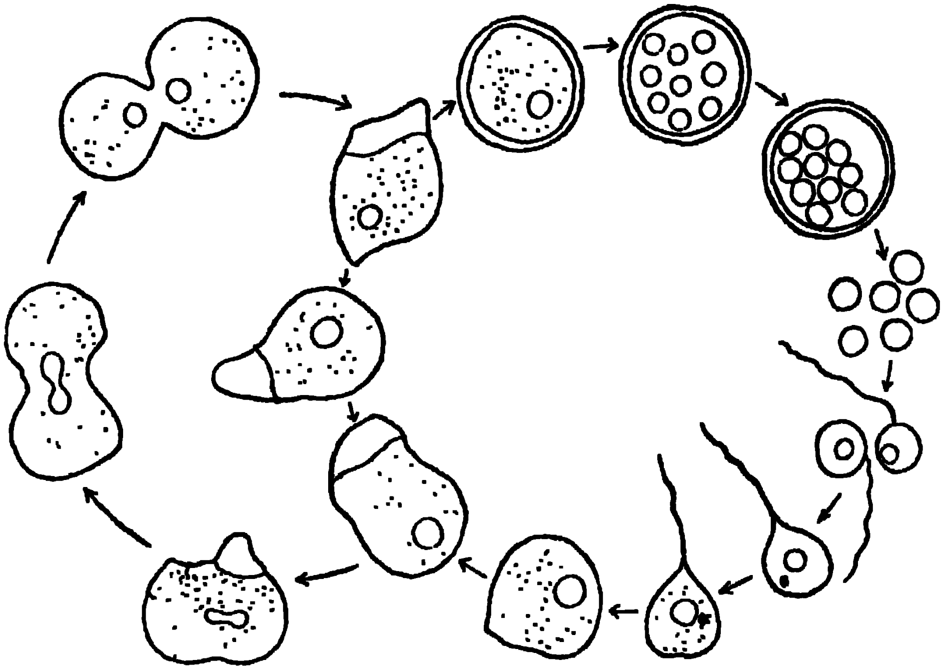

FIG. 64.—DIAGRAM OF THE LIFE-CYCLES OF *Craigia hominis* CRAIG. (After Craig, from the *American Journal of Medical Sciences.*)

ORDER II. THECAMŒBIDA.

Synonyms.—*Filosa* Leidy, 1879; *Testacea.*

Definition.—Amœbæ with a shell composed of different materials cemented on a chitinous base. Through the single opening in this shell pseudopodia, which may be lobose or branched but which never anastomose, project.

FAMILY GROMIIDÆ Eimer and Fickert, 1899

Definition. Thecamœbida with simple shell, composed for the most part of chitin, without calcareous deposits and single chambered.

Genus Chlamydophrys Ehrenberg.

Type Species. *Chlamydophrys enchelys* Ehrenberg.

Chlamydophrys enchelys Ehrenberg.

Synonym.—*Chlamydophrys stercorea* Cienkowsky, 1876, *Leydenia gemmipara* Schaudinn, 1896.

This rhizopod (Fig. 66), which is believed to be parasitic in man in one stage of its life-history, can be found growing in human fæces, as well as in those of the cow, the rabbit, the mouse, and the lizard. It is oval in form, enclosed by a shell, except anteriorly, where the filiform pseudopodia project. The body of the parasite is divisible into an anterior portion, in which lie the contractile and food vacuoles, and a posterior, with the nucleus. Reproduction is by 'bud-fission,' by which is meant that half the protoplasm protrudes at the mouth and forms a new shell, and then separates from the other half, which retains the old shell. If two forms reproduce by 'bud-fission' close together, the daughter cells may partially coalesce (plasmogamy), forming large colonies of twenty or more individuals. The parasites may become encysted.

The sexual process starts by the extrusion of all foreign substances and the collection of the remainder of the plasma and the chromidia into the shell.

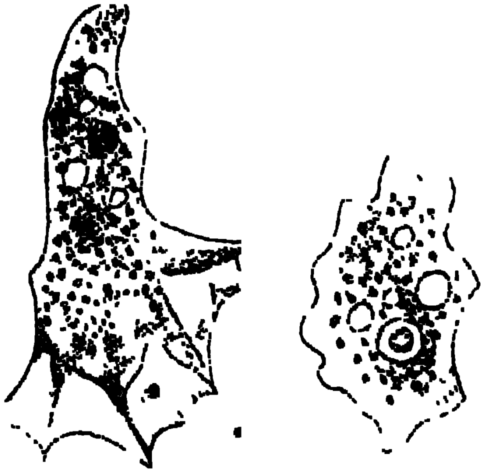

Fig. 65. *Chlamydophrys enchelys* (Leydenia Stage) Ehrenberg. (After Schaudinn.)

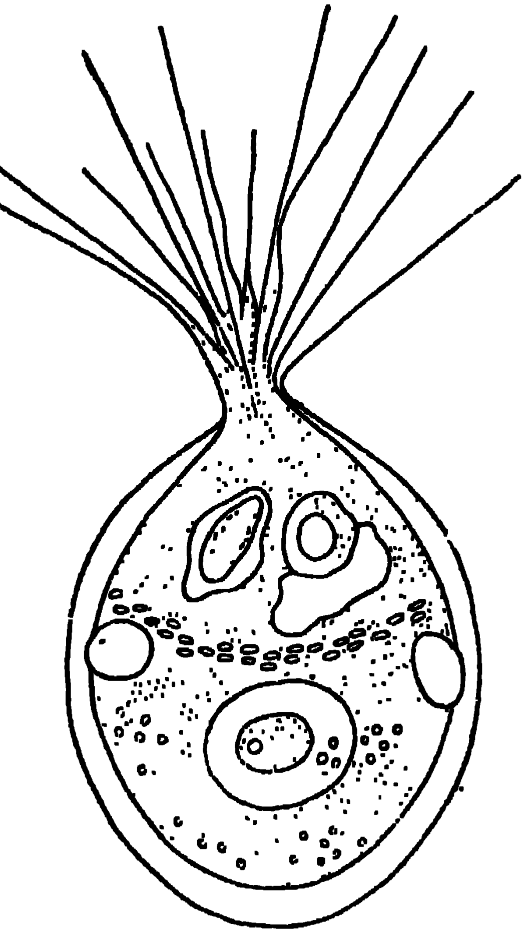

Fig. 66.—*Chlamydophrys enchelys* Ehrenberg. (After Cienkowsky.)

The chromidial mass breaks up into a number of nuclei, never more than eight, around which the plasma divides, forming swarm cells, which, developing two flagella at one pole and escaping from the cell, conjugate with the swarm cells of another individual, and then become encysted. When the cyst ruptures under favourable circumstances, a little amœba escapes, which speedily forms a shell, and becomes in due course an adult Chlamydophrys. If, however, it enters man it may remain in the amœboid stage, and as such was formerly called *Leydenia gemmipara* by Schaudinn. They were, however, originally observed by Lieberkühn in ascitic fluid taken from persons suffering from a malignant growth, but he did not determine their true nature. Leyden, again observing these cells in two similar cases, caused them to be examined by Schaudinn. Lauenstein and Behla have also seen them in a case of cancer.

They are spherical or irregularly polygonal, 3 to 36 μ in diameter, with knobs projecting from the surface. They possess a distinct ectoplasm with hyaline pseudopodia and a large vascular nucleus. Development takes place by binary fission and gemmation (Fig. 65).

Classification.—We have retained the old classification for the organism, and have not placed it in the Foraminifera, as is done by many authors.

CHAPTER XVIII

MASTIGOPHORA AND PROTOMONADINA

Mastigophora—Euflagellata—Protomonadina—Monozoa—Oicomonadidæ—Bodonidæ—Cercomonadidæ—Tetramitidæ—References.

MASTIGOPHORA Diesing, 1866.

Definition.—Plasmodromata with one or more permanent flagella which serve as organs of locomotion, and at times for the capture of food.

Morphology.—The Mastigophora are usually microscopical in size, but have a tendency to colony formation.

The ectoplasm is present in the form of a sheath called the periplast, a term which is really botanical in its meaning. The periplast contains contractile elements called myonemes. The flagellum may be situate anteriorly (tractellum) or posteriorly (pulsellum); there may be but one (monomastigote), two, or four of equal length (isomastigote), one long and one short (paramastigote); one anterior and one posterior (heteromastigote); several flagella placed together (polymastigote), or numerous flagella scattered over the body (holomastigote).

The typical flagellum consists of an elastic axial core more or less enclosed in a contractile sheath from which the 'end-piece' projects. It takes its origin from a granule situated in the cytoplasm, and apparently forming only a swelling at its base. The swelling is, however, a centrosome, to which various names have been applied, such as basal granule or blepharoplast. Sometimes this centrosome is contained in a special nucleus which is called a kinetonucleus. The centrosome-blepharoplast may be single, when there is only one flagellum; or multiple, when there are many flagella. The flagellum may, however, penetrate deeper into the cytoplasm, until it reaches the nucleus. This prolongation is called the rhizoplast, which may represent the central spindle (centrodesmose) of the achromatic elements of the dividing nucleus, and which connects the divided portions of the original centrosome; or it may have arisen simply as an outgrowth from the blepharoplast. Thus, the various parts of the flagellum may be rhizoplast, blepharoplast, sheath or envelope, and end-piece.

If the centrosome is single, it may be intra- or extra-nuclear, and in either case is a centrosome-blepharoplast; if multiple, the portion connected with the nucleus is the centrosome, and that connected with the flagellum is the blepharoplast.

The periplast in the heteromastigotes may be drawn out into an undulating membrane which helps locomotion.

When the periplast is thin or absent the body-form may still be preserved by an internal stiff rod—as, for example, the axostyle of Trichomonas.

There is a difference of opinion as to which is the anterior end of the mastigote. We believe, with Sambon, that the non-flagellate end should correctly be considered as the anterior end, but several authorities hold quite different views, and our anterior end will correspond with many other writers' posterior. Very often there is a depression somewhere on the surface of the animal, generally near the base of the flagellum, which is intended for the reception of food, and is called the mouth or cytostome; more rarely there is an œsophagus leading into the interior of the cell. Nutrition may be holozoic or holophytic, but this hardly concerns us, as the forms to be described are all parasitic, and live in fluids from which they absorb nourishment by their whole surface.

In the cytoplasm there is a nucleus, and in certain forms two nuclei: a trophonucleus for nutrition, and a kinetonucleus for movement. The character of these nuclei will be dealt with in detail in the section Trypanosomidæ. The cytoplasm may also contain food vacuoles, contractile vacuoles, chromatin particles, and metaplastic granules.

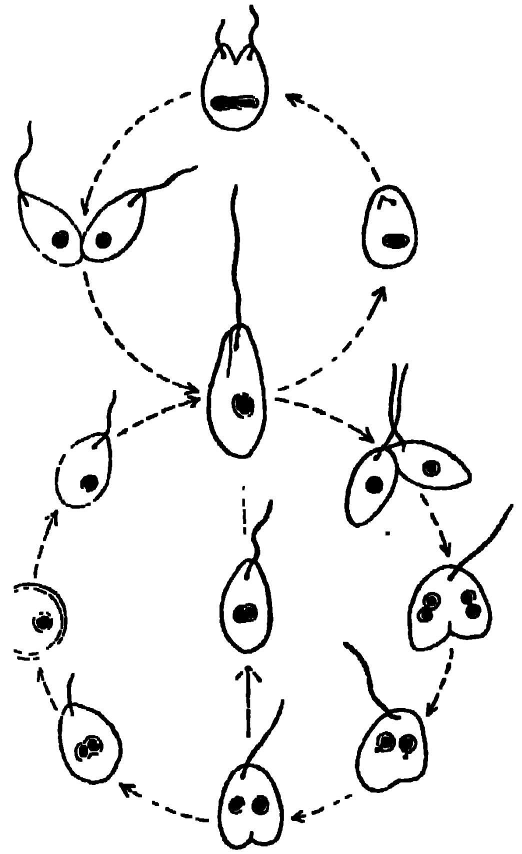

Fig. 97. Diagram of the Life-Cycles of a Mastigote (*Copromonas subtilis* Dobell).

The upper cycle demonstrates simple fission and the lower sporogony.

(After Dobell, from the *Quarterly Journal of Microscopical Science*.)

Life-History.—Reproduction takes place asexually by simple division. Latent or encysted forms are also known.

The whole subject of the structure and life history of the parasitic Mastigophora requires much further research, which, indeed, is being rapidly carried out all over the world—in fact, so rapidly that it is hardly possible to write anything on the subject as a whole which will not quickly be out of date.

Classification.—The Mastigophora may be divided into subclasses as follows:—

A. *Body inflated with gelatinous substance*—Subclass 1, *Cystoflagellata* Haeckel, 1873.

B. *Body not so inflated* :—

I. Periplast markedly thickened, with two flagella arising in the middle of the body, one trailing and one lying in the transverse groove—Subclass 2, *Dinoflagellata* Bütschli, 1885.

II. Periplast thin, with a variable number and arrangement of flagella—Subclass 3, *Euflagellata* Cohn, 1887.

Only the third subclass concerns us.

SUBCLASS EUFLAGELLATA Cohn, 1887.

Definition.—Mastigophora without body inflated with gelatinous substance, and possessing a thin periplast and a variable number and arrangement of flagella.

Classification.—The Euflagellata may be classified into orders as follows :—

A. *Chromatophores often present* :—

I. With cellulose envelope—Order 1, *Phytomonadina* Blochmann, 1895.

II. Without cellulose envelope :—

A. Small forms without oesophagus or vacuole system—Order 2, *Chromomonadina* Klebs, 1892.

B. Large forms with oesophagus and vacuole system—Order 3, *Euglenoidina* Bütschli, 1884.

B. *Chromatophores absent* :—

I. Amoeboid forms in which the food is captured by pseudopodia—Order 4, *Rhizomastigina* Bütschli, 1884.

II. Non-amoeboid forms in which the food is usually captured by flagella—Order 5, *Protomonadina* Blochmann, 1895.

We are only concerned with Order 5, Protomonadina.

ORDER V. PROTOMONADINA Blochmann, 1895.

Definition.—Euflagellata in which chromatophores are absent and in which the individuals are non-amoeboid and usually capture their food by flagella.

Remarks.—As defined above, the Protomonadina is a large order, and includes the Polymastigina of Bütschli and Blochmann, as well as the Binucleata of Hartmann, both of which were treated as separate orders in our previous editions. We, however, foreshadowed a return to Doflein's method of classification, and discussed the whole subject on pp. 282 and 283 of the second edition.

Classification.—So large is this order that, for convenience' sake as well as for morphological reasons, it may advantageously be divided into two suborders after the method of Hartmann and Chagas, which is as follows:—

A. No tendency to bilateral symmetry in undividing forms—Suborder 1, *Monozoa* Hartmann and Chagas, 1911.

B. More or less tendency to bilateral symmetry in undividing forms—Suborder 2, *Diplozoa* Hartmann and Chagas, 1911.

SUBORDER I. MONOZOA Hartmann and Chagas, 1911.

Definition.—Protomonadina without tendency to bilateral symmetry in undividing forms. The anterior flagella vary from one to many, in addition to which a trailing flagellum or undulating membrane may be present.

Classification.—This suborder can be divided into some ten families as follows:—

DIAGNOSTIC TABLE OF THE MONOZOA.

A. *One flagellum present*:—
  I. With a collar—Family 1, *Craspedomonadidæ* Stein, 1878.
  II. Without a collar:—
    (*a*) Kinetonucleus not separate from the nucleus—Family 2, *Oicomonadidæ* Senn, 1900.
    (*b*) Kinetonucleus separate from the nucleus—Family 3, *Trypanosomidæ* Doflein, 1901.
B. *Two flagella present*:
  I. Both anterior:—
    (*a*) Unequal—Family 4, *Monadidæ* Stein, 1878, *emendavit* Senn, 1900.
    (*b*) Equal—Family 5, *Amphimonadidæ* Kent, 1880, *emendavit* Bütschli, 1884.
  II. One anterior and one trailing flagellum:—
    (*a*) Trailing flagellum free:—
      1. In horny sheath and with lip or proboscis-like process—Family 6, *Bikœcidæ* Stein, 1878.
      2. Without sheath or process—Family 7, *Bodonidæ* Bütschli, 1884.
    (*b*) Trailing flagellum in part attached to the body—Family 8, *Cercomonadidæ* Kent, 1880, *emendavit* Bütschli, 1884.
C. *Three to six anterior flagella*, with or without one trailing flagellum (except *Embadomonas* with one anterior and one cytostomic flagellum)—Family 9, *Tetramitidæ* Kent, 1880.
D. *Numerous anterior flagella*—Family 10, *Callimastigidæ* da Fonseca, 1915.

Of these ten families we are concerned with only five, of which one, the Trypanosomidæ, because of its importance, we shall leave till the next chapter; so that at present we will consider the following families only:—

Family 2. Oicomonadidæ.
Family 7. Bodonidæ.
Family 8. Cercomonadidæ.
Family 9. Tetramitidæ.

FAMILY OICOMONADIDÆ Senn, 1900.

Synonym.- *Cercomonadina* Saville Kent, 1880, *pro parte*.

Definition.- -Monozoa with a single flagellum, no collar and no kinetonucleus.

Remarks. This family was formed by Senn for Oicomonas, several allied forms of which are to-day classified in the Trypanosomidæ.

Type Genus. --*Oicomonas* Saville Kent, 1880.

Classification. The various genera of this family may be differentiated as follows:-

A. Without definite nucleus. Chromatin diffuse-- -*Selenomonas* (*Selenomastix*).
B. With definite nucleus: -
  I. *Rhizostyle: not known to be present* :- -
    (*a*) Flagellum anteriorly directed:
      Body oval or roundish *Oicomonas*.
    (*b*) Flagellum trailing or posterior:- -
      1. Body long spindle-shaped -*Ancyromonas*.
      2. Body three-cornered bowed leaf-shaped- - *Phyllomonas*.
  II. *Rhizostyle present* :- -
      Body 6-11 × 3·5 microns. Flagellum springs from a small basal granule, and is continued backwards into the body by a dark staining filament, the rhizostyle *Rhizomastix*.

Only the first genus concerns us.

Genus Oicomonas Saville Kent, 1880.

Synonym. *Cercomonas* Davaine, 1860, *pro parte nec* Dujardin, 1841.

Definition. --Oicomonadidæ, with oval or roundish body and one anteriorly directed flagellum

Remarks.- In 1841 Dujardin formulated the genus Cercomonas, which Wenyon has placed upon a firm basis.

In 1860 Davaine described two varieties of flagellates which he found in cholera motions. The first and larger of these, which he calls A, is without doubt *Chilomastix mesnili*, while the second and smaller is an Oicomonas. Unfortunately Davaine called both these parasites *Cercomonas hominis*, but the genus was one of his own construction, and most assuredly was not the Cercomonas of Dujardin.

In 1880 Saville Kent formed the genus for uniflagellate free-swimming forms, which are capable of temporarily fixing themselves to any object by extending a sarcode thread, which can be withdrawn when they start to swim.

This sarcode thread was the only point of distinction from the genus which Saville Kent called Monas, but which Stein in 1878 had improved, so that it came to be defined as possessing two anterior flagella, one long and one short, while the posterior end was capable of forming a filiform pseudopodium. In view of this, and as the filiform pseudopodium is not an essential character, Oicomonas came to be looked upon as including forms with a single anteriorly directed flagellum, and as such requires investigation by modern cytological methods. In this genus must come all those organisms which resemble Form B of Davaine's *Cercomonas hominis*, as this is not a Cercomonas, and they must include *Monas pyophila* Blanchard.

With regard to the flagellate called *Monas lens* Müller, 1786, and reported as being present in man, it is not a Monas, but was classified by Saville Kent as a Heteromita. It may be a Bodo or a Prowazekia.

Type Species.—*Oicomonas mutabilis* Saville Kent, 1880, found in vegetable infusions.

The more important parasitic species which concern us are:

Oicomonas pyophila R. Blanchard, 1895,
Oicomonas hominis Davaine, 1854,
Oicomonas vaginalis Castellani and Chalmers, 1909,

and these may be differentiated as follows:—

A. With thick cuticle—*Pyophila*.
B. Without thick cuticle, in human intestine—*Hominis*.
C. Without thick cuticle, in vaginal mucus—*Vaginalis*.

Oicomonas pyophila R. Blanchard, 1895.

Synonym. *Monas pyophila* R. Blanchard, 1895.

Definition.—Oicomonas with a thick cuticle.

Historical.—Grimm found this flagellate in the sputum and pus of a pulmonary and of a hepatic abscess occurring in a Japanese woman living in Sappho. The organism requires reinvestigation by modern methods.

Morphology.—The flagellate measures 30-60 microns in length and is heart-shaped, being enclosed in a thick cuticle which extends into the cytoplasm, dividing it into three parts, and is continued along the flagellum for a considerable distance. At its tip the flagellum is free.

Life-History.—Nothing is known as to this.

Oicomonas hominis (Davaine, 1854), *emendavit* Castellani and Chalmers, 1918.

Synonyms.—*Cercomonas hominis* Davaine, 1854, *pro parte*—*i.e.*, Form B.

Definition.—Oicomonas with a thin cuticle.

History.—In 1854 Davaine described two forms, A and B, under the heading *Cercomonas hominis*. Form A is *Chilomastix mesnili*, while Form B is *Oicomonas hominis*.

Morphology.—*O. hominis* is a round or pear-shaped parasite averaging from 8 to 10 μ in diameter, with a long flagellum projecting from the more pointed end. There is no undulating membrane. The nucleus is small, indistinct, and usually situated near the flagellar extremity.

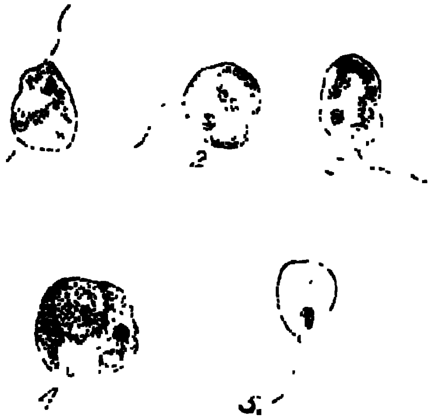

Fig. 68.—*Oicomonas hominis* (Davaine).

1-3, and 5, Flagellate forms; 4, encysted form.

Life-History.- Reproduction is by binary fission, and Perroncito and Piccardi have described encystment.

Habitat.- According to our experience at autopsies, the parasite may live not only in the small intestine, as generally stated, but also in some cases in the large intestine. Oicomonas is readily killed, as observed by Castellani and Willey, by a solution of methylene blue (1 in 3,000).

Oicomonas vaginalis Castellani and Chalmers, 1909.

Synonym.- *Cercomonas vaginalis* Castellani and Chalmers, 1909.

This is a pear-shaped or rounded parasite, measuring 5 to 12 μ in its maximum diameter, and provided with one flagellum, a small nucleus, and food vacuoles, but without a pulsating vacuole. It is not uncommon in the vagina of native women in Ceylon.

Oicomonas perryi Castellani, 1907.

Synonym.– *Cercomonas perryi* Castellani, 1907.

Found by Castellani in Ceylon in monkeys (*Macacus pileatus* and *Semnopithecus priamus*) suffering from diarrhœa. It is morphologically extremely similar to *O. hominis*, being roundish or pear-shaped, 8 to 12 μ in diameter. There is one flagellum originating from the pointed end. The nucleus is situated near the flagellar end. Reproduction seems to be by binary fission, but cysts can be seen

Other Species.- *O. anatis* Davaine, in the alimentary canal of ducks; *O. canis* Gruby and Delafond, in dogs; *O. gallinarum* Davaine, in fowls.

Bodonidæ Bütschli, 1884, *emendavit* Doflein, 1901.

Definition.- Monozoa, free living or parasitic, with one anterior and one posterior (or trailing) flagellum, with or without a kinetonucleus and an undulating membrane.

Nomenclature. In part, at all events, this family represent the Heteromitidæ of Saville Kent, as *Heteromita* Dujardin, 1841, is in part Bodo and in part Cercomonas.

Type genus.- *Bodo* Stein, 1878.

Classification.—The following is a poor attempt to differentiate the genera of the Bodonidæ known to us:- -

A. With an undulating membrane:- -
  I. Kinetonucleus well marked—*Trypanoplasma*.
  II. Kinetonucleus poorly marked—*Trypanophis*.

- B. Without an undulating membrane, but a kinetonucleus may or may not be present:—
  - I. While swimming all flagella are posterior. (Genera with which we are not concerned, as yet not found in man.)
  - II. While swimming all flagella are not posterior:—
    - (*a*) Body with antero-posterior groove—*Colponema.*
    - (*b*) Body without such a groove:—
      - 1. Food believed to enter anteriorly:—
        - (1) Kinetonucleus absent—*Bodo.*
        - (2) Kinetonucleus present—*Prowazekia.*
      - 2. Food believed not to enter anteriorly. (Genera with which we are not concerned, as not yet found in man.)

Trypanoplasma Laveran and Mesnil, 1901, *emendavit*, 1904.

Definition.—Bodonidæ living in the blood and alimentary canal of vertebrates with two flagella—one projecting anteriorly and the other running posteriorly, and raising the periplast into an undulating membrane. Kinetonucleus almost as large as the trophonucleus. Sporogony in the Hirudinea.

Remarks.—This genus, which was first described by Laveran and Mesnil, is interesting, first, because it shows definitely an anterior flagellum, which has disappeared in most trypanosomes, and a posterior flagellum, which, like all trypanosomes, carries the undulating membrane; secondly, because, according to Léger and Keysselitz, members of this genus are parasitic in the alimentary canal of fish, and not in the blood.

Morphology.—The body of a trypanoplasma is flattened, and often curved, with a concave side, thicker than the convex, to which the undulating membrane is attached. The body is soft and of changing form. At the junction of the anterior and middle thirds of the body can be seen two masses of chromatin. The one on the convex side is the trophonucleus, and the other on the concave side the elongated kinetonucleus, in front of which are two small chromatic granules, one of which gives rise to an anterior flagellum which becomes free at once, and the other to a posterior, which, turning backwards, runs the whole length of the cytoplasm, raising the periplast into an undulating membrane.

Life-History.—Division is longitudinal, the kinetonucleus dividing first, and then the flagella.

Often Trypanoplasmata show seasonable variation, the infection being more intense in hot weather. They are evidently pathogenic, producing anaemia associated with serous fluid in the peritoneum, pericardium, and œdema of the organs.

The parasite appears to be spread by leeches, in which the sexual forms conjugate by a fusion of nuclei, after reduction, and of the cytoplasm, from which results an ookinete possessing a trophonucleus and a kinetonucleus.

These ookinetes give rise to male, female, and indifferent forms, which multiply abundantly. Parthenogenesis may occur.

Brumpt infected fish by the bite of leeches, but Keysselitz failed with *Pisciola geometra*, and it is hardly surprising, for he describes the leech as becoming ill, with swelling of the clitellar region, alteration in colour and activity, and finally death, thus showing that this leech could hardly be the usual definitive host. He has already noted the initial stages in *Hirudo medicinalis*. Another genus of leech which spreads these parasites is *Hemiclepsis*.

Classification.—Crawly considers that the generic name should be *Cryptobia* Leidy, but the diagnosis of this genus is vague. With regard to classification, Keysselitz is of the opinion that all so far described species should be considered to belong to one species—*Trypanoplasma borreli* L. and M.

Type Species.—*Trypanoplasma borreli* Laveran and Mesnil, 1901.

Trypanoplasma borreli Laveran and Mesnil, 1901.

In the blood of *Leuciscus erythrophthalmus* (the rudd) and *Phoxinus lævis* (the minnow), and in the alimentary canal of the leech *Piscicola geometra,* and perhaps in *Hirudo medicinalis.*

Trypanoplasma cyprini Plehn, 1903

In *Cyprinus carpis.*

Trypanoplasma (Cryptobia) dendrocœli Fantham and Porter, 1910.

This parasite measured 20 to 40 *μ* in length, with a large and often curved kinetonucleus. It lives in the alimentary canal of *Dendrocœlum lacteum,* and was the first trypanoplasma to be found in the Platyhelminthes.

Trypanoplasma intestinalis Léger, 1905.

This trypanoplasma is very important, because it was found in the œsophagus and anterior part of the stomach of *Box boops*, a salt-water fish.

It is the first trypanoplasma described as existing outside the blood. In addition to typical form, Léger describes globular parasites with three anterior flagella and a rudimentary undulating membrane, which reminds one of *Trichomonas.*

These he considers to be female forms, and says that he has seen conjugation with male forms.

Trypanoplasma ventriculi Keysselitz, 1906

Synonyms.—*Heteromita dahlii Apstein = Diplomastix dahlii.*

This is found in the intestine of *Cyclopterus lampus*, and is apparently a typical trypanoplasma. Discovered by Dahl in 1857.

Trypanoplasma varium Léger, 1904.

In *Cobitis barbatula* (loach), and in *Hemiclepsis marginata.*

Trypanoplasma guernei Brumpt, 1905.

In *Cottus globio,* and develops in *Piscicola*

Trypanoplasma barbi Brumpt, 1905.

In *Barbus fluviatilis*, and in the leech (*Piscicola*).

Trypanoplasma abramidis Brumpt 1905

In the bream (*Abramis brama*) and the leech (*Hemiclepsis*).

Trypanoplasma truttæ Brumpt, 1905.

In *Salmo fario*, and perhaps in *Pisciola.*

Other Species.

T. keysselitzi Minchin, 1909, in the tench; *T. gurneyorum* Minchin, 1909, in the pike; *T. clariæ* Mathis and Léger, 1911, in *Clarias macrocephalus*, *T. congri.*

Trypanophis Keysselitz, 1904.

Bodonidæ in *Cœlenterata*, with two flagella, an anterior and a posterior. The kinetonucleus is situated anteriorly, and is much smaller than the trophonucleus. According to Floyd, a blepharoplastic granule gives rise to the free flagellum. The attached flagellum arises near the basal granule of the free flagellum, and gives rise to a narrow undulating membrane.

Trypanophis grobbeni Poche, 1903.

In the gastro-vascular system of different Siphonophora—*e.g.*, *Halistemma ergestinum.* The parasite is curved somewhat, like a trypanosome.

Genus Prowazekia Hartmann and Chagas, 1910.

Definition.—*Bodonidæ* with a kinetonucleus.

Type.—*Prowazekia cruzi* Hartmann and Chagas, 1910.

The separation of the old genus *Bodo sensû lato* into *Bodo sensû stricto* and *Prowazekia* is not at present generally accepted; for example, Alexeieff and others oppose it, stating that the generic name for all the species included under *Prowazekia* should be *Bodo*, while that for the only species at present under Bodo—viz., *B. lacertæ* Grassi, 1881—should be *Prowazekella* (new genus) *lacertæ* Grassi, 1881. Nor is this the only confusion with regard to *Prowazekia*, for one species—*P. urinaria* Hassall, 1859—has been found in urine which has been passed for six hours or more in the Temperate Zone; and three species—*P. asiatica* Castellani and Chalmers, 1910, Ceylon; *P. cruzi* Hartmann and Chagas, 1910, Brazil; *P. weinbergi* Mathis and Léger, 1910, Indo-China—are found in fæces; while one form—*P. parva* Naegler, 1910—lives in slime on stones at Lunz.

All observers are agreed that these flagellates are non-pathogenic, but the question which is debated is whether they are accidental contaminations of the urine and fæces after being passed out of the body, and the urine problem is further complicated by the question as to whether it was contaminated by the fæces.

With regard to the urinary species, it has been found by Hassall in 1859, Salisbury in 1868, Kunstler in 1883, and Stinton in 1912. He obtained it only twice from the same patient, who was in a hospital ward in Liverpool, and in none of the other patients in the ward; it was not found in the fæces, nor in a vessel of water exposed to the air of the ward, nor in the water-supply. It was not present in later observations taken aseptically, and cultures died rapidly at 37° C. It is therefore concluded to be an accidental contamination.

The intestinal forms are not so easily dismissed, as we have found them in stools collected in sterile petri-dishes, and Mathis and Léger found their species in the fæces of persons in good health and suffering from diarrhœa, even when taken with aseptic precautions. It is possible, therefore, that some, at all events, of the intestinal forms are harmless occasional parasites of man.

Classification. The species may be differentiated as follows:—

A. Posterior flagellum free:—
  I. *Large forms.* More than 8 microns in length as a rule:—
    (*a*) Shape oval:—
      1. Rhizoplast present:—
        (1) Cytostome present—*Urinaria.*
        (2) Cytostome absent—*Asiatica* and *vaginalis*.
      2. Rhizoplast absent—*Cruzi.*
    (*b*) Shape pyriform:—
      Apex sharp—*Weinbergi.*
  II. *Small forms.* Not exceeding 8 microns in length—*Parva.*
B. Posterior flagellum attached to the body for a short distance—*Javanensis.*

Prowazekia urinaria Hassall, 1859.

This species has several times been found in human urine which has been passed some hours.

Morphology. The flagellate appears in three forms—a sausage-shaped form, 10 to 25 μ in length by 2·5 to 6 μ in breadth; a round or oval form, varying from 4 μ in diameter to 15 by 10 μ in measurement; a carrot shaped form, varying from 6 by 3 μ to 25 by 4 μ. The cytoplasm contains a large number of small, highly refractile granules, and contains a trophonucleus and a kinetonucleus, which latter is a relatively large pear shaped body. The body is enclosed by a thin periplast, and possesses two flagella, a shorter anterior and a longer lateral, which arise from blepharoplasts (basal granules), which are connected by rhizoplasts to the kinetonucleus. There is a cytostome situate near the root of the short flagellum.

Bionomics. It moves in a jerky manner, with the short flagellum directed forwards and the long flagellum backwards. The small flagellum is also useful in capturing food, such as bacteria. Food enters by means of the cytostome and forms the usual food vacuoles, which accumulate at the aflagellar end. A contractile vacuole is seen in large flagellates, and may measure 1 to 3 μ in diameter. It is situate near the base of the cytostome, to which it is joined by a minute canal. It contracts every 15 to 30 seconds at a temperature of 20° C. It is thought to be the dilated fundus of the cytostome.

Life-History. It divides in two by binary fission, the blepharoplast apparently dividing first and forming two new flagella, after which the cell nuclei and the cell divide. It can lose its flagella, and can form round or oval cysts 5 to 7 μ in diameter, inside from which after a time it again becomes flagellate, and escapes in its typical form.

Cultivation. In association with bacteria it grows well in urine, on salt agar, nutrient agar, serum agar, blood agar, peptone, salt solution, nutrient broth, and diluted blood-serum at a temperature of 20° C., but is killed by a temperature of 37° C. in one or two hours. It has not been cultivated free from bacteria.

Prowazekia asiatica Castellani and Chalmers, 1910.

Synonym. *Bodo asiaticus* Castellani and Chalmers, 1910.

This flagellate was found in 1909 by Castellani and Chalmers in the stools of cases of ankylostomiasis suffering from diarrhœa in Ceylon. It was studied in detail by Whitmore in 1911, and assigned to the new genus *Prowazekia*, which Hartmann and Chagas had differentiated from the old genus *Bodo*

Morphology. *P. asiatica* is found in the motions in two forms—either as a long, slender flagellate measuring 10 to 16 μ in length by 5 to 8 μ in breadth or as a more rounded form, which has a transverse diameter of 8 to 10 μ. The cytoplasm is alveolar in structure, containing food vacuoles, but no contractile vacuole. The trophonucleus is usually situate in the flagellar third of the cytoplasm, and consists of a nuclear membrane a widish space for the enchylema, and a central karyosome, with usually a centrosome. The kinetonucleus is situate nearer the flagellar extremity, and is connected by a long strand with a small piece of chromatin situate near the aflagellar extremity, and by another strand with one of the two blepharoplasts which lie adjacent to the flagellar extremity. These blepharoplasts are united together, and, as already stated, to the kinetonucleus by strands. Usually there are two, which may lie side by side or one over the other. From these blepharoplasts the two flagella take origin, and quickly pass to the exterior.

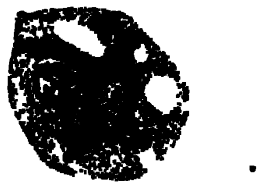

FIG. 69.—*Prowazekia asiatica* CASTELLANI AND CHALMERS: FROM FÆCES.

Reproduction.—Asexual reproduction takes place by metamitosis, but sexual reproduction is unknown. Cyst formation has been observed, resulting in rounded bodies 6 to 7 μ in transverse diameter, possessing tropho- and kineto-nuclei, and enclosing the remains of the flagella.

Culture.—*P. asiatica* is readily cultivated in liquid and in the water of condensation of solid media in symbiosis with bacteria. The most suitable medium is the condensation water of nutrose agar (2 to 4 per cent.), or maltose agar, on which a few drops of albumin-water have been placed, when it can be subcultured and grown indefinitely if the tubes are kept uncapped and subcultures are made twice a week.

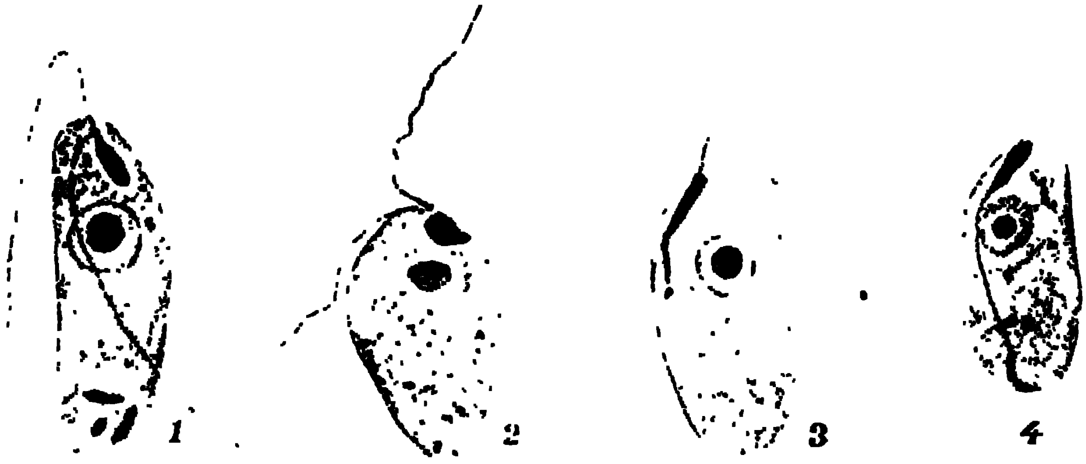

FIG. 70.—*Prowazekia asiatica* CASTELLANI AND CHALMERS: FROM CULTURES. (After Whitmore.)

Pathogenicity.—Probably nil.

Prowazekia cruzi Hartmann and Chagas, 1910.

Oval to pear-shaped forms; length 8 to 12 μ; breadth, 5 to 6 μ, with the flagella at the narrow end. Found in Brazil. Differs from *P. asiatica* by the absence of the strand which originates from the kinetonucleus and terminates into a chromatin granule. Martin has found in human stools in Tsingtau a *Prowazekia* which he believes to be identical with *P. cruzi*.

Prowazekia weinbergi Mathis and Léger, 1910.

Pear-shaped, but rather drawn out into a point; length, 8 to 15 μ; breadth, 4 to 6·5 μ. Flagella at broad end. Found frequently in the motions of men in Tonkin.

Prowazekia parva Naegler, 1910.

Characterized by its small size, the longest forms being 5 to 8 μ. The cysts do not contain flagella.

Prowazekia javanensis Flu, 1912.

Definition. Prowazekia in which the posterior flagellum is attached to the body for a short distance.

Remarks.- Flu believes that there is only one species of Prowazekia. He obtained his variety from an agar culture of human fæces in the Dutch East Indies.

Prowazekia vaginalis Castellani and Chalmers, 1918.

Definition. Prowazekia living in the vaginal mucus.

Remarks. Morphologically identical with *P. asiatica* found in motions, but the investigated strains of the latter will not live in vaginal mucus.

Genus Bodo Stein, 1875.

Definition.- Bodonidæ without undulating membrane or kinetonucleus, but with a rhizoplast. While swimming one flagellum is anterior and the other trailing, without antero-posterior groove.

Bodo stercoralis Porter, 1918.

Discovered in human fæces by Miss Porter. Body measures from 14 μ to 19 μ long and is from 6 μ to 9 μ broad, with large nucleus

Bodo lens Muller, 1786.

Synonyms.—*Monas lens*, *Heteromita lens*.

Remarks.--Usually free living, but said to be found in man once (*vide* 'Animal Parasites of Man,' by Fantham, Stephens, and Theobald).

Genus Toxobodo Sangiorgi, 1917:

Definition.- Bodonidæ of semilunar shape.

Type and only Genus.- *Toxobodo intestinalis* Sangiorgi, 1917.

Toxobodo intestinalis Sangiorgi, 1917.

A flagellate organism semilunar in shape, 6-9·6 × 1·6-4·8 microns, found in the human intestine and grown for ten generations in culture media (peptone water). It has two flagella, and resembles a Bodo, except in shape.

Genus Heteromita Dujardin, 1841.

Bodonidæ round or oval, with two flagella, one at each pole.

Heteromita zeylanica Castellani and Chalmers, 1910.

This flagellate is elongated, 8 to 15 μ in length by 3 to 4 μ in breadth, with single flagellum at each pole, and a nucleus fairly rich in chromatin. No undulating membrane or pulsating vacuole, but with chromidia in the cytoplasm. It is not cultivable. This flagellate we classify provisionally under the genus *Heteromita*. It was found in the stools of persons suffering from ankylostomiasis in Ceylon.

ORDER CERCOMONADIDÆ Saville Kent, 1880, *emendavit* Bütschli.

Definition.—Monozoa with elongate or oval forms, possessing one free anterior flagellum and one trailing flagellum.

Type Genus.—*Cercomonas* Dujardin, 1841, *emendavit* Wenyon, 1910.

Remarks.—It appears to us that this is the only genus which can be classified in this family at the present moment.

Genus Cercomonas Dujardin, 1841, *emendavit* Wenyon, 1910

Synonyms.—*Heteromita* Dujardin, 1841, *pro parte nec Cercomonas* Davaine, 1860, *nec Oicomonas* Saville Kent, 1880.

Definition.—Cercomonadidæ, pear-shaped, with a protokaryon type of nucleus situate near the flagellar extremity, with a basal granule or blepharoplast from which a sort of rhizoplast may run to the margin of the cytoplasm, at which it divides into the two flagella, one of which is anterior, while the other is posterior and closely attached to one side of the body, at the posterior end of which it becomes free.

Type Species.—The type species of the properly defined family is certainly *Cercomonas longicauda* Dujardin, 1841, *emendavit* Wenyon, 1910, even though the first species in Dujardin's description is *C. detracta*, because this latter has never again been described, and has therefore never been examined by modern methods.

Certainly Dujardin's genus Heteromita agrees in description and illustration with many of the features of *C. longicauda*, and therefore we consider it to be a synonym.

There are a number of species described by Dujardin, but until they have been examined by modern methods it is impossible to define them. They are all free-living forms.

Cercomonas longicauda Dujardin, 1841, *emendavit* Wenyon, 1910.

Synonyms.—*Cercomonas parva* Hartmann and Chagas, 1910

Definition.—*Cercomonas* elongate 8-15 × 3-4 microns, with very marked long posterior flagellum.

History.—This flagellate was first discovered by Dujardin in 1841 in an old infusion, and was next described by Wenyon in 1910, being found in cultures made from human fæces. In the same year

Hartmann and Chagas met with it in Brazil. Since then it has only been recorded once.

Morphology. The body is pear shaped, measuring on an average 8-15 microns in length by 3-4 microns in breadth, but Wenyon has met with small forms measuring only some 2-3 microns in greatest length.

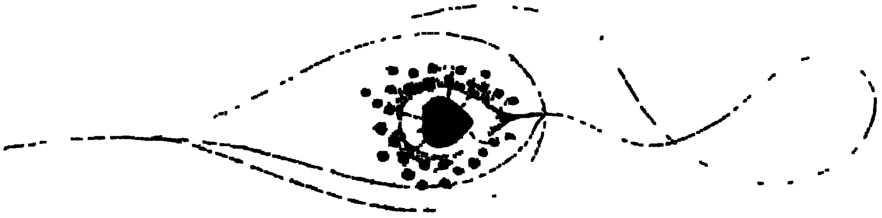

Fig. 71.—*Cercomonas longicauda* Dujardin, 1841.
Type with granules around the nucleus; compare this with Fig. 74.
(After Wenyon, from the *Quarterly Journal of Microscopical Science*.)

The cytoplasm is alveolar and contains a large anteriorly situate nucleus, which has a nuclear membrane enclosing a clear space, in which lies a large karyosome. The nuclear membrane may be drawn out into a cone, at the apex of which lies the granule - blepharoplast- from which either the flagella spring directly or a single rhizoplast passes to the periphery and then divides into the two flagella. In any case, the flagella arise from the anterior broader end, and while one is directed forwards, the other passes posteriorly over the surface of the body, to which it is attached until it reaches the posterior end, when it becomes a free posterior flagellum. The cytoplasm also contains a number of bright refractile granules.

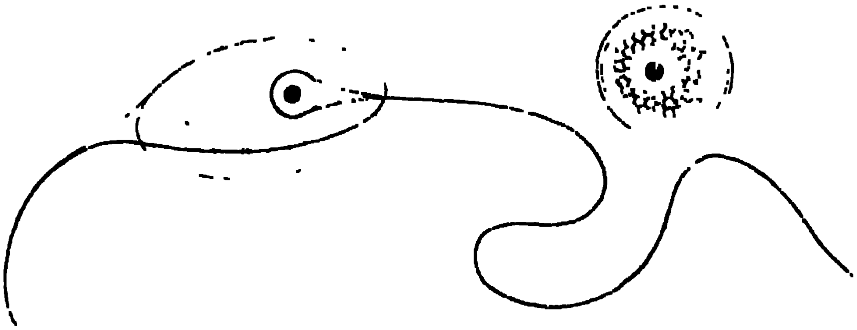

Fig. 72.—*Cercomonas longicauda* Dujardin, 1841.
Type without granules and Cyst.
(After Wenyon.)

Life-History.—Simple fission, with division of the nucleus by promitosis, takes place, while cyst formation is also known.

The cysts measure some 6-7 microns in diameter. They are slightly brownish spherical bodies containing a spherical central nucleus surrounded by bright refractile granules.

Pathogenicity.—It is believed to be non-pathogenic, and to be accidentally present in the fæces.

Cercomonas parva Hartmann and Chagas, 1910.

This is probably the same as *C. longicauda*.

FAMILY TETRAMITIDÆ Kent, 1880, *emendavit* Chalmers and Pekkola, 1917.

Definition.—Monozoa with three to six anterior flagella (with the exception of Embadomonas, which has only two visible flagella, one anterior and one posterior), with or without a rhizoplast, with or without a posterior or trailing flagellum, which may, or may not, form an undulating membrane, with or without an axostyle or a cytostome. Habitat, free living and parasitic.

Type Genus.—*Tetramitus* Perty, 1852.

Classification.—The family may be divided into three subfamilies as follows:—

A. *Without an axostyle*:—
  (*a*) With three flagella—Subfamily I., *Embadomonadinæ* Chalmers and Pekkola, 1918.
  (*b*) With four to six flagella—Subfamily II., *Tetramitidinæ* Chalmers and Pekkola, 1917, *emendavit* 1918.

B. *With an axostyle*—Subfamily III., *Trichomonadinæ* Chalmers and Pekkola, 1917.

SUBFAMILY EMBADOMONADINÆ Chalmers and Pekkola, 1918.

Definition.—Tetramitidæ with or without a cytostome, but without an axostyle and with three flagella only. (Only two are visible in Embadomonas.)

Classification.—The known genera of the subfamily Embadomonadinæ may be recognized as follows:

A. *Without cytostome*:—
  I. With three anterior flagella—(1) *Enteromonas* da Fonseca, 1915.
  II. With one anterior and two posterior flagella—(2) *Dallengeria* Saville Kent, 1880.
  III. With two anterior and one posterior flagella—(3) *Dicercomonas* Chalmers and Pekkola, 1919.

B. *Cytostome present or probably present* (*as a groove*):—
  I. With one anterior, one cytostomic and then free, and one free trailing flagellum—(4) *Trimastix* Saville Kent, 1880.
  II. With one anterior and one posterior flagellum which is generally cytostomic, and with a large cytostome with siderophilous, often folded, border—(5) *Embadomonas* Mackinnon, 1911.

The genera in which we are interested are Enteromonas, Dicercomonas and Embadomonas.

Genus Enteromonas da Fonseca, 1915.

Definition.—Embadomonadinæ without a cytostome or trailing flagellum and with three anterior flagella.

Type and only Species.—*Enteromonas hominis* da Fonseca, found in Brazil.

Enteromonas hominis da Fonseca, 1915.

Definition.—Enteromonas with the characters of the genus.

Remarks.—This parasite was first found by da Fonseca in Brazil in 1915, and subsequently by Chalmers and Pekkola, in the Anglo-Egyptian Sudan, in Europeans and natives.

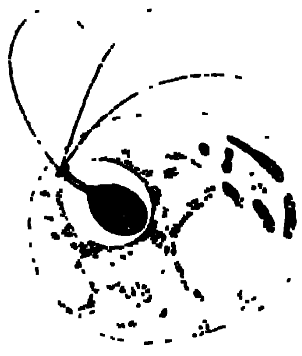

FIG. 73.—*Enteromonas hominis* DA FONSECA, 1915.

Morphology.—The parasite is roundish or oval, without a tail, and with a diameter varying from 5-6 microns. The periplast is not rigid, and encloses an endoplasm, often with inclusions such as bacteria. Situate anteriorly lies the protokaryon type of nucleus, from which a rhizoplast runs to a blepharoplast, from which three anterior flagella arise.

Life-History.—Da Fonseca records longitudinal division.

Pathogenicity.—The flagellate probably causes diarrhœa.

Genus Embadomonas Mackinnon, 1911.

Synonym.—*Waskia* Wenyon and O'Connor, 1916.

Definition.—Embadomonadinæ, with a cytostome and one anterior and one posterior flagellum, and with a siderophilous, often folded, cytostomic margin.

Type Species.—*Embadomonas agilis* Mackinnon, 1911.

Other Species.—The type and the other species may be recognized as follows:—

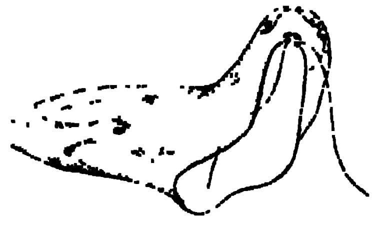

FIG. 74.—*Embadomonas agilis* MACKINNON, 1911.

(After Mackinnon, from the *Quarterly Journal of Microscopical Science*.)

A. *Habitat. intestine of Trichopterous and Tipula Larvæ in British Isles:*—

(*a*) Cytostomic borders feebly siderophilous, cytostomic flagellum exceedingly delicate and inconspicuous—

Size: 4-11 × 1·5-3 microns. Cysts: about 4 × 3 microns. (1) *Agilis*.

(*b*) Cytostomic borders markedly siderophilous, cytostomic flagellum well developed. Size: 7-16 × 5-9 microns. Cysts: 5-6 × 4-5 microns. (2) *Alexeieffi*.

B. *Habitat: intestine of Man in Alexandria*:—

Anterior flagellum long and thin, cytostomic flagellum shorter and stouter.

Size: 4-9 microns long, but with variable width 2-4 microns in narrow forms. Cysts: 4·5-6 microns in length. (3) *Intestinalis.*

Only *Embadomonas intestinalis* Wenyon and O'Connor, 1916, concerns us.

Embadomonas intestinalis Wenyon and O'Connor, 1916.

Synonym.—*Waskia intestinalis* Wenyon and O'Connor, 1916.

Definition.—Embadomonas found in the intestine of man in Alexandria. Size 4-9 microns in length, but with variable width, some 3-4 microns in narrow forms. Cysts 4·5-6 microns in length.

Remarks.—This flagellate was found by Wenyon and O'Connor in two cases in the Orwa-el-Waskia section of the 19th General Hospital in Alexandria.

Morphology.—The flagellate is pear-shaped, with a cytostome at the anterior end, from which (or slightly nearer the cytostome) a thin anterior flagellum takes origin, while a second stouter and shorter arises from the inner part of the anterior wall of the cytostome, from which it projects for a considerable distance.

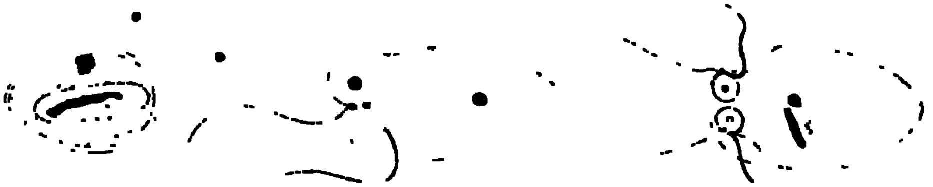

FIG. 75.—*Embadomonas intestinalis* (WENYON AND O'CONNOR, 1916). Showing dividing form, flagellate, and cyst. (After Wenyon and O'Connor.)

The cytoplasm is pale, frequently vacuolated with an anteriorly situate nucleus, which has a nuclear membrane and a central karyosome. On the surface of the nuclear membrane there are two granules from which the flagella arise.

Life-History.—Forms with two cytostomes and four flagella have been seen, indicative of division.

The cysts are pear-shaped bodies of a pearly-white appearance, and quite structureless unless stained, when certain nuclear structures can be made out.

Pathogenicity.—There is no evidence that it is pathogenic.

SUBFAMILY TETRAMITIDINÆ Chalmers and Pekkola, 1918

Definition.—Tetramitidæ with or without a cytostome with four to six flagella, but without an axostyle.

Classification.—Eight genera belong to the subfamily—viz.:—

Tetramitus Perty, 1852.
Callodictyon Carter, 1865.
Costiopsis Senn, 1900.
Chilomastix Alexeieff, 1911.
Tetrachilomastix da Fonseca, 1915.
Copromastix Aragão, 1916.
Tricercomonas Wenyon and O'Connor, 1917.
Protetramitus Chalmers and Pekkola, 1918.

And they may be differentiated as follows:—

A. *Without cytostome:*—
   1. With rhizoplast. (1) *Protetramitus* Chalmers and Pekkola, 1918.
   2. Without rhizoplast (2) *Copromastix* Aragão, 1916.
      (3) *Tricercomonas* Wenyon and O'Connor, 1917.

B. *Cytostome probably present:*
   At all events there is a deep ventral longitudinal furrow—
   (3) *Callodictyon* Carter, 1865.

C. *Cytostome present:*—
   I. Trailing flagellum is free:—
      (*a*) Body dorso-ventrally compressed, ventral surface with deep depression which serves as a sucker and contains the cytostome and two short free flagella; the two thick long trailing flagella issue from this depression—(4) *Costiopsis* Senn, 1900.
      (*b*) Body more or less symmetrical and not compressed or arranged as above, with three anterior and one free trailing flagellum—(5) *Tetramitus* Perty, 1852.
   II. Free trailing flagellum absent:—
      (*a*) Three anterior flagella—(6) *Chilomastix* Alexeieff, 1911.
      (*b*) Four anterior—(7) *Tetrachilomastix* da Fonseca, 1915.

Of these genera we are only concerned with Copromastix, Tricercomonas, Chilomastix, and Tetrachilomastix.

Genus Copromastix De Beaurepaire Aragão, 1916.

Definition. Tetramitidinæ without cytostome and rhizoplast.

Copromastix prowazeki Aragão, 1916.

Found in cultures of human fæces in Brazil.

Genus Tricercomonas Wenyon and O'Connor, 1916.

Definition.—Tetramitidinæ without cytostome and with three anterior and one trailing flagellum.

Remarks.—This genus is like Cercomonas in many ways, but cannot be classified in the family Cercomonadidæ; and as it shows a resemblance to Protetramitus, we place it here.

Type Species.—The type and only species is *Tricercomonas hominis* Wenyon and O'Connor, 1916.

Tricercomonas hominis Wenyon and O'Connor, 1916.

Definition.—Tricercomonas of small size and active movements, with spherical or ovoid body distinctly flattened on one side and with the posterior end drawn out and terminating in a flagellum, which can be traced forwards along the flattened side to the anterior end of the body, where three anterior long flagella take origin. Habitat, the intestine of man in Egypt.

Morphology.—In addition to the characters given above, the body, which measured 4–8 microns in length, is seen to be somewhat grooved along the course of the posterior flagellum. No definite cytostome could be seen. The cytoplasm contains bacilli and cocci, a nucleus with a central karyosome, and a nuclear membrane, which is drawn out into a cone-like elevation, from the summit of which the flagella take their origin.

Life-History. As forms with two nuclei have been seen it is presumed that binary division may take place. The cysts are oval, 6–8 microns in length and about half this breadth, containing one to four nuclei of the same type as the flagellate.

Pathogenicity. It is believed to be non-pathogenic.

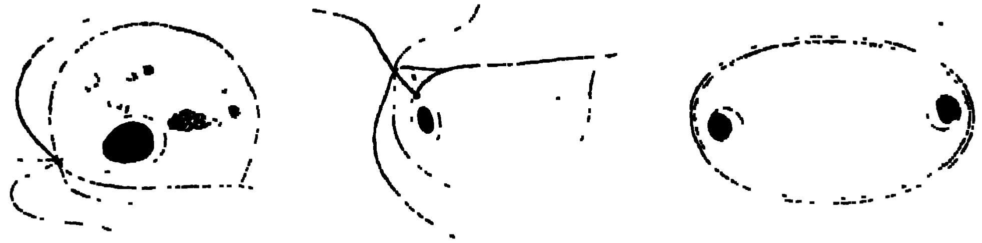

FIG. 70.—*Tricercomonas intestinalis* WENYON AND O'CONNOR, 1915.
Two flagellate forms (compare side view with Fig. 71) and one cyst
(After Wenyon and O'Connor, from the publications of the Wellcome Bureau of Scienti[illegible]ch.)

Genus Chilomastix Alexeieff, 1911.

Synonyms.—(1) *Cercomonas* Davaine, 1880, *pro parte nec* Dujardin, 1841; (2) *Trichomonas* Roos, 1893, *nec* Donné, 1837; (3) *Monocercomonas* Epstein, 1893, *nec* Grassi, 1879; (4) *Macrostoma* Alexeieff, 1909, *nec* Latreille, 1825; (5) *Fanapepea* Prowazek, 1911; (6) *Tetramitus* Brumpt, 1912, *nec* Perty, 1852; (7) *Difämus* Gäbel, 1914; (8) *Cyathomastix* Prowazek and Werner, 1914.

Definition.—Tetramitidinae with large cytostome, three anterior flagella, but no free trailing flagellum.

Type Species.—*Chilomastix caulleryi* Alexeieff, 1909. *Synonym*: *Macrostoma caulleryi* found in the intestine of tadpoles.

Other Species.—*C. mesnili* Wenyon, 1910; *C. motella* Alexeieff, 1912; *C. bittencourti* da Fonseca, 1915; *C. capræ* da Fonseca, 1915; *C. cuniculi* da Fonseca, 1915.

These species may be differentiated as follows:—

A. *Characters known to us* :—

I. *Size large ; 20-25 microns in length* :—

Flagella easily seen in cysts which resemble *C. mesnili* cysts in size and appearance—(1) *Caulleryi*.

II. *Size medium* ; 11-18 *microns in length* :—

(*a*) Cytostome long; cysts about 7 × 5·6 microns in which the anterior flagella are difficult to see—(2) *Mesnili*.

(*b*) Cytostome very short; cysts large, about 8 × 6 microns, in which the anterior flagella are very distinct—(3) *Bittencourti*.

III. *Size small* ; 7-12 *microns in length* :—

(*a*) Nucleus with a central karyosome connected to the blepharoplast by a rhizoplast; size 9-12 microns in length—(4) *Capræ*.

(*b*) Nucleus without a central karyosome and without a rhizoplast; size 7-9 microns in length—(5) *Cuniculi*.

B. *Characters unknown to us* :—

Found in species of *Motella*—(6) *Motellæ*.

Chilomastix mesnili Wenyon, 1910.

Synonyms.—(*a*) *Cercomonas hominis* Davaine, 1860, *pro parte* ; (*b*) *Monocercomonas hominis* Epstein, 1893, *nec* Grassi, 1879; (*c*) *Trichomonas intestinalis* Roos, 1893, *pro parte nec* Leuckart, 1879; (*d*) *Macrostoma mesnili* Wenyon, 1910; (*e*) *Fanapepea intestinalis* Prowazek, 1911; (*f*) *Tetramitus mesnili* Brumpt, 1912; (*g*) *Difāmus tunensis* Gabel, 1914; (*h*) *Cyathomastix hominis* Prowazek and Werner, 1914; (*i*) *Tetramitus bocis* Brumpt, 1912; (*k*) *Chilomastix intestinalis* Kuczynski, 1914.

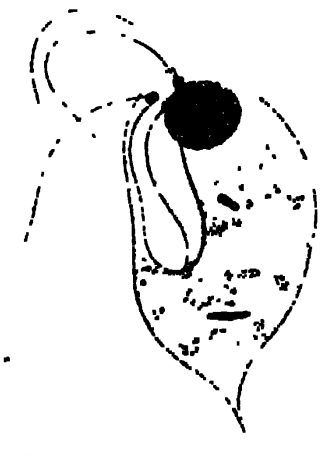

FIG. 77.—*Chilomastix mesnili* WENYON 1910.

Note the membrane raised by the cytostomic flagellum.

Definition.—Chilomastix of medium size, with long cytostome and with cysts about 7 × 5·6 microns, in which the anterior flagella are difficult to see.

Historical.—This flagellate appears to have been first noted by Davaine in 1860, being called Form A of *Cercomonas hominis*. After this it was noted by Roos in 1893, and by Epstein in the same year. It was rediscovered and properly described by Wenyon in 1910, and later noted by Prowazek in 1911, Nattan-Larrier in 1912, Brumpt in 1912, Gaebel in 1914, Chatterjee in 1915, Wenyon in 1915, Da Fonseca in 1915 and 1916, Fantham and Porter in 1915, Archibald, Hadfield Logan, and Campbell in 1916, Wenyon and O'Connor in 1917, Castellani in 1917, and Chalmers and Pekkola in 1918.

Remarks.—The parasite is widely distributed all over the world.

Morphology.—Its shape varies, but it is generally pear-shaped, measuring some 11-18 microns in length if the caudal appendage is included, and some 1·6-4·0 microns less if this is excluded. There is a large cytostome situate anteriorly. The cytoplasm contains a large, roundish, oval or slightly irregular chromatic nucleus, anterior to which lies two or three granules, from which the three anterior flagella take their origin. No rhizoplast can be seen. The margins of the cytostome are thickened, and appear to contain a fourth or *posteriorly directed flagellum* in the inner siderophilous rim, while the outer rim appears to be homologous with a *parabasal*.

Life-History.—Reproduction takes place by binary fission and cyst formation. The cysts are usually egg-shaped, measuring 7 × 5·6 microns. The cyst wall is separated from the parasite by a clear space, while the cytoplasm contains a nucleus, a blepharoplastic mass, and at times the mouth margins can be seen. Division forms with two nuclei have been noted.

Pathogenicity.—There is a difference of opinion. Some observers consider it to be non-pathogenic, while others hold that it is may cause diarrhœa.

SUBFAMILY TRICHOMONADINÆ Chalmers and Pekkola, 1917.

Definition.—Tetramitidæ with an axostyle.

Classification.—The ten genera belonging to this subfamily may be differentiated as follows:—

DIAGNOSTIC TABLE OF TRICHOMONADINÆ.

A. *Cytostome absent*:—
I. Three anterior flagella—(1) *Protrichomonas* Alexeieff, 1911.
II. Four anterior flagella—(2) *Monocercomonas* Grassi, 1879.

B. *Cytostome present*:—
I. Without undulating membrane:—
(*a*) *Without trailing flagellum*:—
1. Periplast thickened in places; four anterior flagella—(3) *Polymastix* Bütschli, 1884.
2. Periplast not thickened; six anterior flagella—(4) *Hexamastix* Alexeieff, 1912.
(*b*) *With trailing flagellum*:—
1. Three anterior flagella:—
(1) Without parabasal—(5) *Eutrichomastix* Kofoid and Swezy, 1915.
(2) With parabasal wound around the axostyle—(6) *Devescovina* Foà, 1905.
2. Four anterior flagella—(7) *Tetratrichomastix* Mackinnon, 1914.

II. With undulating membrane:—
  1. Three anterior flagella—(8) *Trichomonas* Donné, 1837.
  2. Four anterior flagella—(9) *Tetratrichomonas* Parisi, 1910.
  3. Five anterior flagella—(10) *Pentatrichomonas* Chatterjee, 1915.

Of these genera, Trichomonas, Tetratrichomonas, and Pentatrichomonas concern us.

Genus Trichomonas Donné, 1837.

Definition.—Trichomonadinae with a cytostome, an undulating membrane, and three anterior flagella

Remarks.—In his work 'Recherches microscopiques sur la nature du mucus,' Donné (1837) described and figured an organism which he found in innumerable quantities in vaginal mucus.

He considered that it possessed a single flagellum which at times was bifurcated distally, a series of three to five cilia with very rapid rotatory movement, and that at times it was elongated posteriorly into a tail. The name was first spelt Tricomonas but afterwards altered to Trichomonas.

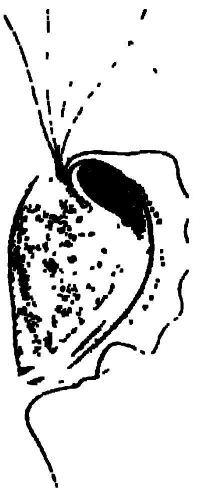

FIG. 78.—*Tetratrichomonas gallinarum* (Martin and Robertson, 1912). (× 2[illegible] Diameters.)

Dujardin (1841) described *T. limacis* from *Limax agrestis* in much the same terms, and so did Perty (1852) with regard to *T. batrachorum*, though he depicted the axostyle, but Stein's figures of Perty's organism show clearly the three anterior flagella, the undulating membrane the posterior free flagellum the axostyle the nucleus and the cytostome, and in this way was laid the foundations upon which the main features of the genus were placed.

Returning now to the type *T. vaginalis*, this was restudied in 1884 by Blochmann, who illustrated the three anterior flagella, the undulating membrane, the axostyle and the nucleus, but in the same year Kunstler produced a much better illustration showing four anterior flagella taking their origin from a blepharoplast from which the undulating membrane also arose, while this shows a trace of a parabasal. The nucleus is also represented, while the axostyle shows exceedingly clearly. He also saw the cytostome. Bensen (1910) figured two blepharoplasts, one of which is connected with the nucleus by means of a rhizoplast, and he also gave an illustration of a cyst. Thus the type species *T. vaginalis* was brought into line with the results of researches upon the species found in animals, of which a number have been carefully described and drawn by Dobell, Alexeieff, Martin and Robertson, Kuczynski, and by Kofoid and Swezy.

The only difficulty is with the type *T. vaginalis*. Does it possess three anterior flagella or four? If the latter, then the genus Trichomonas has as a synonym Tetratrichomonas, and a new name must be found for the forms with three anterior flagella.

Type Species.—*Trichomonas vaginalis* Donné, 1837.

Morphology.—The essential points in the general morphology are the pear-shaped body, the small anterior and ventrally situate cytostome without siderophilous lips, and the three anteriorly springing flagella arising (according to Wenyon) from the anterior of the two granules into which the blepharoplast is divided. From the posterior granule arises a posterior flagellum, which, passing backwards, forms the undulating membrane and finally terminates in a free posterior portion. From the same granule arises another stiff rod-like structure, the *parabasal*, which serves as a support for the undulating membrane, and often there is a row of granules lying parallel to this rod. Springing from the blepharoplast and directed posteriorly over the nucleus is a peculiar body, clear, with bounding lines, which projects from the posterior end as a spine and often contains chromatinic granules. This organella is the axostyle, called also the *baguette interne*. It may be a supporting structure, but it may also be concerned in movement. It does not stain with nuclear stains, and therefore appears clear, while in the living organism it is a refractile rod.

The nucleus is usually more or less oval, and possesses a membrane, inside which the chromatin is distributed in the form of granules.

Two chromatinic granules (axoplasts) are often found where the axostyle leaves the cytoplasm.

Life-History.—Binary division with its nuclear changes have been carefully studied by Kofoid and Swezy. Multiple fission has also been described. Transference from host to host is by the typical cysts

Classification.—A very large and increasing number of species of doubtful value are in existence: e.g., *T. bactrachorum* Perty, 1852, in frogs; *T. suis* Gruby and Delafond, in pigs; *T. limacis* Dujardin, in snails; *T. lacertæ* Blochmann, in lizards; *T. caviæ* Davaine, in guinea-pigs; *T. perroncili* Castellani, 1907, in monkeys; *T. columbarum*, in pigeons. Plimmer and others have also recorded a Tetratrichomonas in the blood of snakes (Fig. 79), and this probably came as an infection from the alimentary canal. Martin and Robertson have also described forms in fowls, and Kuczynski has contributed an elaborate paper on the morphology of the genus.

Four species are said to occur in man—*T. vaginalis*, *T. hominis*, *T. dysenteriæ*, and *T. pulmonalis*.

While some differences do exist in the animal forms, still there is nothing of a specific nature to be found in the human and it is quite possible that they are all one species, and that they are the same as that found in the rat—viz., *T. intestinalis*, with three anterior flagella, unless, indeed, *T. vaginalis* really possesses four flagella, but on this point we are not certain; moreover, Künstler was often wrong with regard to the number of flagella (*vide Polymastix melo-*

dontha, which he said had six flagella, and *T. intestinalis*, which he depicted with four flagella).

There is, however, a peculiar matter which must be referred to. Schaudinn stated that trichomonas becomes an ameba, and that two of these amebae, after giving off reduction bodies, became encysted together and conjugated. The zygote divided into several portions, leaving a considerable *nucleus de reliquat*. Gauducheau has described ameboid forms becoming a trichomonas, but such observations have failed to meet with confirmation so far, and are therefore *sub judice*.

Trichomonas vaginalis Donné, 1837.

Synonym.—*Trichomonas irregularis* Salisbury 1868.

This parasite lives in the vagina when the reaction of the mucus is acid. It is found in Europe, and we have observed it in Ceylon and in equatorial Africa. It has also been reported to occur in the urethra in men, after cohabitation with women infected with the parasite.

It is not transferable to rabbits, guinea pigs, or dogs. It has not been cultivated, nor is it understood how women become infected.

T. vaginalis is fusiform or pear-shaped in appearance, length from 15 to 25 μ, and breadth from 7 to 12 μ. The non-flagellate extremity is pointed and the flagellate extremity rounded. The parasite is generally considered to be harmless but we have, however, found it much more frequently in women suffering from vaginitis than in normal women.

Trichomonas hominis Davaine, 1854.

Synonyms. *Cercomonas hominis* Davaine, 1854; *C. intestinalis* Lambl, 1875; *T. intestinalis* Leuckart, 1879; *Monocercomonas hominis* Grassi, 1882; *Cimaenomonas hominis* Grassi, 1883.

The utmost confusion has existed between this species, *Oicomonas hominis* and *T. vaginalis*. It has been found in cases of diarrhea in Europe, India, and Ceylon but in small numbers may be found also in the intestine of individuals apparently healthy; it has also been reported from the mouth cavity and stomach. It seems to prefer to live in alkaline mucus.

T. hominis is pear-shaped, with a breadth of from 18 to 25 μ, with three flagella at its broadest end, and an undulating membrane. The cytoplasm contains a rather indistinct nucleus, and one or several non-pulsating vacuoles.

It has not been transmitted to animals, nor has it been cultivated. It can reproduce by longitudinal division, but forms are to be seen indicating encystment and conjugation. Alexeieff considered at one time the bodies described as trichomonas cysts to be in reality an ascomycetes fungus, which he called *Blastocystis enterocola* and Brumpt used the term *Blastocystis hominis*.

Trichomonas dysenteriæ Billet 1907.

This *Trichomonas* was first found by Billet in the fæces, and later in 1912 by Gauducheau, who believes that it becomes an amœba in one stage of its life-history. The latter observer divides the life-history of a *Loeschia* into—(1) Stage of parasitism in the tissues; (2) stage of saprophytism in the lumen of the bowel or in cultures when it lives on bacteria; (3) stage of free existence when it is a flagellate. He considers that *Loeschia undulans* Castellani 1904, is allied to this species, although Castellani is inclined to believe that it is a stage of an *Oicomonas*.

Trichomonas pulmonalis Schmidt 1895.

This form has been found by Schmidt and St. Artault, Leyden and Jaffé, in the sputum and lungs of persons suffering from phthisis, gangrene, and putrid bronchitis.

Other Species. *T. batrachorum* Perty, 1852, in the cloaca of *Rana temporaria*, *R. esculenta*, *Bufo vulgaris*, and *Hyla arborea*, in Germany and Italy; *T. suis* Gruby and Delafond, in the alimentary canal of pigs; *T. limacis* Dujardin, in the gut of *Limax agrestis*; *T. lacertæ* Blochmann in the cloaca of *Lacerta agilis*, *T. caviæ* Davaine, in the large bowel of guinea-pigs; but this last may perhaps be separated off into a separate genus, *Trichomastix*, with one long flagellum directed across the body. *T. perronciti* Castellani, 1907, in monkeys suffering from diarrhœa, is very similar morphologically to *T. hominis*. *T. columbarum* Prowazek and Aragao, 1909, is found in the buccal mucosa of pigeons. Plimmer has shown that flagellates of the type of *Trichomonas* can be found in the blood of snakes.

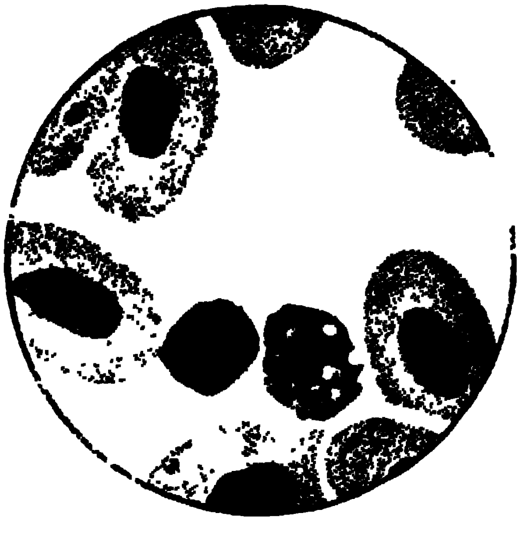

FIG. [illegible] OF TRICHOMONAS TYPE FOUND IN THE BLOOD OF A LEOPARDINE SNAKE.

(After Plimmer.)

Tetratrichomonas Parisi, 1910.

Definition.—Trichomonadinæ with a cytostome, an undulating membrane, and four anterior flagella.

Type Species.—*T. prowazeki* Alexeieff, 1909, found in salamanders and tritons.

Remarks.—Alexeieff (1909) found a trichomonas-like parasite in the terminal intestine of *Salamandra maculosa*, *Triton cristatus* and *Alytes obstetricans*, and subsequently in *Hæmopis sanguisuga*. This parasite, measuring 10 to 14 by 4 to 7 microns, possessed four free unequal anterior flagella and an undulating membrane thrown into long loose folds, as well as a thinnish axostyle and a nucleus rich in chromatin and bounded by a very definite membrane. He named this organism *Trichomonas prowazeki*, but as it possesses four and not three anterior unequal flagella, Parisi created a new genus with it as the type.

Tetratrichomonas vaginalis Castellani and Chalmers, 1919.

Künstler described *Trichomonas vaginalis* with four flagella, and we have seen forms in the human vagina with four flagella.

Tetratrichomonas intestinalis Chalmers and Pekkola, 1919.

Found in human fæces in Egypt by Wenyon and O'Connor, and later by Chalmers and Pekkola in the Sudan.

Genus Pentatrichomonas Chatterjee, 1915.

Definition.—Trichomonadinæ with a cytostome, an undulating membrane, and five anterior flagella.

Type Species.—*Pentatrichomonas ardindelteili* Derrieu and Raynaud, 1914, found in the intestine of man in Africa and India.

Remarks.—Chatterjee instituted this genus for a flagellate which he found in the intestine of man in Bengal, and which at the time he called *P. bengalensis*. This organism agrees in most particulars except measurement with that mentioned above under the heading *Hexamastix* Derrieu and Raynaud, and therefore Chatterjee's generic name takes the place of this Hexamastix, but Derrieu and Raynaud's specific name has priority, and the parasite becomes known as *Pentatrichomonas ardindelteili* Derrieu and Raynaud, 1914, until some definite difference between the two is established.

More recently Chatterjee states that he has found this organism to be present in thirty-two cases of chronic dysentery.

Pentatrichomonas ardindelteili (Derrieu and Raynaud, 1914).

This is the only species and hence also the type, and has the characters of the genus. It is found in man.

REFERENCES.

There is no one paper or book which deals at all adequately with the Mastigophora; the best we can recommend is Saville Kent's 'Infusoria,' Doflein's latest edition, and Fantham, Stephens, and Theobald's (1916) 'Animal Parasites of Man.' But none of these are any use without Dujardin, Davaine, and Stein, combined with Bütschli, Kunstler, Klebs, Wenyon, Dobell, Kofoid, and Swezy, etc. Chalmers and Pekkola have attempted statements with regard to the Tetramitidæ, with a view to clearing up the existing confusion.

CHAPTER XIX

TRYPANOSOMIDÆ

Preliminary remarks—Trypanosomidæ—Herpetomoninæ—Trypanosominæ—Incertæ sedis—Leucocytozoön—Spirochætacea—References.

PRELIMINARY REMARKS.

In this chapter we complete the study of the Monozoa by considering the forms allied to Herpetomonas and to Trypanosoma, which have been gathered together into one family, the Trypanosomidæ of Doflein, and follow this by a description of Leucocytozoön and the Spirochætes, of which the classification is uncertain.

FAMILY TRYPANOSOMIDÆ Doflein, 1901.

Definition. Monozoa possessing one flagellum, without a collar and with the kinetonucleus separate from the nucleus.

Classification. This family may conveniently be divided into two subfamilies as follows:—

(*a*) Undulating membrane absent or rudimentary and the kinetonucleus on the flagellar side of the trophonucleus—Subfamily 1. *Herpetomoninæ* Castellani and Chalmers, 1919.

(*b*) Undulating membrane well developed and the kinetonucleus on the aflagellar side of the trophonucleus—Subfamily 2. *Trypanosominæ* Castellani and Chalmers, 1919.

SUBFAMILY HERPETOMONINÆ Castellani and Chalmers, 1919.

Definition. Trypanosomidæ in which the undulating membrane is either rudimentary or absent, and in which the kinetonucleus is situate on the flagellar side of the trophonucleus and remains there.

Type Genus.—*Herpetomonas* Saville Kent, 1881.

Classification. The various genera which used to be gathered together in the family Herpetomonidæ were:—

1. *Herpetomonas* Kent, 1881.
2. *Leptomonas* Kent, 1881.
3. *Crithidia* Léger 1902, *emendavit* Patton, 1908.
4. *Leishmania* R. Ross, 1903.

5. *Toxoplasma* Nicolle and Manceaux, 1908.
6. *Piroplasma* Patton, 1895.
7. *Achromaticus* Dionisi, 1898.
8. *Histoplasma* Darling, 1906.

Unfortunately, there has been much confusion with regard to these genera, due to lack of certain knowledge with regard to the morphology and life-histories of the type species. The controversy was keenest with regard to the points as to whether *Herpetomonas* and *Leptomonas* were or were not the same genus; whether *Herpetomonas* and *Crithidia* are good genera, or simply stages in the life-cycle of a trypanosome. Briefly, the position is this: In 1851 Burnett discovered a flagellate in the house fly, and called it *Bodo muscæ-domesticæ*, for which Kent created the genus *Herpetomonas* in 1881; but two pages earlier in his book Kent created the genus *Leptomonas* for a flagellate which Bütschli had found in the intestine of *Trilobus gracilis* in 1876. The only distinguishing features between these two genera are the presence of a contractile vacuole and the flexibility of the body in *Herpetomonas*, but modern research fails to confirm the presence of this contractile vacuole in *Herpetomonas*, and flexibility *per se* is insufficient to separate the two genera. Prowazek, however, in 1904, emended *Herpetomonas*, describing *H. muscæ-domesticæ* as possessing two flagella united by a membrane and arising from a flagellar situated diplosome; but Patton, in 1909, and Mackinnon in 1910, have demonstrated that this is merely a stage in the division of *H. muscæ domesticæ*; and Chatton and Léger, in 1911, demonstrated that there was an axostyle present in *Leptomonas drosophilæ*; and Chatton later showed that the diplosome of *H. muscæ-domesticæ* was merely the remains of this axostyle. Therefore it would appear that the two genera are indistinguishable, and might therefore be united, and, if so, the older name *Leptomonas* would by the law of priority come into use, to the exclusion of the name *Herpetomonas*; and this may happen, but it cannot be adopted at present, because the type species of the genus *Leptomonas*—namely, *L. bütschlii* Kent, 1881—has, as yet, been incompletely studied, and may eventually be found to be the same as, or different from, *Herpetomonas*; therefore we continue to retain the two genera *Herpetomonas* and *Leptomonas* in the same condition as in our last edition—that is to say, indistinguishable from one another.

With regard to the controversy as to whether there is a genus *Crithidia* or not, the answer is much simpler. There can be no doubt that crithidia like forms exist in the life-cycle of many trypanosomes; but the work of Patton, Porter, and Swingle has clearly shown that there is a separate genus, *Crithidia* Léger, 1902, emended Patton. Further, we believe that Miss Porter is correct when she states that *Crithidia* should be placed in the family Trypanosomidæ on account of the presence of an undulating membrane.

With regard to *Leishmania*, a better knowledge of the life-history has shown that this is merely a *Herpetomonas* or *Leptomonas*, but at the present time we retain it as a separate genus, as the full life-cycle has never been completely traced.

So far we have been considering genera in which there is no doubt that one stage of the life-cycle is flagellate; now we turn to the other genera, concerning which doubt is freely expressed as to whether they belong to the *Mastigophora* at all.

With regard to *Toxoplasma*, it was considered by some observers to be allied to *Leishmania*, but it contains only a single nucleus, without evidence of a kinetonucleus, and without the appearance of a flagellate stage on cultivation; and its life-cycle is little known, as is that of an apparently allied genus, *Elleipsisoma* França, 1911, while the relationship is further complicated by the genus *Toddia* França, 1911, which is said to arise from the infective granule. There appears to be more flagellate evidence for the genus *Globidium* Neumann, 1909. The so-called *Leucocytozoön piroplasmoides* Thiroux and Teppaz appears to be allied to *Toxoplasma*, having only one nucleus, and not developing any flagellate forms on cultivation. Finally, the work of Yakimoff and Kohl-Yakimoff indicates that *Toxoplasma* is related to the Hæmogregarines, especially as Splendore's flagellate stage has not been confirmed by Laveran's work.

The genus *Piroplasma* used to be classed with *Herpetomonas* because flagellate forms had been found by several observers, but these findings have been discredited because (1) they were discovered in the old faulty air-dried smears; (2) the possibility of their being intestinal flagellates of the genus *Prowazekia*, which entered the blood before death in diseased animals; (3) they are really trypanosomes, and not development stages of *Piroplasma* ; (4) the careful work of Nuttall and his collaborators have failed to demonstrate a flagellate stage.

Achromaticus was placed with the Herpetomoninæ because, according to Gonder, it always has a trophonucleus and a kinetonucleus, while Neumann maintains that it becomes flagellate in the bat mite, *Pteropus vespertilionis*. On the other hand, Yakimoff, Stolnikoff, and Kohl Yakimoff deny the presence of the double nucleus, and consider the parasite to be a typical *Piroplasma*.

According to Darling, *Histoplasma* becomes flagellated in the lungs, and therefore belongs to the Herpetomoninæ, though Rocha-Lima considers it to be a yeast, a view which we adopt.

Rhynchoidomonas belongs to the Trypanosominæ.

We therefore recognize the following as definitely belonging to the Herpetomoninæ:—

1. *Herpetomonas* Kent, 1881.
2. *Leptomonas* Kent, 1881.
3. *Crithidia* Léger, 1902, *emendavit* Patton, 1908
4. *Leishmania* Ross, 1903.
5. *Hæmocystozoōn* Franchini, 1913.

These five genera may be differentiated as follows:—

(*a*) Undulating membrane absent:—
  Genera: *Herpetomonas*, *Leptomonas*, *Leishmania*, *Hæmocystozoön*. (Probably all belong to one and the same genus, *Herpetomonas*.)

(*b*) Rudimentary undulating membrane present.—Genus *Crithidia*.

Morphology.—The flagellate stage of the Herpetomoninæ is usually an elongated spindle-shaped mass of cytoplasm composed of an inner granular endoplasm surrounded by a periplast (ectoplasm). In the cytoplasm lies a chromatinic mass, the trophonucleus, which, when properly treated, appears to be of the nature of a protokaryon. On the flagellar side of this lies another mass of chromatin called the kinetonucleus, and further back on the same side a minute bead—the blepharoplast—from which the flagellum passes through the cytoplasm, either directly, and so forming no undulating membrane and becoming a free flagellum, or it carries the cytoplasm with it, forming a rudimentary undulating membrane.

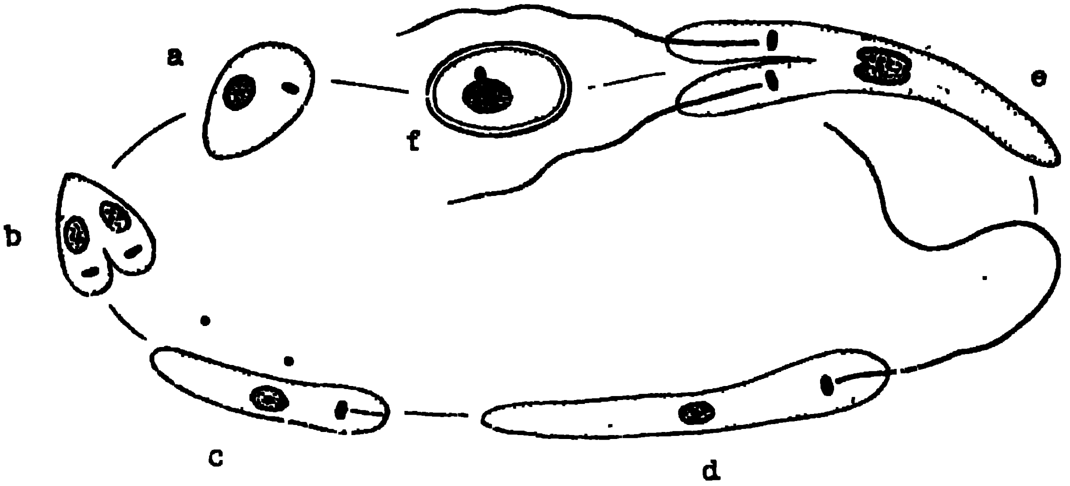

FIG. 80.—THE LIFE-HISTORY OF A HERPETOMONAS. (After Fantham.)

Life-History.—The flagellate forms are usually the inhabitants of the intestine of the arthropoda, but some live in plants.

They can multiply in their arthropodal host by longitudinal division of the flagellate stage, but this may become rounded binucleate cysts, which, passing from one host with the fæces, can infect a new host.

In the new host it appears as a non-flagellate binucleate rounded form, often called a Leishmania-like body, or the Leishmaniform stage, which develops in due course into the flagellate stage again.

Thus in the life-cycle there are the following stages:—

1. The flagellate stage.
2. The post-flagellate or encysted stage.
3. The Leishmaniform stage.
4. The flagellate stage again.

The Herpetomoninæ are distinct forms, and are not stages in the life-cycle of a trypanosome.

Hereditary Infection.—In an important paper O'Farrell in 1913 traced the infection of the ovum of the tick *Hyalomma ægyptium* by *Crithidia hyalommæ*. Usually the flagellate stage is passed in hæmocœlic fluid of the tick, but about the time of and during oviposition a considerable number of the flagellates enter the ovary, and some penetrate by their aflagellar extremity into the ova, where they become the Leishmaniform stage, which may form large plasmodial masses which break up into small resting forms. This flagellate is therefore strictly parasitic in the tick and its life-history

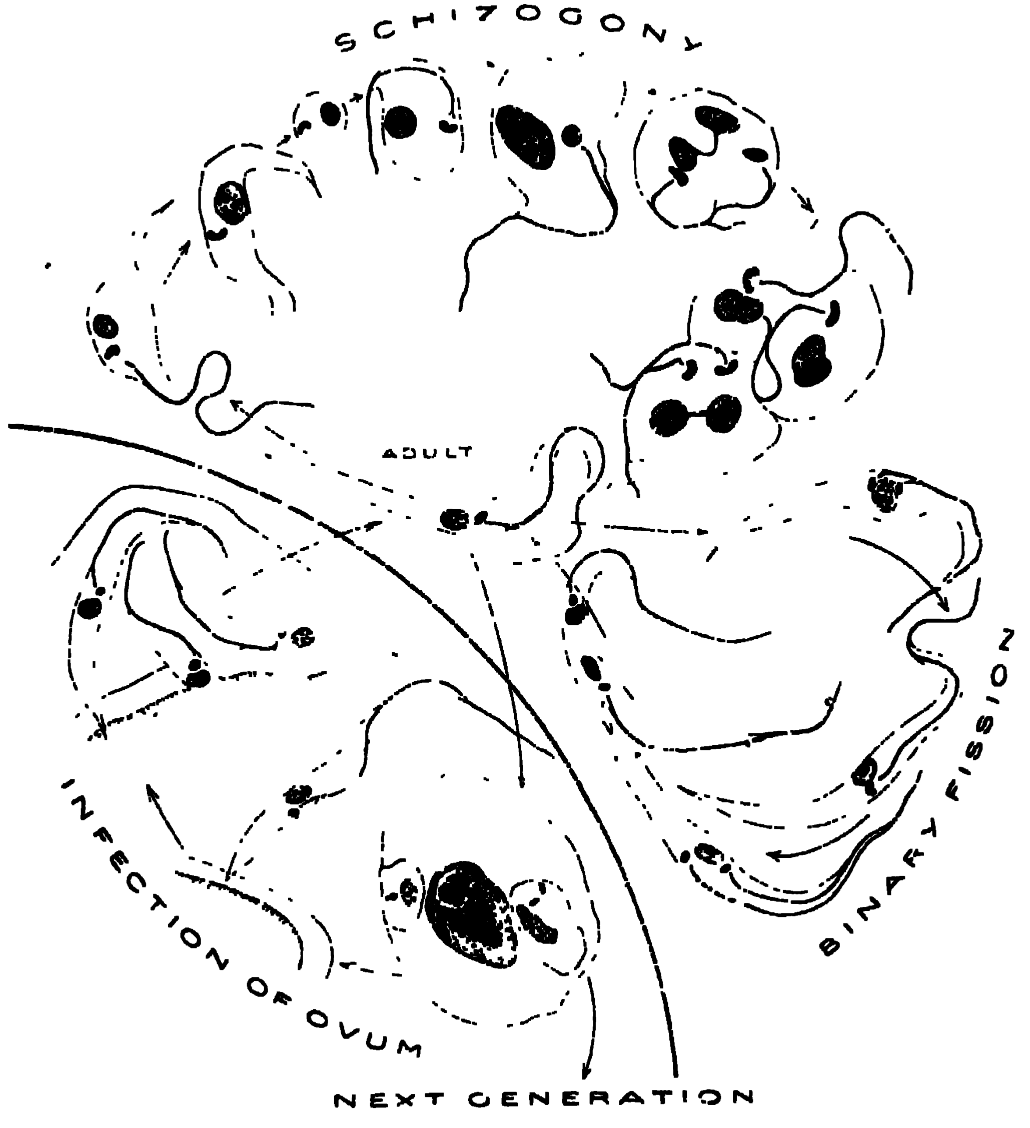

FIG. 81.—THE LIFE-CYCLE OF *Crithidia hyalommæ* O'FARRELL, 1913. (After O'Farrell.)

It demonstrates hereditary infection. The arrows in the infection of the ovum except the two on the right-hand side, are wrong. The left upper arrow should run from the adult to the ovum; the other two arrows should be omitted.

resembles that described by Porter for *Crithidia melophagia* in the fly *Melophagus ovinus*.

Pathogenicity.—In an able paper published in 1916 Fantham and Porter have shown that by feeding and by inoculation of various forms of herpetomonads and crithidias acute and chronic attacks of *herpetomoniasis* can be induced in vertebrates. Thus *Herpetomonas jaculum*, from *Nepa cinerea*, by feeding, produced the disease in mice, birds, a snake, frogs, newts, and fish; *H. stratiomyiæ* from *Stratiomyia chameleon* in a mouse; *H. pediculi* from *Pediculus corporis* in mice; *H. culicis* from *Culex pipiens* in birds; *H. ctenocephali* from a flea in a dog; *Crithidia gerridis* from *Gerris paludum* in dogs, lizards, mice, and frogs. In the infected animals both flagellate and Leishmaniform parasites were present.

These experiments are of great importance, and support the views expressed by Archibald that the method of infection of kala-azar in man is from aquatic insects and *per os*. Experimental herpetomoniasis is characterized by insidious onset followed by rapid illness, splenic and often hepatic enlargement, attacks of fever, emaciation, and often death.

Evolution of Herpetomoniasis.—As a result of the above-mentioned experimental work, Fantham and Porter have deduced the view that, in the case of the herpetomonads, disease is in the making to-day, and that as the result of change of habitat (brought about by ingestion or insect-faecal contamination of a bite), a herpetomonas may find itself in a vertebrate host, and there, taking on its Leishmaniform stage, becomes pathogenic, producing the disease *herpetomoniasis*, which may be acute or chronic. In the acute disease the flagellate forms abound, while in the chronic there are many more Leishmania-like forms.

Vertebrate Reservoir. As a variety of the chronic infection may be mentioned the vertebrate reservoir.

In 1914 Sergent, Lemaire, and Sanevet found herpetomonad flagellates in the blood and organs of a gecko in areas in Algeria in which Oriental sore was endemic, and suggested that the possible carrier was a phlebotomus. In the same year Chatton and Le Blanc found Leishmania-like forms in the red blood-cells of geckos in Tunis.

In 1915 Bayon found herpetomonas in the alimentary canal of *Chameleon pumilus* at Robbin Island, and also in a fly, *Scatophaga hottentota*, and suggested the possibility of infection of the vertebrate by swallowing a fly.

In 1914 Lindsey suggested that the oral Leishmaniasis of Paraguay might have its reservoir in rattlesnakes and its carrier in ticks or Simulium flies.

On the other hand, the very careful work carried out by Archibald in the Sudan has apparently excluded *domestic animals* as possible reservoirs of kala-azar in that region, where dogs are not readily susceptible to the virus, a fact which rather tends to differentiate the parasites of Sudan kala-azar from those of the Mediterranean.

Method of Infection.—As indicated above, the method of infection would be by swallowing the arthropod or some of its fæcal matter containing cysts, or by fæcal contamination of its cutaneous bite, or by both methods.

Archibald's evidence is against an insect as the infective agent of kala-azar in the Sudan, which he suggests is water-borne, in which case it might come from the fæces of insect larvæ or an aquatic arthropod.

Treatment of Infections.—Preparations of arsenic and of antimony are of great benefit in treating cases of herpetomoniasis or Leishmaniasis.

Prevention.—Dodds, Price, and Young seem to have had some success in segregating the infected human cases and removing the healthy to new abodes, and on theoretical grounds it would appear that if herpetomoniasis was endemic in any region, this should be examined for—

(*a*) Possible vertebrate reservoir;
(*b*) Possible arthropod carrier;

and if these are found, even if they are only possible, steps should be taken to protect the inhabitants from them.

Genus Herpetomonas Kent, 1881.

Synonyms.—*Bodo* Stein, *pro parte*; *Cercomonas* Dujardin, *pro parte*; and perhaps *Leptomonas* Kent.

Definition.—Herpetomoninæ elongated, rod-like, with a single flagellum. The kinetonucleus is situated near the posterior end, so that the flagellum is not attached to the side of the body, but becomes free at once and projects posteriorly. There is no undulating membrane. The contractile vacuole is situate quite close to the posterior extremity. The trophonucleus lies about the middle of the parasite, and possesses an achromatic substance with chromatic granules interspersed. The anterior end is tapering.

Type Species.—*Herpetomonas muscæ-domesticæ* Burnett, 1851.

History.—The genus *Herpetomonas* was created in 1881 by Saville Kent for Burnett's *Bodo muscæ-domseticæ*, and since then many flagellates have, rightly or wrongly, been classified under this genus. The life-cycles have been studied by Léger in 1903, Prowazek, 1904; Patton, 1907-08; Berliner, 1909; and Miss Porter, 1911. At the present time there are two different views concerning the characters of the genus: (*a*) Prowazek's view, supported by Chatton, Alilaire, and Berliner, that it is biflagellate; (*b*) Patton's view, supported by Miss Porter and others, that it is uniflagellate (a view which our observations support).

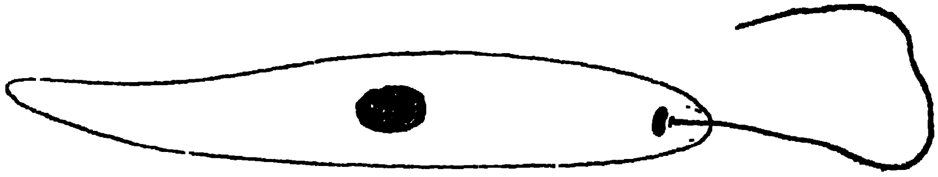

FIG. 82.—DIAGRAM OF A HERPETOMONAS.

Remarks.—The species of Herpetomonas, though not parasitic in human beings, are important to the student of tropical medicine, as they are parasitic in insects. Thus, *Herpetomonas muscæ-domesticæ* Burnett is parasitic in the intestinal canal of 8 per cent. of the house-flies (Prowazek), while others are found in fleas and bugs.

As already stated, there is considerable difference of opinion concerning the status of the Herpetomoninæ at the present moment. A number of observers, including Léger and Sambon, look upon them as merely stages in the life-history of trypanosomes; while others, such as Novy, McNeal, Ross, and Patton, hold that they are probably distinct from the blood trypanosomes. Woodcock, however, is correct when he says that those with trypaniform characters will probably be found to be stages in the life-cycle of trypanosomes, while the more typical herpetomonads will be found to be separate and distinct from these parasites.

In other words, some of the forms found in blood-sucking flies, leeches, etc., may be stages in the life-cycle of trypanosomes, while other forms, together, with those found in non-blood-sucking flies, and perhaps those found in larvæ, may (though it is open to question in the larvæ of blood-suckers) belong to a truly separate genus. The life-history of these forms has been mainly studied by Prowazek and Patton, whose results differ remarkably.

Herpetomonas muscæ-domesticæ Burnett 1851.

Synonyms.—*Bodo muscæ domesticæ* Burnett, 1851; *Cercomonas muscæ-domesticæ* Burnett, 1851; *Leptomonas muscæ-domesticæ* Burnett, 1851.

This flagellate is found in *Musca domestica* L., *Homalomyia scalaris* Fabricius, *Pollenia rudis* F., *Theicomyza fusca* Macquart, *Lucilia* sp.?, *Pycnosoma pulorum*, *Scatophaga lutaria* F., *Neuroctena anilis* Fallen, and *Homalomyia corvina* Verrall.

Miss Mackinnon has given a careful account of the morphology and life-history of *Herpetomonas muscæ-domesticæ* which is found in the house fly *Musca domestica* Linnæus.

Morphology.—The preflagellate stage takes place in the mid-gut, or more rarely the hind-gut, of the fly in the form of small round or oval bodies, 3 to 4 μ by 2·5 μ, which possess a circular trophonucleus and a rod-shaped kinetonucleus, while a rose-pink area in specimens stained by Giemsa, running from the kinetonucleus to the end of the cell, indicates the position of the future flagellum. This stage passes into the flagellate stage which takes place in the mid-gut when the Herpetomonad appears as a rather elongated (25 μ by 2·5 μ) body, which is blunt at the aflagellar end, and furnished with a flagellum which measures 30 μ, and arises from a blepharoplast situate near the kinetonucleus. The rhizoplast measures 4 μ, and is markedly thickened. The rod-shaped kinetonucleus is situate 6 μ from the flagellar extremity, and measures 2 μ by 0·8 μ. The trophonucleus is situate almost centrally, and measures 3 μ by 2 μ. The Doppelfaden of Prowazek is present as a line from the kinetonucleus via the trophonucleus far into the aflagellar end of the body.

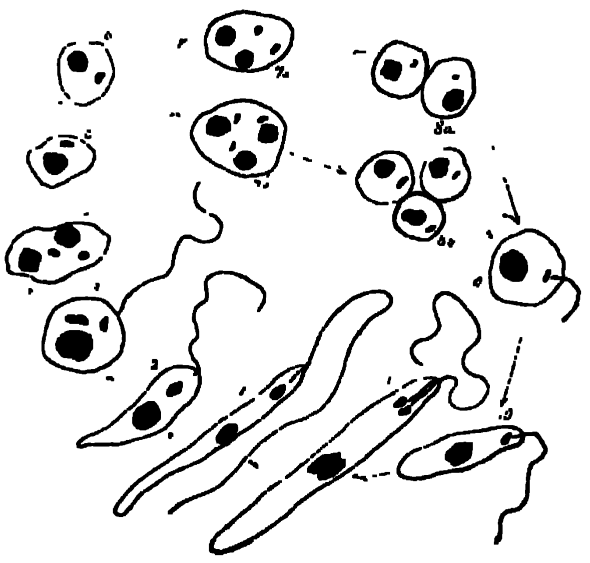

FIG. 83.—THE LIFE-CYCLE OF *Herpetomonas muscæ-domesticæ* BURNETT.

(After Patton.)

1, Fully developed parasite; 2-5, stages of encystment; 6, encysted or preflagellate form; 7a-8a, multiplication of the preflagellate form by simple division; 7b-8b, multiple division; 9, young flagellate stage; 10, other form; 11, longitudinal division commencing.

Life-History.—*Herpetomonas muscæ-domesticæ* multiplies by longitudinal division, in which the rhizoplast divides first, and each half is seen to have a separate blepharoplast, but there does not appear to be a splitting of the flagellum; on the contrary, Miss Mackinnon believes that the new flagellum grows out from one of the blepharoplasts, but for some time the two flagella lie close together, and this may last until the new flagellum has reached the length of the old flagellum. It is in this stage that *the deceptive appearances of a biflagellate organism* is produced. The kinetonucleus divides, and the trophonucleus also divides amitotically, the karyosome dividing first; after this the cytoplasm divides. Division takes place so rapidly that the organisms become smaller and smaller, and, attaching themselves to the epithelium of the hind gut, encyst—*i.e.*, pass into the post-flagellate stage of aflagellar cysts (3 to 4 μ by 3·5 to 2·5 μ), possessing tropho- and kineto-nuclei. These cysts pass out in the fæces, and are accidentally ingested by the fly along with food.

Hereditary Infection. No sign of hereditary infection could be found, nor of sexual reproduction.

Other Observations. Prowazek describes asexual reproduction by longitudinal division, in which the trophonucleus divides first, then the kinetonucleus, and lastly the flagellum, while Patton fails to find the division of the flagellum, and states that the second flagellum is developed as an outgrowth from the kinetonucleus. Prowazek has seen sexual conjugation, which Patton fails to find. Prowazek describes encystment, and considers that the infection is carried by the fæces, with which latter statement Patton agrees. Prowazek finds that the male and female parasites penetrate into the eggs of the fly, and undergo therein an autogamy by ethogenesis, in which the kinetonucleus carries out the development, by parthenogenesis, in which the trophonucleus is active, and by an indifferent type, in which both nuclei participate. There are, however, many transitional forms between these stages. Patton's description of the life-cycle is quite different, and resembles that which he has given for *Crithidia gerridis* (vide p. 369). He further supports this life-cycle by his previous description of a *Herpetomonas* in *Culex pipiens*.

Herpetomonas jaculum Léger, 1902

The parasite which was found in the alimentary canal of *Nepa cinerea* by Léger, has been studied in detail by Miss Porter.

Morphology. This *Herpetomonas* in the flagellate stage measures 15 to 33 μ in length by 1 to 4 μ in breadth, and is surrounded by a clear, flexible ectoplasm provided with myonemes, inside which is a granular endoplasm with granules arranged in such a way as to suggest a cytopharynx. The trophonucleus is oval, the kinetonucleus is fairly large, and chromidia are found widely separate from one another. A blepharoplast lies close to the well-developed flagellum.

Life-History. The flagellate attaches itself to the wall of the gut or to débris, and divides until small motionless forms result, which, shortening and encysting, form the 'post-flagellate stage.' It now escapes from its host as minute cysts in the fæces, which are deposited on the leaves of water plants. The fæces are eaten by the young *Nepa*, *i.e.*, there is contaminative or casual infection, and now the ingested cysts, which are small oval bodies, with tropho- and kineto-nuclei, form the preflagellate stage of the life-cycle, which passes into the flagellate adult stage.

Hereditary Infection. In addition, Miss Porter has seen flagellate forms pass through the wall of the gut near the ovaries, into which they penetrate and encyst, all of which is suggestive of hereditary infection.

H. bütschlii Saville Kent, 1881

In *Trilobus gracilis*, but it has not been perfectly studied.

H. pycnosomæ Roubaud, 1904

In *Pycnosoma putorium* Wiedmann, in Africa.

H. davidi Lafont, 1909

Described in *Euphorbia pilulifera* by Lafont, in Mauritius, Ceylon, and Réunion, East and West Africa, West Indies, Portugal, and India. We have often found this species in Ceylon. The parts of the plants affected are not healthy, and the disease is called 'flagellosis.' Miss Robertson has found a similar parasite in cotton plants in Uganda. It measures 10·5-16·5 × 1·5 microns.

Other Species.—*H. gracilis* Léger, 1902, in the Malpighian tubules of the larvæ of *Tanypus*; *H. lesnei* Léger, 1903, in the mid-gut, near the Malpighian tubules of *Dasyphora pratorum*. *H. subulata* Léger, 1903, in the gut of *Tabanus glaucopis* and *Hæmatopota italica* Meigen. *H. sarcophagæ* Prowazek, 1904, in the gut of *Sarcophaga hæmorrhoidalis*, *H. bombycis* Levaditi, 1905, *H. vespæ* Porter, 1911, in the gut of *Vespa crabro*, *H. ctenophthalmi* Mackinnon, 1909, in *Ctenophthalmus agyrtes*, *H. drosophilæ* Chatton and Alilaire, 1908, in *Drosophila confusa*.

Genus Crithidia Léger, 1902, *emendavit* Patton, 1907

Definition. Herpetomonidæ, in which the schizont is characterized by an attenuated posterior end, to which the flagellum is attached by a rudimentary undulating membrane. The kinetonucleus is situated close to the trophonucleus, either on the flagellar sides or slightly and rarely a little on the aflagellar aspect of this structure.

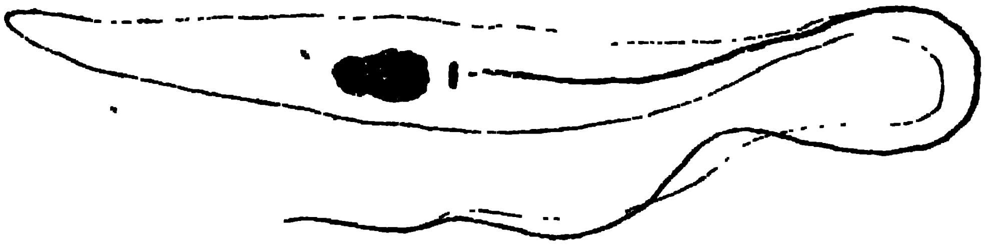

FIG. 81.—DIAGRAM OF A CRITHIDIA.

Remarks. In 1902 Léger created this genus for a flagellate organism which he found in the alimentary canal of *Anopheles maculipennis*, and in 1907 Patton worked out the life history of *Crithidia gerridis*.

Crithidia gerridis Patton, 1908.

This flagellate is a parasite in *Gerris fossarum Fabricius* and in a species of Microvelia, and in a water-bug allied to *Perittopus* found in Madras. The flagellate is found in the crop of the insect as a round, oval, or pear shaped body, 4 to 6 μ in length and 3 to 4 μ in breadth, in which lie a circular trophonucleus and a rod shaped kinetonucleus.

The parasite grows and becomes vacuolated, showing, when coloured, a small pink staining area between the kinetonucleus and the periphery, which later becomes a distinct pink rod, and is a rudimentary flagellum attached by a rudimentary undulating membrane to the cell. This membrane shows as a faint pink band between the flagellum and the body of the parasite.

Later the flagellum can be seen arising from an achromatic area, the blepharoplast, close to the kinetonucleus, and running along the periphery of the parasite.

The kinetonucleus increases in size, and the trophonucleus shows its chromosomes, while chromatic particles appear in the cytoplasm.

The kinetonucleus now approaches the trophonucleus, and elongates and divides, while the flagellum thickens and splits longitudinally, so that there are two kinetonuclei and two flagella.

The trophonucleus and the cytoplasm now divide, so that two daughter cells are formed, which in turn divide, forming rosettes of eight to forty or more cells, measuring 6 to 10 μ in length by 4 to 8 μ in breadth.

Eventually the rosettes break up, and the rounded parasite has a central nucleus and a kinetonucleus at one side, and from a point close to this a flagellum passes round its circumference, giving it an undulating contour. The parasite elongates, and the posterior end is drawn out along the flagellum; the length is now 15 to 45 μ and the breadth 2 to 4 μ. They are often found agglomerated together.

Longitudinal division now takes place rapidly, and the parasites pass down the intestinal tract and shorten, until they become round bodies with long flagella. A change then takes place, the flagellum becoming absorbed and

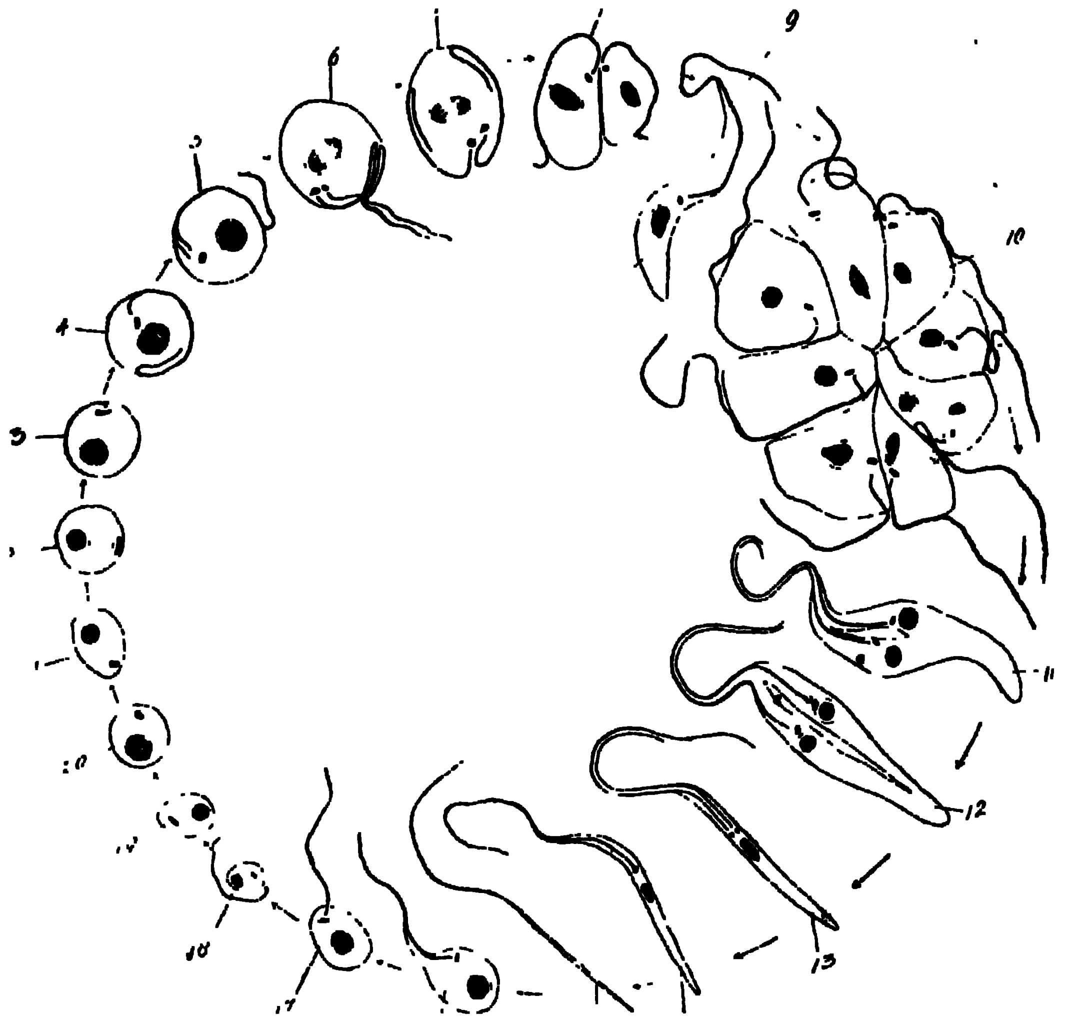

FIG. 85.—THE LIFE-CYCLE OF *Crithidia gerridis* PATTON.
(This is a diagram constructed from Patton's drawings.)

14, Crithidial form; 15, very slender forms; 16-18, rounded forms losing their flagella; 19-3, preflagellate round forms, gradually increasing in size; 4, 5, formation of the flagellum, 6-8, division; 10, agglomeration; 11-13, division.

finally detached, and the parasite appearing as a rounded body with a tropho- and a kineto-nucleus. The life-history is completed by the bodies being discharged with the fæces into the water, and so taken up by a new host. The ovaries and eggs were not infected. This is an excellent example of Minchin's contaminative method of infection.

Miss Porter has fully traced out the life-history of *C. gerridis* found in *Gerris paludum* in England, and confirms Patton's researches.

Crithidia melophagia Flu, 1908.

Flu has described *Crithidia melophagia* in *Melophagus ovinus*, a parasite of the sheep. He gives an account of asexual and sexual reproduction. The latter is characterized by a process of reduction, followed by conjugation with the formation of an oökinete and the infection of the eggs of the insect, which may cause a second generation of flies to carry the organism (Fig. 90).

Other Species.—*C. fasciculata* Léger, 1902, in the intestines of females of the species *Anopheles maculipennis* and in *Culex fatigans* Wied.; *C. campanulata* Léger, 1903, in the intestine of *Chironomus plumosus*; *C. minuta* Léger, 1903; this parasite is found in *Tabanus tergestinus*, and is characterized by having a thick rounded end; *C. cleti* Hindle and Lewis, 1912, in *Cletus varius* Dall, *C. pulicis* Porter, 1911, in *Pulex irritans* L., *C. hystrichopsyllæ* Mackinnon, 1909, in *Hystrichopsylla talpæ*, and a number unnamed by Miss Robertson in Hemiptera in Uganda; *Crithidia hyalommæ* O'Farrell, 1913.

Genus Leishmania R. Ross, 1903.

Synonyms. *Piroplasma* Laveran and Mesnil, 1903, *Helcosoma* Wright, 1903, *Herpetomonas* Rogers, 1904.

Definition. Herpetomoninae, living principally in endothelial cells, but also found in leucocytes and in the peripheral blood of mammals as small, oval, cytoplasmic masses with tropho- and kineto-nuclei, and developing into flagellate bodies in cultures.

Remarks.—Three species are known in man, morphologically similar, but pathogenetically different: *Leishmania donovani* Laveran and Mesnil, 1903, *L. infantum* Nicolle, 1908, and *L. tropica* Wright, 1903, and probably there are other varieties.

With regard to these species there is a general consensus of opinion that *L. tropica*, with its variety *americana*, is distinct from *L. donovani* and *L. infantum*. In respect to the two last-named forms it has been argued that they are identical because:—

I. Both attack adults and children.

II. A monkey immunized against *L. infantum* is refractory to *L. donovani*.

On the other hand, there are some differences, viz.:—

I. It is true that both attack adults and children, but the latter are much more easily infected by *L. infantum*.

II. *L. infantum* infects dogs readily, while these are more refractory to *L. donovani*.

III. *L. infantum*, according to one experiment by Nicolle and Manceaux, only produces a local cutaneous lesion when inoculated under the skin of a monkey, while *L. donovani*, under similar conditions, according to Row and Korke, produces a local cutaneous lesion, with or without a general infection, when inoculated into or under the skin.

For the present, we shall treat *L. donovani* and *L. infantum* as separate parasites.

The Sudan parasite is considered by Archibald to be distinct from *L. infantum* because:—

I. It behaves like *L. donovani* in that it does not readily infect dogs experimentally.

II. It behaves like *L. donovani* in that it produces a local cutaneous lesion, with or without a general infection, when inoculated into the skin of a monkey.

He further believes that it is a special variety of *L. donovani* because:—

I. It has signs of a coccal stage in its life-history. This has been objected to by Wenyon and Laveran, but has been confirmed by Smallman in two cases from Malta and by Statham and Butler in Sierra Leone.

II. Experimental evidence is not in favour of its being insect-borne. On the contrary, careful feeding experiments suggest that the method of infection is oral, while a study of the epidemiology and other facts make it probable that it is water-borne. The feeding experiments have been confirmed by Basile, though objected to by Laveran while the epidemiology supports facts noticed by Bousfield Thomson, and Marshall.

III. The local lesion produced by intracutaneous inoculations into monkeys does not exhibit any eosinophile leucocytes, which is different from the lesions produced by *L. tropica*, but it is not known whether this occurs or not in those due to *L. donovani* and *L. infantum*.

We therefore recognize it as *L. donovani varietas archibaldi*.

Leishmania donovani Laveran and Mesnil, 1903.

Definition.—*Leishmania*, producing in man the signs and symptoms of tropical kala-azar, in experimental monkeys general and local infections, but not readily infecting dogs.

History.—The history is fully given in Chapter XLVII., p. 1289, and it need only be remarked that the parasite discovered by Leishman in 1900 was described by himself and by Donovan in 1903; while Rogers, in 1904, cultivated the parasite at 22° C. and discovered the flagellate stage.

Christophers, in 1904, considerably added to our knowledge of these parasites, and Patton, in 1906 and 1907, showed that they were not merely found more commonly in the leucocytes of the peripheral blood than had been previously believed, but that they could develop into typical flagellates in the bed-bug, *Clinocoris rotundatus* Signoret, 1852 (which is the same as *C. macrocephalus* Fieb), but this is apparently more in the form of a natural culture than of a cyclic development.

Development in the Bug.—According to Patton, the parasites are ingested by the bug enclosed in the large cells or leucocytes, as just mentioned, and develop into fully flagellated forms without reference to the temperature of the external air.

The first change begins usually by an increase in size up to 4 to 7 μ and a vacuolation of the cytoplasm on the second day, but may be deferred for several days.

The single parasite may proceed directly to flagellation by the appearance of an area stained bright pink by Giemsa, and called 'the flagellar vacuole.' This vacuole, which has a dark centre, rapidly increases in size up to 1 to 3 μ, and, passing to the surface, sends out a small pink brush, which forms the flagellum by merely growing longer. There appears to be no doubt that the flagellum forms in this vacuole, and is not directly connected with the kinetonucleus.

The flagellate form has a dark blue, granular cytoplasm with a circular trophonucleus, which stains deeply in the centre, and a kinetonucleus lying

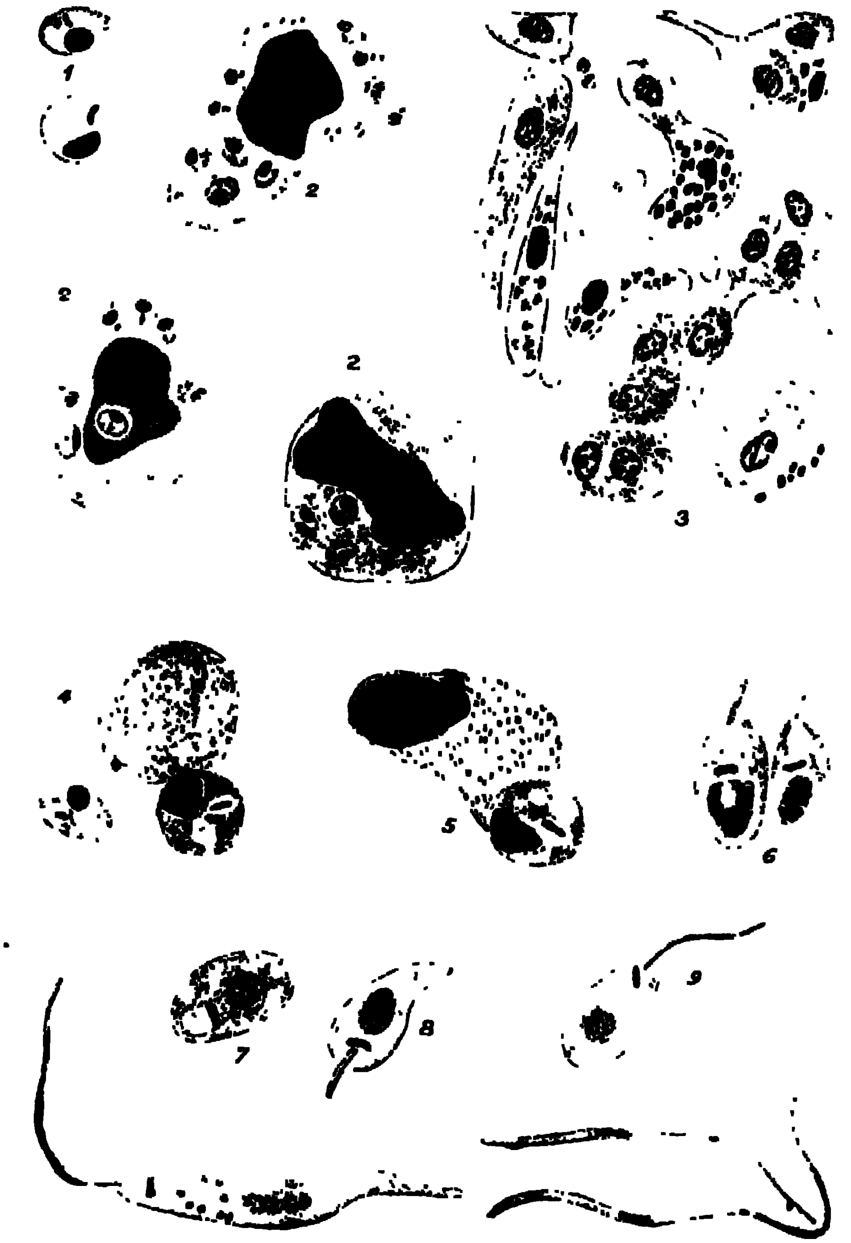

FIG. 86.—*Leishmania donovani* LAVERAN AND MESNIL

1, Free binucleate forms (after Christophers); 2, endothelial cell and leucocytes containing parasites (after Christophers); 3, capillary in the liver, showing endothelial cells containing parasites (after Christophers); 4, two parasites escaping from a leucocyte in the alimentary canal of the bug (after Patton); 5, further development in the bug (after Patton); 6, flagellate forms in the bug (after Patton); 7-11, culture forms (after Leishman); 7, 8, 9 show the development of the flagellum.

across the long diameter, and situated near the trophonucleus, and possessing a long flagellum consisting of a number of filaments adhering closely together, inserted into a pale area near the kinetonucleus. These parasites may divide into two equal or unequal flagellate forms, and apparently may go on so dividing for a length of time.

Instead of proceeding directly to flagellation, the parasite may show a division of its nuclei into two, with the formation of two flagella, and then division into two flagellate parasites, or the nuclei may multiply without division of the cytoplasm, so that forms containing four to eight nuclei may be found together, which eventually break up into separate flagellate forms. Patton has traced the development into the post-flagellate stage, and believes that if the bug is fed upon human or monkey's blood the flagellates are quickly destroyed, but if not so fed the cycle of development is completed in ten to twelve days after a single feed. He believes that this destruction of the flagellates by warm blood is the cause of the endemicity of the disease.

Donovan suggests that the true host may be *Conorhinus rubrofasciatus*, but Patton finds that the parasite in this bug degenerates and never flagellates.

Further, the evidence so far collected does not support the possibility of the bug, the flea, the mosquito, the phlebotomus, the domestic fly, the louse, or the tick as being the causal agent. It will be remembered that all these arthropods possess flagellates of their own, which the researches of Fantham and Porter, and Laveran and Franchini, have shown to be capable of producing disease and death in mammals when injected (*vide* p. 363).

As examples of flagellates occurring in bugs we may quote:-- *Herpetomonas lygæi* in *Lygæus militaris*, found in the Sudan and investigated by Archibald; *H. hospei* in *Lygæus hospes*; *H. aspongopi* Aders in *Aspongopus viduatus* (Sudan); *H. pyrrhocori* in *Pyrrhocoris aptera*; also Crithidia in *Cletus varius*, *Gerris fossorum*, *Conorhinus rubrofasciatus*, *Leptocoris trivittatus*; also a trypanosome in *Neotoma fuscipes*. It is therefore possible that the last word has not yet been said with regard to arthropods and their flagellates as the causal agent of kala-azar.

Archibald's experiments with the Sudan variety are very suggestive that the infection may be *per os*. The cycle may possibly be from man via the fæces to some water arthropod, from which it may escape also via the fæces into water, and so via the mouth into the alimentary tract and system of man, but this is not yet proved. With reference to this it should be remembered that Fantham and Porter infected young rats by feeding with *Nepea cinerea* containing *Herpetomonas jaculum*.

The present state of our knowledge with regard to this parasite is that it is the cause of the disease called kala-azar; and that it is probably spread by means of some arthropod, but the particular carrier is not known.

Geographical.—**The parasite is known to occur in India, Ceylon, China, Arabia, Egypt, and the Sudan, and many parts of Africa.**

Morphology.— **The parasite is round, oval, or pyriform in shape, measuring 2 to 3·5 μ in length by 1·5 to 2 μ in breadth, with a granular cytoplasm containing two chromatic masses. The larger, more rounded, stains slightly; the smaller, rod-shaped, stains deeply. From the latter a linear structure (Mesnil and Novy's rhizoplast) runs to the acute end. A vacuole is also often present.**

Distribution in the Body.—**The parasites are found sometimes in large numbers in endothelial cells in the capillaries of the liver, spleen, bone-marrow, lymphatic glands, and mucosa of the intestine, in the blood from the femoral, portal, and hepatic veins, and more rarely in the circulating blood shortly before death.**

Parasites liberated from the large cells are apparently taken up by mono-

nuclear, polynuclear, and rarely eosinophile leucocytes, and may be occasionally seen in films obtained from the finger even in early stages of the disease, though more frequently near the end.

Treutlein has stated that the parasite is to be also found in red blood cells, but probably they are merely lying in the concavity of the red corpuscle.

Life-History.—Multiplication in man takes place by simple binary fission and by multiple division into three or more bodies. Division begins at the broad end, but cytological details are still wanting, and the rest of the life-cycle is unknown.

Cultivation.—Cultures are obtained by adding the spleen-juice to a sterile sodium citrate solution and incubating at 22° C., as done by Rogers, or the N.N.N. medium may be used (p. 377).

Inoculation.—Monkeys, rats, and less readily dogs can be infected.

Pathogenicity.—*Leishmania donovani* is the cause of Indian kala-azar.

Archibald's Variety of **Leishmania donovani.**

Definition.—*Leishmania donovani*, which does not readily infect dogs experimentally, with signs of a coccal stage in its life-history. There is evidence that infection is by means of water. Habitat, Anglo-Egyptian Sudan.

Remarks.—This parasite has been investigated by Bousfield, who reported also a natural canine infection therewith (this, however, has not been confirmed by Archibald's many investigations), and also by Marshall, who infected monkeys and performed many careful experiments. Archibald's reasons for believing that this parasite is a variety of *L. donovani* are:—

1. *Coccal Bodies.*—Certain coccal bodies have been noted by Archibald in liver smears obtained from a case clinically simulating kala-azar. Material obtained by liver puncture from this case produced kala-azar when inoculated into a monkey, and Archibald suggests the hypothesis that these coccal bodies represent a stage in the life-history of the Leishman-Donovan parasite.

2. *Epidemiology.*—In the Sudan the evidence collected by Archibald does not suggest that the disease is insect-borne. This observer produced the disease in monkeys by carrying out careful feeding experiments, and suggests that the disease may be water-borne, a point which agrees with the observations of Bousfield, Thomson, and Marshall, that the disease exists more commonly in villages situate near water than in those farther away. A large number of domestic animals have been examined by Archibald, and none have been found to act as natural hosts of the virus; even experimental evidence shows that dogs are not readily susceptible to the virus—a fact which tends to differentiate the parasites of Sudan kala-azar from those of the Mediterranean.

Clinically the disease resembles that met with in other countries. As an aid to its diagnosis and as indication for splenic puncture being carried out, Archibald records the fact that peripheral blood films from suspected cases show evidence of blood destruction, leucopenia, and increase of large mononuclears and large lymphocytes, together with an absence of eosinophiles. The comparative or total absence of eosinophiles are suggestive of the disease; further, during the course of the disease an increase or diminution of the eosinophiles in the peripheral blood is some criterion as to whether recovery from kala-azar is likely to result.

Leishmania infantum Nicolle, 1908.

Synonym.—*Leishmania donovani* Laveran and Mesnil, 1903, *pro parte.*

History.—In 1904 Cathoire observed peculiar bodies in films from the spleen of a child who had died of an ill-defined malady in Goulette, in Tunisia. These bodies Laveran recognized as *L. donovani*. In 1905 Pianese announced his discovery of Leishmania bodies in large mononuclear cells in the smears from the liver and spleen of children dying from a type of infantile splenic anæmia, which he proposed to call infantile Leishmania anæmia in order to distinguish it from other forms of infantile splenic anæmia. In 1907 Nicolle and Cassuto observed the parasites in the spleen of a child in Tunisia suffering from irregular fever, splenomegaly, etc., and Nicolle named this disease infantile kala-azar, which is a most suitable name. After this it was described in Crete in 1907 by Aichel: in Sicily, Stromboli, and Calabria by Gabbi and Feletti; in 1910 it was found in Malta by Critien, in Lisbon by Alvares, while Gabbi proved that the disease 'ponos,' as seen in Spezzia, was the same disease; and Christomanos, Aravandinos, and Michaelides found it in the Grecian islands and Greece itself. In 1911 Christomonas found it in several places in Greece and Asia Minor, while Batinos found it in Corfu, Kefalinos in Patras, and it was found to be widely distributed in Southern Italy and Sicily. Martzinowsky has observed cases in Moscow, Tashim Ibrahim in Tripoli, Lemaire in Algiers, and Sluka and Zarfl in Tashkent in Turkestan. Marshall reports the disease among children of about twelve years of age in the Sennar province of the Sudan.

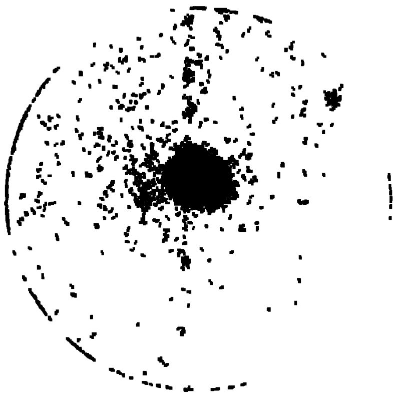

FIG. 87.—*Leishmania infantum* NICOLLE FROM THE LIVER OF A DOG EXPERIMENTALLY INFECTED.
(From a microphotograph by Basile.)

It is thus seen that *L. infantum* is mainly found around the Mediterranean basin, but may extend to Moscow and to Turkestan; probably its geographical distribution is but little known at present.

The study of the life-history began by the experiments of Nicolle, who in 1908 successfully inoculated a dog in Tunis intrahepatically and intraperitoneally with splenic blood from a case of infantile kala-azar, monkeys were also inoculated successfully.

Later, Manceaux, Comte, Laveran, Pettit, Jemma, Di Cristina, Cannata, Alvares, da Silva, Pulvirenti, and Tomaselli, successfully inoculated dogs, monkeys, and guinea pigs, and Volpino produced a purely local lesion somewhat analogous to Oriental sore by inoculating the cornea of a rabbit from an infected dog.

In 1908 Nicolle and Comte recorded the discovery of spontaneous kala-azar in dogs in Tunis, and eventually found 1·8 per cent. to be infected in the spring, but this percentage was raised by the Sergents to 7·2 per cent. in the summer in Algiers, and Sevenet has found that in Algiers 1·6 per cent. show infection in the spring and 8·8 per cent. in the summer. Basile, in an endemic region, Bordonaro, near Messina, found twenty-seven infected dogs out of thirty-three examined by trephining the head of the femur and making smears of the bone-marrow, and he obtained also a very important fact when he found infected dogs in *every* house where kala-azar had been found by Gabbi; and still more interesting is the observation that infected dogs were found in houses without cases of kala-azar, but subsequently a case has already occurred in one of these houses. Canine kala-azar has also been found in Catania, slightly in Rome, in 0·69 per cent. of dogs in Greece by Cardamatis, in 2·66 per cent. in Lisbon, also in Malta by Critien and Babington, and in a few dogs in Colombo by Castellani in 1911. It must be noted, however, that Colombo, being one of the greatest harbours of the world, some of the dogs found are in reality imported dogs. Negative results are reported by Donovan in Madras in 1,150 dogs, by Fülleborn in Hamburg in 50 dogs, by Wenyon in Bagdad in 110 dogs, by Jemma, Cristina, and Cannata in Palermo in 127 dogs, and by Archibald in the Sudan. For a long time cats were examined with negative results, but recently Ed. and Et. Sergent, Lombard, and Quillchini, have found a four-month-old kitten to be infected in Algeria. It will thus be seen that of all the endemic centres of infantile kala-azar, Palermo alone affords no evidence of natural canine kala-azar.

As the result of his work Basile, supporting Nicolle, has come to the conclusion that infantile and canine kala-azar are one and the same disease. He reared a number of dogs in the laboratory in Rome (where canine kala-azar is rare), and some of these he took to Bordonaro, where they contracted canine kala-azar and died. The parasites were found in the bone-marrow, spleen, and liver (Fig. 87), and also in *Pulex serraticeps*, taken from them during the last stages of the disease. The dogs in Rome were subsequently killed, and found to be free from *L. infantum*. *P. serraticeps* from a laboratory dog whose bone-marrow contained no Leishmania were isolated and kept at 22° C. in two glass vessels, and eventually one lot was fed on spleen-juice from a case of canine kala-azar, while the others were kept as controls. After a time the intestines of the fleas were dissected out and divided into two portions one was used for smears, and the other was made into an emulsion and injected subcutaneously into a young dog one month old, the bone-marrow of which had been shown to be free from Leishmania, while another dog was used as a control.

The smears from the infected fleas showed numerous specimens of Leishmania in a state of multiplication, while the control fleas were free. After fifteen days the dog became ill with fever and loss of appetite and dejection, and showed the parasites in the peripheral blood. In twenty-nine days the dog died, probably as a result of an operation to obtain bone marrow from the tibia. Natural infection by flea-bites was effected by introducing a sick dog covered with fleas into a cage containing a bitch and two thirty-day-old puppies, whose bone-marrow had been found free from infection. In thirty days these dogs were found to be infected, and subsequently the puppies died, but the other dogs lived, Controls were not infected. Basile found *P. serraticeps* in the bedclothes and mattresses of families who kept dogs in the house, and some of these fleas were brought to Rome from dogs or mattresses of people living in Bordonaro, and were fed upon laboratory-reared marrow-examined, clean dogs, whose peripheral blood and liver had also been examined for parasites with negative result. The dogs became ill and died, and the parasites were found in the bone-marrow, liver, and spleen. Control dogs were then killed and found healthy.

Basile concludes that *P. serraticeps* is the carrier of the disease. In Bordonaro he examined 1,000 fleas from dogs and the beds of families, but found only four infected with Leishmania. With regard to *P. irritans*, Basile finds that it is frequently a parasite of the dog, and that among specimens caught in the bed of a child suffering from kala-azar one was found to contain Leishmania. From experiments he believes that fleas are infective from December to March. There is one curious point noted, that Leishmania was found in spleen, liver, and bone marrow only a few days before death, though the fleas had bitten the dogs three months earlier.

With regard to the objections to this work, Gabbi has pointed out—

1. Canine and human fleas placed in contact with pure cultures of Leishmania on Nicolle's blood-agar show blood in the gut, but no Leishmania.
2. Leishmania in culture with intestinal bacteria from the flea or in culture with the juice from the same do not develop.
3. Starving fleas placed in contact with spleen-juice obtained by puncture from a child with kala-azar do not become infected with Leishmania.

Mazocchi in Piedmont finds that the fleas of dogs possess flagellate bodies of a crithidia-like nature, distinct from Basile's description of the Leishmania bodies found by him.

Alvares and Pereira da Silva's experiments with *Ctenocephalus serraticeps* support Basile, and they believe the infection to be contaminative via the fæces.

The main objection to Basile's experiments is that they were conducted in Rome, in which place dogs may acquire natural canine kala-azar; secondly, the question has to be solved as to whether the bodies seen in the flea are or are not Leishmania, and if not, whether they are some parasite naturally occurring in the flea.

Basile describes the forms found in the flea as follows:—

In the mid-gut Leishmania-like forms as oval, rounded, or pyriform bodies, 2 to 3 μ in length, with an excentrically-placed trophonucleus, and generally a kinetonucleus. Large forms, 4 to 6 μ by 2 to 3·5 μ, are also seen, and more posteriorly pyriform bodies, 6 to 8 μ by 1·5 to 2·5 μ, which latter are provided with flagella measuring about 3 μ in length.'

Basile concludes that there is a cycle of development with preflagellate, flagellate, and post-flagellate forms. But a number of fleas have been found to possess natural parasites belonging to the genera *Herpetomonas* and *Crithidia*, and Miss Porter has definitely proved that *Crithidia pulicis* is a true parasite of *P. irritans*. The list of known flea parasites is:—

Crithidia pulicis Wenyon, 1908, in *Xenopsylla cleopatræ*.
Crithidia ctenophthalmi Patton and Strickland, 1908, in *Ptenophthalmus ægyrtes*.
Crithidia hystrichopsyllæ Mackinnon, 1909, in *Hystrichopsylla talpæ*.
Crithidia pulicis Porter, 1911, in *Pulex irritans*.
Herpetomonas ctenophthalmi Mackinnon, 1909, in *Ptenophthalmus ægyrtes*.

There are also a number of unnamed flagellates recorded—*e.g.*, a species of *Herpetomonas* by Balfour in 1906 in *Læmopsylla cleopatræ*, which may be the same as Wenyon's *Crithidia*. It does not appear certain that Miss Porter's *Crithidia* and Wenyon's *Crithidia* are the same, and if they are not, then Miss Porter's *Crithidia* must be given a different name.

The identity of infantile kala-azar and canine kala-azar is supported also by Bandi's experiments on agglutination. Animals inoculated by him with cultures of *L. infantum* developed agglutinins for this species, and nearly in the same amount also for the Leishmania isolated from dogs, and *vice versâ*.

Franchini states that *Anopheles maculipennis* can be infected with cultural forms of Leishmania. Gabbi inculpated at one time *Musca domestica* as a carrier.

Morphology.—*L. infantum* so closely resembles *L. donovani* as to be indistinguishable morphologically.

Life-History.—It exists in the peripheral blood, bone-marrow, spleen, and liver in children, and suspicion is aroused that it may be spread by fleas, and that aflagellate and flagellate organisms seen in these parasites may be stages in the life-cycle.

Culture.—It is easily cultivated upon the Nicolle, Novy, MacNeal (or N.N.N.) medium, as was first shown by Nicolle. The organisms develop in the condensation liquid and on the moist surface of the agar. It can be subcultured indefinitely. No distinct differences can be discerned between the three species of Leishmania in culture. *L. infantum* can to a certain extent be distinguished from *L. donovani* by the fact that the latter is less easily inoculable with success into dogs.

Pathogenicity.—It is the cause of infantile kala-azar, and at one time was considered to be the cause of canine kala-azar, which we will now describe.

Canine Kala-Azar.—There are two types of canine kala-azar—an acute and a chronic.

Acute canine kala-azar, usually appears in young dogs, when it is associated with fever (39° to 40° C.) of a remittent type, followed by loss of appetite, wasting, tremors, motor disturbance in the hind-limbs, and rarely diarrhœa. The animal finally dies in a comatose condition at the end of three to five months.

Chronic canine kala-azar begins without any apparent symptoms, except, perhaps, loss in weight, but as it progresses anæmia sets in, and tremors, together with motor disturbances of the hind-limbs, may be noticed. It is therefore milder than the preceding, is very chronic, and associated with considerable enlargement of the spleen. The inoculated dogs have several times been reported to exhibit symptoms resembling dumb rabies. Post mortem examination exhibits that the spleen has a thickened capsule, with hypertrophy of the lymphoid elements; the epithelium of the blood-lacunæ are much hypertrophied, and full of parasites. The liver cells show fatty degeneration; parasites are found in the liver cells and in the endothelium of the lymphatics. The interstitial tissue of the kidney is increased, and parasites occur in the endothelial cells. Parasites may be found in the round-celled infiltration under the capsule of the kidney. The suprarenal bodies show cloudy swelling of the cortical cells, infarcts in the medulla, and vacuolation of the cells, which may be invaded in patches by the parasites. The pancreas showed a hypertrophy of the connective tissue, with the presence of the parasites in the endothelium of the lymphatics. The bone-marrow showed large numbers of mononuclear cells with parasites. The heart muscle showed cloudy swelling. No parasites are found in the lungs.

There is a growing suspicion that this is quite distinct from any human disease, because-

1. Canine Leishmaniasis exists in places like Marseilles, where there is no Mediterranean kala azar, and this disease exists in Palermo, where Canine Leishmaniasis, according to Caronia and di Giorgio, is absent.
2. Spagnolio says that in Bordonaro, in 1910, Basile found Canine Leishmaniasis in 70 per cent. of dogs examined. From 1910 onwards a number of dogs were destroyed, and in 1914 a very large number were killed because of threatened rabies. In 1915 some seventeen dogs were examined for Leishmania and found negative, and yet the human endemic disease had not diminished.

It is known to occur in Africa, Europe, and Asia, but not in America or Oceania.

The formation of a local sore on the cornea of a rabbit must be remembered as indicating the possibility of a local disease like that caused by *L. tropica*.

Leishmania tropica Wright, 1903.

Synonyms.- -*Helcosoma tropicum* Wright, 1903; *Crithidia cunninghami* Carter, 1909; *Sporozoön furunculosum* Firth, 1891.

History.- This parasite was described by Wright in a case of Oriental sore, and later Martinowski and Bognoff found the same parasites in Bouton d'Alep. It is believed by some that this parasite was first described by Cunningham in 1885, and more completely studied by Firth, who called it *Sporozoön furunculosum* Firth, 1891; if this is so, the correct name of the parasite should be *L. furunculosa* Firth, 1891.

It was specially investigated in 1905 by James in Delhi sore, Lahore sore, and Frontier sore. Nicolle has obtained cultures of the parasite on the McNeal Novy medium, and Carter describes sexual forms. Carter, Balfour, and Nattan-Larrier believe, in our opinion correctly, that there are several varieties or species included under the term *L. tropica*; thus Carter maintains that the Cambay sore is different from the 'clou de Gafsa' of Africa. Werner, Carini, and Splendore have shown that the sore may spread to or begin on mucous membranes.

Distribution.- It is found principally in Asia, in India, China, Asia Minor, Persia, etc., but also occurs in Africa, Algeria, Tunisia, on the Niger and in the Egyptian Sudan, in Mexico, Panama, and South America.

Morphology.- It differs in no morphological respect from *Leishmania donovani* in the human body, though certain minor differences have been described in the flagellate forms in cultures.

Cultivation.- In 1908 Nicolle first cultivated the parasite on blood-agar and on the modified Nicolle, Novy, McNeal medium often called 'N.N.N.' It grew slowly both in the liquor of condensation and on the agar at 20° to 22° C., producing flagellate and division forms on the fourth day, which increased in numbers by the eighth to tenth day, when rosettes appeared and increased in such numbers that the masses were visible to the naked eye. After this a tendency to agglutination develops and increases until after one or two months the parasites die. The typical flagellate of these cultures is herpetomad-like, measuring with the flagellum 40 to 45 μ with a breadth of 2 to 4 μ, but the flagellum alone measures 16 to 20 μ. There is no undulating membrane, but a trophonucleus and kinetonucleus can be seen. Three types of flagellates can be seen in cultures—viz., one almost spherical, a second short and stumpy, and a third long and narrow. Subcultures are best made from the tenth to the fifteenth day, and these can be repeated apparently indefinitely. Forty-five generations have been recorded during a period of eighteen months.

It is usual to state that there are no differences between the cultural forms of *L. tropica* and *L. donovani*, but Row considers that there are several points of difference—viz., that the flagellate forms of *L. tropica* are longer and larger, that the flagellum is longer, while the growth is quicker and may take place at higher temperatures than in *L. donovani*.

Inoculation.—Martzinowsky, Wenyon, and Patton have successfully inoculated themselves, and other people have also been successfully inoculated from cases of Oriental sore. The incubation period varies from sixteen days to six and a half months, and the papule is generally ushered in with febrile symptoms lasting several days. The inoculated sore begins as a papule, and becomes a nodule; when excised and examined it presents the typical appearances of Oriental sore, and contains *L. tropica*.

Successful inoculations are recorded from man to monkeys and dogs, from monkeys to man, other monkeys and dogs, from dogs to dogs, and from cultures to man, monkeys, and dogs.

Immunity.—Infection confers immunity if the cure is complete, and if a sufficient interval has elapsed between the cure and the reinfection; if not, a condition of hypersensibility is produced, as demonstrated by a shortened incubation period. Kala-azar infection in dogs affords immunity against *L. tropica* during and after the attack; Oriental sore protects monkeys partially or completely against *L. donovani*.

Insect Carriers.—No insect at present has been demonstrated to be the true host of *L. tropica*. *Musca domestica* may possibly be a carrier because the parasites can retain their vitality therein, and may be transferred to any raw surface, and thus induce infection, but it is not a true host, though Row has found the contents of the gut to be infective, and believes that infection can be spread by its fæces. There can be no doubt that a natural culture producing flagellates and, according to Patton, even post-flagellate forms, can take place in the bed-bug *Clinocoris rotundatus*, but all attempts at transmission have failed, and the same condition of affairs holds good for *Stegomyia fasciata*. Phlebotomus is suspected, but there is no experimental evidence. Flu suspects ticks as being the possible carriers in Dutch Guiana. Pediculi have no supporters, and *Stomoxys* is not regarded as a likely carrier. As Patton has recorded the presence of *L. tropica* in the peripheral blood, it might not be necessary for a blood-sucker to ingest juices from the local sore.

Pathogenicity.—It is the cause of specific sores found in the skin and on mucous membranes in Asia, Africa, and America, and which are commonly known as Oriental sore, but which also have a large number of local names, such as pian-bois, espundia, Delhi sore, Bagdad button, clou de Gafsa, ulcer of Bauru, etc.

Laveran and Nattan-Larrier have created the variety *americana* (*L. tropica* Wright var. *americana* Laveran and Nattan-Larrier) for the Leishmania found in *Espundia*, characterized by a flattened nucleus. Vianna has created a new species, *L. braziliensis*, for a Leishmania observed by him in cases of ulcer, but Marchoux doubts whether this new species is justifiable, as it has no distinctive characters.

SUBFAMILY TRYPANOSOMINÆ CASTELLANI AND CHALMERS, 1919.

Definition.—Trypanosomidæ in which the kinetonucleus is situate in certain stages of the life-cycle between the trophonucleus and the aflagellar extremity of the body. A well-developed undulating membrane is present.

Type Genus.—*Trypanosoma* Gruby, 1843, *emendavit* Laveran and Mesnil, 1901.

Classification.—A brief history of the discovery of the more important species of this family has been given in Chapter I. The genera which have been described are:

Trypanosoma Gruby, 1843, *emendavit* Laveran and Mesnil, 1901.
Trypanoplasma Laveran and Mesnil, 1901, *emendavit* 1904.
Trypanophis Keysselitz, 1904.
Endotrypanum Mesnil and Brimont, 1908.
Schizotrypanum Chagas, 1909.
Rhynchoidomonas Patton, 1912.

But Trypanoplasma and Trypanophis belong to the Bodonidæ, and not to the Trypanosomidæ (*vide* p. 337).

Endotrypanum would appear to be an immature trypanosome, without an undulating membrane, and parasitic in red corpuscles. In 1905 Nissle drew attention to the occasional invasion of red cells by trypanosomes, and in 1904 Moore found peg-shaped bodies in the red blood-corpuscles of cattle suffering from trypanosomiasis in Southern Nigeria.

With regard to Schizotrypanum, it was at first classified as a trypanosome, but when its peculiar schizogony became known, it was thought necessary to separate it therefrom under a separate generic name, and to this we now adhere.

The subfamily therefore contains the genus Trypanosoma, of which we shall presently suggest a classification (*vide* p. 395), and the genera Endotrypanum, Schizotrypanum, and Rhynchoidomonas.

Trypanosoma Gruby, 1843.

Synonyms.—*Amœba* Mayer, 1843; *Paramœcium* Mayer, 1843; *Globularia* Wedl, 1850; *Undulina* Lankester, 1871; *Herpetomonas* Kent, 1878; *Hæmatomonas* Mitrophan, 1883; *Trypanosomonas* Danilewsky, 1885; *Trypanozoön* Luehe, 1906.

Definition.—Trypanosominæ, with the periplast raised into a longitudinal undulating membrane, along which the single flagellum runs.

Historical. The history of the genus has been largely detailed in Chapter I., and we need only remind the reader it commenced by Valentin, in 1841, reporting minute bodies in the blood of *Salmofario* Linnæus, the brown trout, which induced Gluge to bring forward his discovery of *Trypanosoma sanguinis* in frog's blood, while Gros, in 1845, found them in mice and moles. Later, in 1850, Wedl found the same parasites in the blood of birds and mammals, while Chaussat in the same year and Lewis in 1879 found them in rats, and Danilewsky studied their structure and started interest in them.

Morphology.—The usual form in which trypanosomes are found in vertebrate blood is that of an elongated, spindle-shaped mass of cytoplasm composed of an inner granular endoplasm, and surrounded by ectoplasm (periplast). The shape of the parasite is, however, by no means always a spindle, but, on the contrary, varies considerably in different species, and may even be rounded.

In the endoplasm is situated a trophonucleus, often called the 'nucleus,' concerning the structure of which there is considerable difference of opinion. Some authorities—*e.g.*, Prowazek, etc.—with regard to the nucleus of *T. lewisi* and *T. brucei*, and Miss Robertson, with regard to *T. raiæ*, say that the nucleus is complex and resembles the description already given for that of *Hæmoproteus noctuæ*, that of *T. lewisi* having eight chromosomes and a centrosome connected by a strand.

Other authorities, like Ross and Moore, Breinl and Hindle, consider that observers have been led astray by using dried films; for, according to them, though pretty pictures of the parasite are produced by this method, still, such delicate structures as the details of the nucleus are ruined; and therefore, in order to study these bodies accurately, the films must be fixed while wet in such a reagent as Fleming's fluid, and suitably stained. If this is done properly, according to them, it is seen that the nucleus is a vesicle bounded by a nuclear membrane, and having in its centre one small chromatin sphere, called by some the intranuclear centrosome.

Situated somewhere in the cytoplasm, and generally near the aflagellar extremity, is another mass of chromatin, the kinetonucleus. From this kinetonucleus a faint strand—the rhizoplast—proceeds, which ends in a little bead—the blepharoplast—from which the flagellum, which is also composed of chromatin, arises. A more primitive arrangement is for the kinetonucleus to contain the blepharoplast, which is really only a centrosome. Under these circumstances the flagellum will arise from the kinetonucleus. When the blepharoplast is separate from the kinetonucleus it is a moot point as to whether there is or there is not another centrosome in that nucleus.

The flagellum runs outwards through the endoplasm to the ectoplasm, which it raises into a membrane, the undulating membrane, and turns, and runs along the remaining length of the cytoplasm, in which it may end, or it may project as a free lash beyond the cytoplasm. In this course it presents three portions: (1) The root in the endoplasm; (2) the undulating portion in the ectoplasm, and (3) the free portion. In some stages of the life-history the flagellum, instead of turning along the undulating membrane, projects from its blepharoplast through the endo and ecto-plasm to the outside of the parasite.

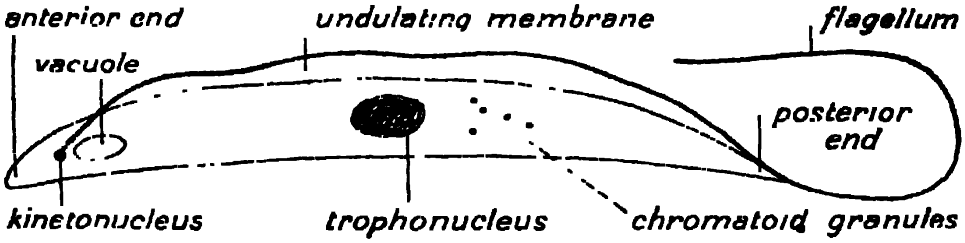

FIG. 88. - DIAGRAM SHOWING THE STRUCTURE AND POLARITY OF A TRYPANOSOME.

The undulating membrane, therefore, is the layer of ectoplasm (periplast) raised from the surface of the parasite by the second portion of the flagellum along a line sometimes called dorsal, and may be prolonged a certain distance along what is generally considered to be its free portion. The membrane is variously described as being homogeneous or strengthened by myonemes as in *Hæmoproteus noctuæ*.

Besides these structures the endoplasm often contains a vacuole, looked upon by some observers as a contractile vacuole, while others deny its existence. There is no doubt about its existence in *Trypanosoma castellanii*. Chromatoid granules can also be seen in the cytoplasm.

Before leaving this part of the subject it must be noted that many authors have given various names to the trophonucleus, kinetonucleus, centrosome, and blepharoplast. We use the terms in the same sense in which they have been used by Minchin and Woodcock—viz., the principal nucleus is a trophonucleus, because it is believed to be largely concerned in nutrition; it contains an achromatic body, which is the centrosome. The smaller nucleus is a kinetonucleus, because it is mainly concerned in motion; while the little bead connected with the flagellum is looked upon as a blepharoplast, because it is an achromatic body connected with a cilium or a flagellum.

We now come to a point on which there is a great difference of opinion—viz., the polarity of the parasite. There can be no doubt, in our opinion, that, as a rule, the anterior end of a parasite should be the non-flagellate end, as first suggested by Sambon, because, in wending its way through the blood, that end goes first, and the undulating membrane and flagellum follow, and blood being the natural habitat of the parasite, this method of propulsion must be considered to be normal. Moreover, morphologists (Woodcock) support this view. There is, however, no doubt that, at times, the flagellate end can be in front.

Movement is largely caused by the undulating membrane, while the flagellum assists; but creeping or gregarinoid movements have been noted by Léger, and zigzag movements by Gray and Tulloch, and in both of these the non-flagellate ends go first. In this work anterior, therefore, means the non-flagellate end of the trypanosome and posterior the flagellate end.

The anterior end is very variable, and may be even amœboid, while the posterior end is generally tapering, because the cytoplasm extends some way along the flagellum.

It has already been noted that the body of the parasite is slightly compressed laterally, and the edge with the undulating membrane is considered to be dorsal. In some species a supporting structure somewhat of the nature of an axostyle has been described.

The measurements of the parasite are from the non-flagellate extremity to the kinetonucleus, from that to the anterior end of the trophonucleus, from that to the posterior end of the trophonucleus, from that to the tip of the flagellum, the sum of these giving the length; while the width is taken in the region of the trophonucleus.

Stephens' method of measurement is, after outlining the parasite, to draw a straight line on a piece of transparent paper, and to mark one end, which is made to coincide with one extremity of the outlined trypanosome and then transfixed by a vertical needle. The transparent paper is now rotated so that the line runs in the long axis of the parasite. Where it deviates another pin is inserted and the first removed. The transparent paper is again rotated to take in another portion of the axis of the parasite, and this is repeated until all the deviations of the parasite have been followed and the distal extremity reached.

The results of careful measurements have been to show that some trypanosomes are polymorphic and others are not.

Food is absorbed by osmosis from the liquid in which the parasite is living.

Life-History.—The life-history of a trypanosome is not as yet fully known, but it is recognized that it has an alternation of generations associated with an alteration of hosts, one generation being usually completed in the blood of a vertebrate, and the other in the alimentary canal and its appendages of some blood-sucking invertebrate.

In the Vertebrate.—If an uninfected or clean non-immune is infected by the bites of infective invertebrates, at first no parasites are to be found in the peripheral blood, and some days must elapse before they appear. This interval is *the incubation period.* What takes place during this period is but little known, the only observations being those by Fantham, who saw a few rounded forms fifteen to eighteen hours after inoculating *T. castellanii* and *T. rhodesiense* into rats; and those by França, who reports the presence of similar forms at a later stage of incubation. These are probably multiplication forms, which are the parent forms of the trypanosomes presently to be seen in increasing numbers in the blood.

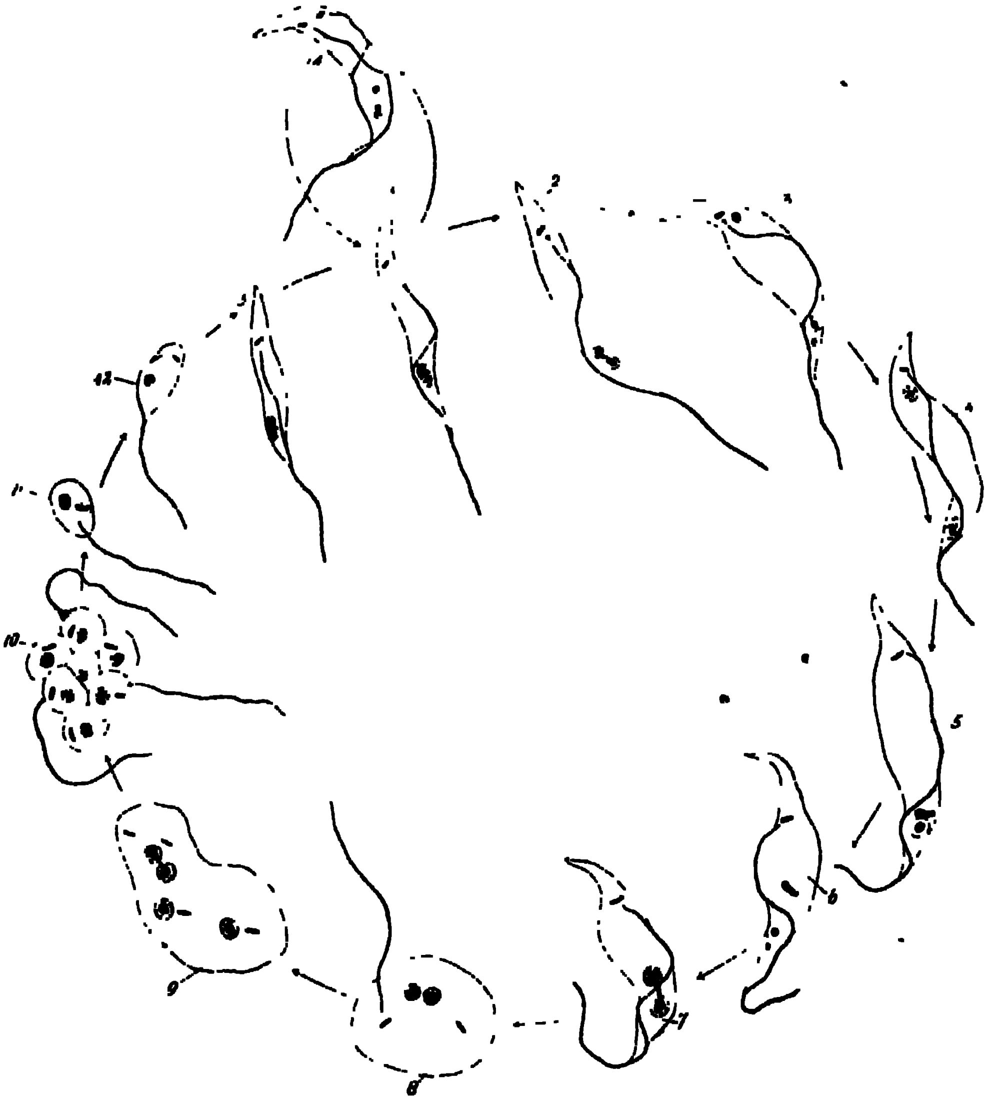

FIG. 69.—DIAGRAM OF THE LIFE-CYCLE OF *Trypanosoma lewisi* SAVILLE KENT, 1880, IN THE BODY OF THE RAT.

1, Trypanosoma lewisi; 2-10, stages in rosette formation; 11-13, development of a small flagellate form into a trypanosome; 14, binary fission.

(Constructed from drawings by Moore, Breinl, and Hindle in the *Annals of Tropical Medicine and Parasitology*.)

When the parasites are present in the peripheral blood, they usually show a marked pleomorphism. Thus, in *T. castellanii* Miss Robertson finds short forms 14 to 20 μ in length, medium forms 20 to 24 μ in length, and long forms 23 to 33 μ in length. Until recently it was usual to consider these variations as being probably indicative of sexual differentiation, but she concludes that this is not so, but that they are variations due to different stages of growth and subsequent division. The multiplication of the trypanosome in the blood is usually by longitudinal fission, but it may also take place by schizogony, with or without entering an endothelial or other cell. The number of trypanosomes in the blood varies considerably from time to time, apparently in more or less regular cycles, and their disappearance appears to be associated with the encystment in the lungs, spleen, bone-marrow, etc., in the form of the latent bodies described by Breinl, Fantham, and others. During their life in the vertebrate it was, at one time, thought that they could propagate their species—in part, at all events—by granules, which are comparable to the 'infective granule' described by Balfour for spirochaetes, because Fry demonstrated that *T. brucei* could throw off granules, and his observations had been confirmed by Ranken. This granule-shedding was described as taking place in the liver, spleen, lungs, and lymphatic glands. At first the granule was simply a free pyriform body, but later it developed a flagellum and became actively motile. Its further history was, however, untraced in trypanosomes

There can be no doubt that there is a reaction on the part of the cells of the vertebrate against the trypanosomes with the formation of antibodies in the form of trypanolysins, etc., but more will be said on this subject later.

Binary Fission. A binary fission takes place with or without growth. This is brought about by amitotic division of the kinetonucleus and trophonucleus, followed by the formation of a new flagellum in the daughter parasite and the division of the cytoplasm.

The details of the division are as follows:—

1. The kinetonucleus swells up and forms a vesicle through which the chromatin is evenly distributed.
2. The chromatin forms a band across the middle of the vesicle.
3. The band elongates and divides into two portions.
4. The two portions move apart, all trace of the vesicle disappears, and the two new kinetonuclei are formed.
5. The blepharoplast divides at the same time as the kinetonucleus.
6. Either the old flagellum divides or a new flagellum develops from one of the new blepharoplasts. The process varies in different species.
7. The central karyosome of the trophonucleus either divides and the two portions move to opposite poles of the nucleus, but are connected by a fine line, or the chromatin forms an equatorial plate,

which divides transversely, and each half goes to an opposite pole, or the chromatin gathers around opposite poles.

8. The connecting line disappears and two new trophonuclei are formed.

Rosette Formation.—The medium-sized parasite, according to Moore, Breinl, and Hindle, grows into large forms, which pass through the following development:—

1. The trophonucleus undergoes reduction by amitosis, the reduction body disappearing.

2. The kinetonucleus gives off a body, which travels—increasing in size as it proceeds—to the trophonucleus, with which it perhaps fuses, but this is not definitely known.

In *T. castellanii* a strand forms between the kineto- and trophonuclei, instead of this travelling body, which is seen in *T. lewisi* and *T. equiperdum*.

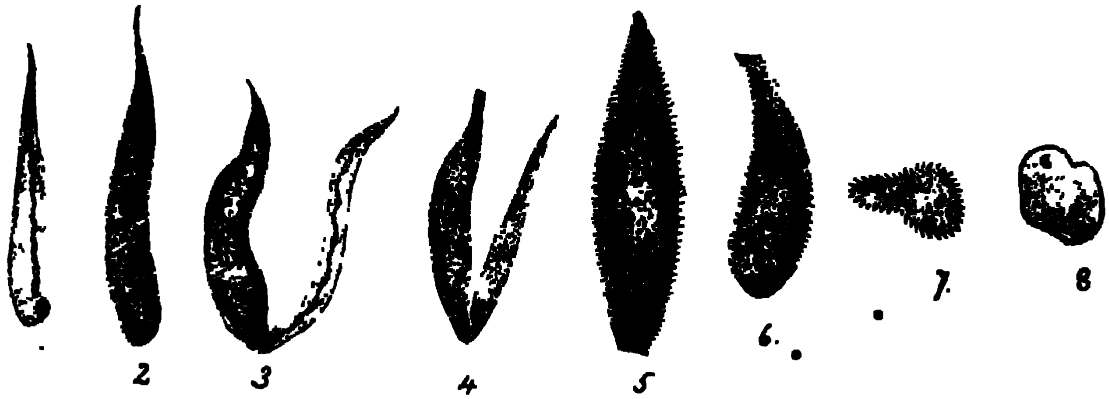

FIG. 90.—*Crithidia melophagia* FLU.

(After Flu.)

1, Microgamete; 2, macrogamete; 3, zygosis; 4, oökinete and degenerating microgamete; 5-8, oökinete in the alimentary canal and ovary.

3. The tropho- and kineto-nuclei divide to form fusion masses consisting of two, four, seven, or more small parasites, which at first possess only the old flagellum, but in which later new flagella form (the rosette formation). This stage is not definitely known in *T. castellanii*.

4. The small parasites, which must be looked upon as representing latent phases, separate from the fusion mass. These small parasites grow into medium-sized parasites, thus completing the cycle.

All observers are agreed as to the rosette formation, and with regard to the process from the kinetonucleus, this was first pointed out by Miss Robertson, whose work is therefore confirmed. The band is said to be composed of volutine. As to the latent phases, we believe that they are the same as the peculiar aflagellate round and oval forms described several years ago by Castellani, in the cerebro-spinal fluid of sleeping-sickness patients, and which he compared to the amœboid forms found by Plimmer in the brains of animals infected with nagana.

The development of Schizotrypanum differs in many points from this description, for the trypanosome enters an endothelial cell in the lung, or a cardiac muscle fibre, or a neuroglia cell of the central nervous system, or a striped muscular fibre. In these situations it becomes simply a rounded body, which possesses trophonucleus and kinetonucleus, but has lost its flagellum and undulating membrane. This body undergoes repeated divisions, and each division eventuaally becomes a trypanosome.

In the Invertebrate Host.—Theoretically, it would be expected that sexual forms, male and female, would be found in the blood of the vertebrate, and that these, taken into the alimentary canal of the blood-sucker, would conjugate and produce oökinetes, and perhaps oöcysts, from which forms would be produced which might infect the proboscis of the same individual, or, by entering into the eggs, infect a new generation, which alone might be the means of dissemination of the parasite. But these theoretical views have so far not been confirmed by actual observations, which must now be discussed seriatim.

So-called Sexual Forms.—According to Prowazek, *T. lewisi* can be differentiated into three forms—(1) male, (2) female, (3) indifferent; and, according to Prowazek, Lühe, Nocht, and Mayer, the same can be seen in *T. castellanii*; but according to Holmes, only males, females, and young females can be seen in *T. evansi*.

Male Forms.—These are defined to be very slender trypanosomes, actively motile, with an elongated nucleus, which stains well.

Female Forms.—Broad, sluggish trypanosomes, with reticulated protoplasm and a round nucleus, both of which stain poorly. They possess a slender, undulating membrane and a short flagellum.

Indifferent Forms.—These are the forms most commonly met with, possessing granular cytoplasm and a not very well-defined nucleus.

It must be admitted that between these there are all stages of intermediary forms, so that they are not sharply defined; and some of these may be simply the ordinary trypanosome in various stages of growth and division, as described above.

Miss Robertson has probably arrived at the truth when she says that the short forms (13-20 microns) of *T. castellanii*, the so-called female forms, are really the adults, which by growth become the indifferent forms which are merely steps in the formation of the slender forms, so-called male forms, which are the dividing stage of this trypanosome.

Chagas has shown that *Schizotrypanum cruzi* in the lungs may lose its flagellum and become curved into an arc, the extremities of which fuse, forming at first a ring, which subsequently becomes a sphere, with a trophonucleus and a kinetonucleus, the latter of which is expelled in female forms, while it is retained in male forms. In this manner the macrogametocytes and the microgametocytes arise. Each of these divides into eight macrogametes, which are uninuclear, and eight microgametes, which have a trophonucleus and kinetonucleus united by a filament. These gametes escape from the cyst which is formed by the periplast of the original trypanosome, and enter red blood-cells, in which they develop into sexually differentiated trypanosomes—*i.e.*, females with one and males with two nuclei. These are the forms which infect the *Lamus*, or invertebrate host, and do not multiply in the vertebrate host.

Method of Transmission.—The blood of the infected vertebrate is not always infective for the invertebrate host. Thus Miss Robertson has shown, with regard to *T. castellanii*, that the tsetse-fly cannot be infected by feeding just before an outburst of multiplication in the vertebrate host, or during the period of destruction which precedes a paucity period or at the summit of an exalted period, or during certain periods of rapid multiplication, when the absolute and relative numbers of the short forms mentioned above are diminished.

Immediately after infection the invertebrate host can *mechanically* convey the infection to a *clean* host, and this power persists for about twenty-four hours, after which the invertebrate host becomes non-infective and remains so for a varying period, which was found by Kleine not to be less than eighteen days as regards *Glossina palpalis* and *T. castellanii*, and by Kinghorn and Yorke to be about fourteen days in *G. morsitans* infected with *T. rhodesiense*, after which the flies become again infective, and apparently remain so for a very long period, probably for the rest of their lives. These facts prove definitely that the parasites undergo some changes of an important nature in the flies in question, and that the second infective period cannot possibly be classed as mechanical. The fact that *Lamus megistus* remains infective ten to twenty-five days after feeding on a host infected with *S. cruzi* also proves that the infection is not mechanical. We therefore draw the conclusion that the trypanosome undergoes part of its life-cycle in the invertebrate host, and the first question which naturally arises is the fate of the so-called 'male' and 'female' forms found in the blood of the vertebrate. Are they true male and female forms, and do they conjugate and form an oökinete or zygote, or do they not?

Conjugation. It is difficult to be certain that conjugation has been seen, and not division. It has been described by Keysselitz as occurring in leeches fed on a carp infected with *Trypanoplasma borreli*, by Prowazek in lice fed on rats infected with *T. lewisi*, and by Flu in *Crithidia melophagia*, to which reference will be made under the heading of Crithidia.

On the other hand, careful observers like Miss Robertson and Captain Patton have quite failed to see this process in their studies of trypanosomes and herpetomonads. The conclusion is that conjugation has not been proved to be present in trypanosomes so far.

Development without Conjugation. According to most observers, there is no conjugation, but development takes place asexually in the invertebrate host. This development varies in different species, and may be classified as follows:

A. Development in the proboscis.
B. Development in the anterior portions of the alimentary canal.
C. Development in the whole alimentary canal.
D. Development associated with infection of the salivary glands.
E. Rectal encystment—fæcal infection.
F. Ovum infection.

A. *Proboscian Development.* Roubaud has described a form of asexual development of *T. castellanii* and *T. brucei* in the proboscis of *Glossina palpalis* in which the undulating membrane disappears; the flagellum is shortened, and the kinetonucleus approaches the trophonucleus, while the parasite becomes attached to the wall of the proboscis, and multiplies, forming masses of parasites, the whole process occupying only a few minutes.

Though he thinks that this method of development explains the infection of man and animals by tsetse-flies in Africa, he was unable to produce infection of susceptible animals by inoculation of these forms.

This form of development occurs in *T. vivax* and in *T. cazalboui.*

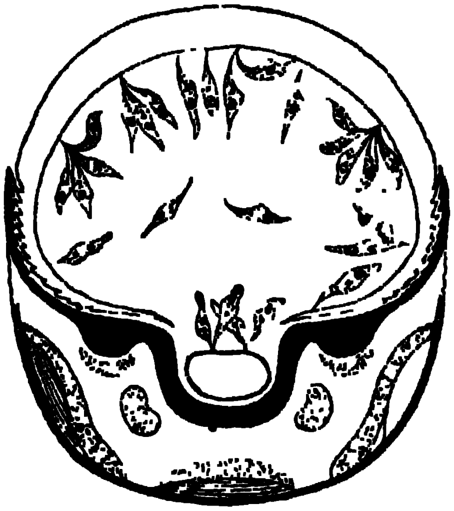

FIG. 91. PROBOSCIAN DEVELOPMENT. (After Roubaud.)

B. *Anterior Development.* Miss Robertson has shown that the trypanosomes of fresh water fish, when ingested by the leech *Hemiclepsis marginata,* first of all undergo rapid multiplication by unequal binary fission, giving rise to small crithidial like individuals, which also multiply in the crop, and then towards the end of digestion pass forward as long, slender trypanosomes into the proboscis sheath, and are capable of infecting a new host; while the crithidial forms which remain in the crop become Leishmania like bodies which multiply again when fresh blood is ingested. The development of *T. vittata* of the milk tortoise *Emyda vittata,* takes place in a somewhat similar manner in the leech *Glossiphonia* sp. (?).

C. *Entire Canal Development.* This form of development is exemplified by *T. rajæ* in the leech *Pontobdella muricata,* but in this case the trypanosomes in the crop give rise to binucleate, rounded, Leishmania-like forms without locomotor apparatus, which pass into the intestine, where they become flagellate, and appear as crithidial forms and multiply rapidly. During hunger periods they become Leishmania-like bodies, only to revert to the crithidial form when food is ingested. These crithidial-like forms become long, slender trypanosomes, which pass forward into the proboscis and are the infective agents.

D. *Salivary Gland Infection.*—According to Bruce and his collaborators, if *G. palpalis* is fed with *T. castellanii*, the proboscis is not involved in the further development. The fly now becomes non-infective for some twenty-eight days on an average. The trypanosomes in five to seven days disappear (possibly become intracellular), but later return in a small percentage of flies, and multiply in the fore, mid, and hind guts, generally as long, moderately broad forms, with protoplasm which stains well, and contains an oval central nucleus, a small micronucleus, undulating membrane, and a flagellum with a blepharoplast. After twenty-eight days it is found that the salivary glands become infected with the short, stumpy forms already mentioned above, and now the fly is found to be infective and to remain so for long periods. These short stumpy forms have been noted by Kleine in the intestine. Miss Robertson finds that the trypanosomes infect the salivary glands from the gut via the proboscis and the salivary ducts.

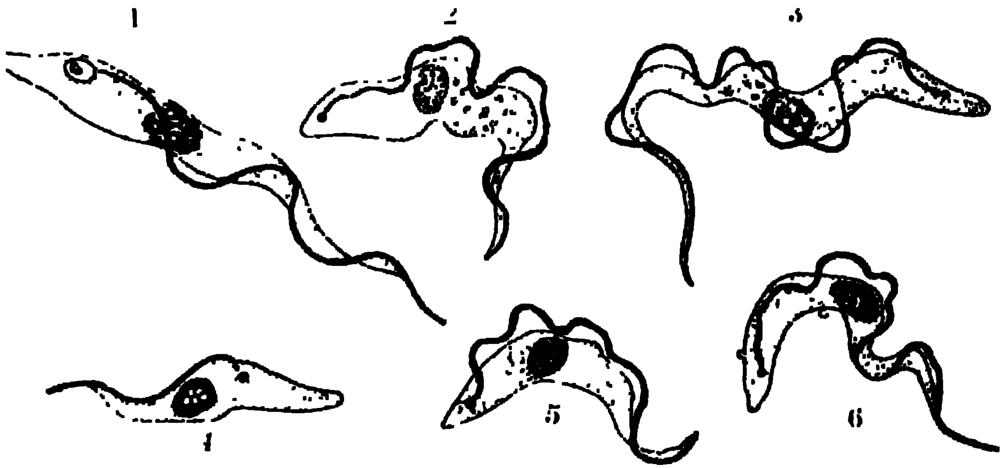

FIG. 92.—DEVELOPMENT OF *T. castellanii* KRUSE, 1903.

1, In the vertebrate blood; 2 and 3, in the mid gut; 4 and 5, in the hind-gut; 6, in the salivary glands of the tsetse-fly.

(After Bruce, Hamerton, Bateman, and Mackie.)

Kinghorn and Yorke have shown that the salivary glands of *Glossina morsitans* become infected in somewhat similar manner with *T. rhodesiense*.

Chagas has seen trypanosomes in the body cavity and salivary glands of *Lamus megistus*, which are without doubt the forms which are inoculated in infections.

E. *Rectal Encystment.* Minchin finds that the crithidial forms of *T. grayi* become encysted in the rectum of *G. palpalis*.

F. *Ovum Infection.*—This has not been proved to take place.

Conditions Influencing Development.—Kinghorn and Yorke have shown that the development of *T. rhodesiense* in *G. morsitans* is markedly influenced by the temperature of the air, 75° to 85° F. being more favourable than 60° to 70° F., and, under favourable conditions, the first stage of development can take place, but not the later stages, and flies may remain with the parasites incompletely developed for eighty days. Humidity is without effect. Another important matter, as we shall see later, is the effect of the next following clean feed after an infected feed.

Methods of Infection.—In nature there can be no doubt that infection can take place in more than one way, and Minchin has pointed out that the different methods may be :—

1. CONTAMINATIVE.—This is the infection of the host by swallowing encysted parasites. At present there is no proof that this exists in trypanosomes. But Minchin has shown that *T. grayi* becomes encysted while lying in the proctodæum of *Glossina palpalis*, by a shortening of the flagellum and an excretion of a cyst-wall, which, beginning at the anterior extremity, gradually spreads round the shortening parasite while the flagellum is being absorbed. The cysts which lie quite free from the proctodæum are first pear-shaped and then oval, and the trophonuclei and kinetonuclei break up into chromidia. Minchin believes that these cysts will be found to infect some vertebrate, but there is no proof of this at present.

2. INOCULATIVE.—The spread of a trypanosome from one vertebrate host to another was demonstrated by Bruce while studying *T. brucei*, and also by the same observer, Nabarro, and Kleine, for *T. castellanii*, both diseases being spread by tsetse-flies, though with regard to the former it had long been known that the tsetse-fly was the carrier of the disease.

There are, however, two ways in which a blood-sucker can spread an infection: (*a*) the direct; (*b*) the indirect.

(*a*) *The Direct.*—In this the blood-sucker simply transmits the parasite unchanged.

(*b*) *The Indirect.*—In this method the parasite undergoes a cycle of development in the blood-sucker, the nature of which has been fully discussed already.

It would appear probable that it is only in the natural hosts that forms develop which are infective for the invertebrate.

Effects upon the Vertebrate Host.—Trypanosomes may produce pathological effects on their vertebrate host, or may apparently be harmless, and certain harmless trypanosomes will only live in some particular vertebrate and die when injected into others, but no pathogenic trypanosome is restricted to one host.

The best known of the former are *T. gambiense*, *T. castellanii* and *T. rhodesiense*, the causes of sleeping sickness; *S. cruzi*, of American trypanosomiasis; *T. evansi*, of surra in horses, etc., in India and elsewhere; *T. brucei*, of nagana in cattle and horses, etc.; *T. vivax*, of disease in cattle, sheep, and goats, in the Cameroons; *T. nanum*, of cattle sickness in the Anglo-Egyptian Sudan; *T. dimorphon*, of the Gambia horse sickness; *T. cazalboui*, of souma, a disease of cattle in the French Sudan, and *T. pecaudi*, of sheep in the same place; *T. equinum* of mal de caderas in South America; *T. equiperdum*, of dourine in horses in Europe and Africa.

SYMPTOMS.—The pathogenic effects of the parasites show themselves in the production of fever, skin eruptions, emaciation, local or general œdema, and disease of the nervous system. Secondary bacterial affections are also common. The mortality is often high.

MORBID ANATOMY.—The lesions are often insignificant, but inflammation and enlargement of the lymphatic glands is characteristic, and dropsy and inflammation of the meninges are also found, which in human trypanosomiasis takes the form of meningo-encephalitis, as will be described later.

INOCULATIONS.—The parasites can be spread from one animal and from one species to another by inoculation of infected blood.

AGGLUTININS.—While in the body of the host agglutinins are formed, for if blood containing trypanosomes is treated with the serum of an animal which has had one or more injections of blood containing the same parasite, a rapid massing of the parasites into rosettes, with the anterior ends pointing inwards and the flagella outwards, takes place.

This is called agglomeration, and may last a few minutes, the parasites being unaffected, or may persist till they die.

REDUCING POWER. Trypanosomes have been shown by Nauss and Yorke to have a marked reducing power on hæmoglobin.

PRECIPITINS.—Mayer has shown that the serum of a dog infected by *T. brucei* is precipitated by a salt extract of the same parasite, but not by that of *T. equinum*, thus proving the presence of specific precipitins.

IMMUNITY. Active immunity, due to the action of the leucocytes (Laveran and Mesnil) or to cytolysins (McNeal), can be produced in certain cases, but it is not carried from mother to young. Léger and Ringenbach have shown that the serum of animals affected with nagana and surra, also *T. equinum*, *T. castellanii*, and *T. congolense*, is trypanolytic for homologous and allied trypanosomes, but not for others.

Chalmers and O'Farrell have shown that *T. castellanii* can be separated from *T. rhodesiense* by immune serum reactions *in vitro* and *in vivo*.

INVOLUTION FORMS.—Degenerated, vacuolated involution forms may be seen as a result of immunity coming on or of treatment by drugs. Advanced forms after treatment with immune serum have been noted by Chalmers and O'Farrell.

TOXINS.—Uhlenhuth, Hübener, and Worthe have demonstrated the presence of endotoxins in *T. equiperdum*, which observation supports McNeal's suggestion as to their presence, and also the work of Martin, Darre, and Leber. Free toxins do not exist, but endotoxins can be set free by trypanolysis.

Local Reservoirs.—The long-continued infectivity of *Glossina palpalis* after the removal of man from a district points to either long duration of infectivity in the fly or to a local reservoir, which may perhaps be found in antelopes, and perhaps other animals in the case of *T. castellani*.

Cultivation.—McNeal and Novy cultivated *T. lewisi* in the water of condensation of blood-agar tubes in 1903, and obtained, at 37° C., and also at the room temperature, good cultures, in which *T. lewisi* varied in size from minute forms 1 to 2 microns in length up to 50 to 60 microns, and colonies of rosettes were seen with all the flagella turned inwards. The flagellum in cultivated forms projects directly from the kinetonuclear end of the parasite.

The following have been cultivated: *S. cruzi*, by Chagas; *T. brucei*, by McNeal and Novy, and by Laveran and Mesnil; *T. equinum*, by R. Thomas and Breinl, *T. equiperdum*, by Thomas and Breinl, with slight success; *T. castellanii*, by Thomas, Breinl, Gray, and Tulloch, with partial success; *T. evansi*, by Novy, McNeal, and Hare, and by Thomas and Breinl, but were found to be non-virulent, and subcultures could not be obtained.

Effects upon the Invertebrate Host.—The effects of trypanosome infection upon the invertebrate host has been but little studied, except with reference to *T. castellanii* and *Glossina palpalis*, and the result may be tabulated as follows:

A. NON-INFECTION OF THE FLY.—1. The trypanosomes introduced by the infective feed may entirely disappear, being digested in some fifty to seventy hours.

2. The trypanosomes may multiply in the crop, but disappear after the next feed if non-infective.

3. The trypanosomes may grow and multiply in the gut, and yet be all swept out by the next feed if clean.

4. The trypanosomes may survive and develop in the crop for twelve days, providing that blood is always present, but no trypanosomes appear in the gut, and the infection dies out.

B. INFECTION OF THE FLY DOUBTFUL.—In the third instance quoted above infection may take place; everything depends upon the effects of the second feed.

C. INFECTION OF THE FLY.—The trypanosomes persist after the clean feed has displaced the blood from the gut, but the infection also depends upon the strain of trypanosome, as there is undoubtedly a struggle for existence between the trypanosome and the chemical defences of the fly against *T. castellanii*.

Type Species.—*Trypanosoma rotatorium* Mayer, 1843.

It is necessary, for purposes of classification, that the reader should clearly understand the nature of the type species.

Trypanosoma rotatorium Mayer, 1843.

Synonyms.—*Paramœcium loricatum*, seu *costatum* Mayer, 1843, *Amœba rotatoria* Mayer, 1843, *Trypanosoma sanguinis* Gruby, 1843, *Monas rotatorium* Lieberkühn, 1870, *Undulina ranarum* Ray Lankester 1871, *Paramœcioides costatus* Grassi, 1872.

History.—Gluge in 1842 discovered in the blood of frogs an organism resembling that which had been discovered by Valentin in the previous year in *Salmo fario*, the brown trout, and which was thought to be related to the genus *Amœba* of Ehrenberg, but which from his description and from his figures is more probably a trypanosome. Gluge's description is also very short, and he is followed by Mayer, in 1843, who describes two forms—an *Amœba rotatoria* and a *Paramœcium loricatum*, or *costatum*—but in November of the same year Gruby gave a clear description of the organism, and applied the generic term 'Trypanosoma' to it, so that it becomes the type species of the genus, from which any variation in the classification of the species must be made.

Ogawa has studied this parasite in the frog in 1913, as well as Doflein and Mendeleeft-Goldberg.

Gruby's Original Description.—'Its elongated body is flattened, transparent, curved like a centre-bit; the cephalic end is terminated in a thin, elongated filament; the caudal end is terminated also in a pointed filament. The length of the animal is 40 to 80 *μ*, its breadth is 5 to 10 *μ*, the filamentous pointed cephalic end has the greatest mobility, the length of the cephalic filament is 10 to 12 *μ*; its body is elongated, flat, and toothed like the blade of a saw all along the length of one of its margins; it is, as I have above mentioned, supple and twisted two or three times around its axis, like an auger or a corkscrew, which is the reason why I propose to name this hæmatozoön "*Trypanosoma*."'

Zoological Distribution.—It has been found in *Rana esculenta* Linnæus, in *R. temporaria* Linnæus in Europe; in *R. speciosa* in the Congo; in *R. trinodis* in the Gambia. Whether the species found in *Hyla arborea* are truly *T. rotatorium* or not is uncertain.

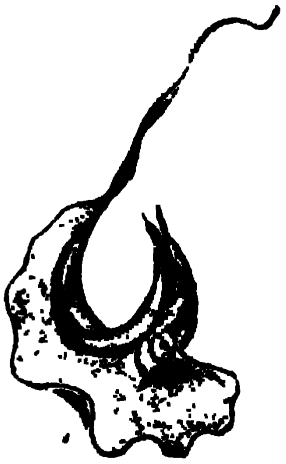

FIG. 93.—*Trypanosoma rotatorium* MAYER (After Dutton and Todd.)

Morphology.—The pleomorphism exhibited by this form is so varied that it requires classification, for, as Chalachnikov has shown, the following varieties exist:

1. *Flattened Forms.*—(*a*) Simple plain forms; (*b*) plain forms rolled on themselves; (*c*) spiral forms.

2. *Pectinated Forms.*—(*a*) Pectinated spiral forms; (*b*) cornucopial forms. In all these forms the undulating membrane is much folded, and has a thickened edge. The flagellum, which is short, starts from the kinetonucleus, which is situate at a variable distance from the aflagellar extremity. The trophonucleus is round or oval. The usual length varies from 40 to 80 *μ*, the breadth from 5 to 40 *μ*, and the flagellum is about 10 to 12 *μ* long.

Doflein finds that in the blood and internal organs forms intermediate between the flagellate and the non-flagellate organisms are found. The latter cannot divide.

Life-History.—The life-history is but little known. Asexual multiplication takes place by the trypanosome becoming round and losing its locomotor apparatus, and dividing by mitosis. It is but rarely inoculable into other frogs, but it grows in cultures, especially upon Novy-McNeal's medium, but the cultures are not inoculable. In the cultures leptomonas and rosette forms are seen. The researches of França show that it is capable of developing in the leech (*Helobdella algira*), in which it gives rise to leptomonas-like forms, which are to be seen located against the walls of the gastric intestinal pouches. Frogs can be infected by the bites of infected leeches or by the inoculation of the intestinal contents.

Cultivation.—It has been cultivated in acid bouillon-blood media by Ponselle in 1917.

Classification.—The question is unsettled as to whether there are more than one species included under the term *T. rotatorium*.

Pathogenicity.—It is believed to be non-pathogenic. This immunity of the frog has been studied by Doflein and others.

Classification.—If the section on evolution contained in Chapter V. be read, it will be seen that we believe that new diseases can arise at the present time; that organisms usually harmless in a given environment may become so altered under certain circumstances that they may become pathogenic; and that this change, though merely at first chemical, may subsequently become structural.

The researches of O'Farrell, Fantham, and Porter, already referred to under the Herpetomoninæ, seem to indicate that the original trypanosomes were parasites of such invertebrates as Annulates, Arachnids, and Hexapoda, from which they spread to vertebrates.

With regard to man, it would appear as though his infection was of comparatively recent date, and that in him and in the tsetse-flies which infect him the adaptation of the trypanosomes to the new environments is not yet complete, and therefore the differential characters of the various species infecting him have not yet become completely crystallized.

It therefore appears to us that a natural division of the numerous species of trypanosomes would be into -

A. Trypanosomes infecting invertebrata:—
  I. Trypanosomes of Hirudinea.
  II. Trypanosomes of Arachnida.
  III. Trypanosomes of Hexapoda.

B. Trypanosomes infectin[illegible]ld-blooded vertebrates:-
  I. Trypanosomes of Pisces.
  II. Trypanosomes of Amphibia.
  III. Trypanosomes of Reptilia.

C. Trypanosomes infecting warm-blooded vertebrates:—
  I. Trypanosomes of Aves.
  II. Trypanosomes of Mammalia.

It is not our purpose to write accounts of all known trypanosomes, but merely those which infect man, and to sketchily describe some of those which produce disease in the mammalia, and to draw attention to others which can be classified in the series of divisions given above.

With regard to the trypanosomes of mammals, it appears to us, from an evolutionary point of view, to be correct to divide them into two sections --viz.:- –

A. Non-pathogenic mammalian trypanosomes.
B. Pathogenic mammalian trypanosomes.

As it is the last section only with which tropical medicine is concerned, we shall restrict our further remarks on classification until we come to these organisms.

A New Classification.--Although, for purposes of general information, we have given the usual classification, still, it must be obvious even to the casual reader that the genus Trypanosoma comprises an enormous number of species, some of which are of very diverse form.

We feel that the time has arrived in which to bring forward a fuller and more useful classification, based upon morphological and physiological characters, especially as classifications have been outlined by Nöller, while Minchin, had he lived, would probably have brought forward one.

In the Trypanosominæ the definitive, and hence primitive, host is the invertebrate, and we should expect to find some trypanosomes which were solely denizens of these animals, and apparently this is so. Unfortunately, their full life history still requires much elucidation, but such forms as *Cystotrypanosoma intestinale* Roubaud, 1911, are worthy of more consideration; and it is obvious that such forms deserve separate classifications, and should form part of a tribe *Cystotrypaneæ*, with *Cystotrypanosoma* as type genus and *C. intestinale* as type species.

As evolution proceeds so life-histories tend to become complicated. In this case the complication is the introduction of a vertebrate intermediary host, and with the change in environment one meets with the large, relatively slow-moving, trypanosome of the cold-blooded vertebrate and the smaller, quicker-moving, trypanosome of the warm blooded vertebrate. They appear to us to deserve to be ranked into tribes and to merit more study. The type of the first is obviously Glugea's parasite, and of the second the organism found, by one of us, to be the cause of sleeping sickness.

These various ideas may be crystallized as follows:—

A. Live *only* in a definitive invertebrate host:—
  Type genus: *Cystotrypanosoma* Roubaud, 1911– Tribe 1, *Cystotrypaneæ* Chalmers, 1918.
  Type species: *C. intestinale* Roubaud, 1911.

B. Live in a definitive invertebrate host and in a cold-blooded intermediate vertebrate host:—
  Type genus: *Trypanosoma* Gruby, 1843—Tribe 2. *Trypanosomeæ* Chalmers, 1918.
  Type species: *T. rotatorium* Gruby, 1843.

C. Live in a definitive invertebrate host and in a warm blooded intermediate vertebrate host:—
  Type genus: *Castellanella* Chalmers, 1918– Tribe 3, *Trypocastellanelleæ* Chalmers, 1918.
  Co-type species: *C. gambiensis* (Dutton, 1902).
  C. castellanii (Kruse, 1903).

In the present work we are chiefly concerned with the third tribe, '*Trypocastellanelleæ*.'

SERIES A: TRYPANOSOMES INFECTING INVERTEBRATA.

TRIBE 1: CYSTOTRYPANEÆ.

This tribe has not yet been fully studied, but provisionally it can be classified as follows:—

A. *Forms carefully studied*:—

Snout long, no free flagellum forms like *T. dimorphon*:—

1. Trophonucleus round—*Rhynchoidomonas* Patton, 1910.
2. Trophonucleus elongate—*Cystotrypanosoma* Roubaud, 1911.

B. *Forms not yet fully studied*:—

We still retain the old term *Trypanosoma sensû lato* for these forms, pending further investigation, and divide them into:—

I. Trypanosomes of Hirudinea.
II. Trypanosomes of Arachnida.
III. Trypanosomes of Hexapoda.

Forms Carefully Studied.

Genus Rhynchoidomonas Patton, 1910.

Definition. *Cystotrypaneæ* with large kinetonucleus situated on the aflagellar side of the rounded trophonucleus, with distinct undulating membrane and with the aflagellar end drawn out considerably.

Rhynchoidomonas luciliæ Patton, 1910.

This parasite is found in the Malpighian tubes of *Lucilia serenissima* Walker, and *Musca nebula* Fabricius, in India. It moves by sharp jerking movements, and has no free flagellum, but a pointed flagellar extremity and a pointed aflagellar extremity. The kinetonucleus is large and circular, while the trophonucleus is also large. The cytoplasm contains many chromatoid granules.

Genus Cystotrypanosoma Roubaud, 1911.

Definition.—*Cystotrypaneæ* with small terminal kinetonucleus situate on the aflagellar side of an elongated trophonucleus. There is no free flagellum. It gives rise to pyriform cysts.

Cystotrypanosoma intestinale Roubaud, 1911.

This parasite is found in the intestine of a species of *Lucilia* at Bamako in French West Africa.

Forms not yet Fully Studied.

Trypanosomes belonging to the invertebrate and not due to the sucking of contaminated blood have been found in the tsetse-fly, in mosquitoes, in ticks, and perhaps in leeches, but it is doubtful about the last named.

The presence of the Herpetomonas, Crithidia, and Trypanosoma in blood-sucking Arthropods may, therefore, be peculiar to those animals, or only acquired from their hosts. Hence it is quite possible for serious errors to arise in working out the life history of these parasites, especially as infection of the blood-sucker may come from the eggs.

SECTION I.: TRYPANOSOMES OF *Hirudinea*.

Trypanosoma inopinatum is believed to be a true parasite of the leech *Helobdella agira*, though, according to some observers, it is the same as the parasite of the frog.

SECTION II.: TRYPANOSOMES OF *Arachnida*.

T. christophersi Novy, 1907, found in *Rhipicephalus sanguineus*, fed on dogs.

SECTION III.: TRYPANOSOMES OF *Hexapoda*.

Trypanosoma boylei Lafont, 1902, has been found in *Conorhinus rubrofasciatus*, an insect which attacks man in Mauritius and Réunion.

Trypanosoma tullochi Minchin, 1907.—This parasite closely resembles *C. castellanii* from which it can be differentiated by the central round nucleus and the small centrosome. It is found in *G. palpalis*.

T. culicis Novy, 1907, is found in various Culicinæ. Novy strongly advocated the view that the trypanosomes found in mosquitoes which Schaudinn had fed on *Athene noctuæ* infected with halteridium should be defined as *T. noctuæ* Schaudinn, 1904, a parasite of *Culex pipiens*, and the same for *T. ziemanni* Schaudinn, 1904, also in *Culex pipiens*; and, further, that the trypanosome found by Durham in *Stegomyia fasciata*, which had been fed on bats, should be looked upon as belonging to the mosquito

T. triatomæ Kofoid and McCulloch, 1916, is a parasite of *Triatoma protracta*, found in nests of the wood-rat *Neotoma fuscipes*.

SERIES B: TRYPANOSOMES INFECTING COLD-BLOODED VERTEBRATES.

TRIBE 2: TRYPANOSOMEÆ.

At present this tribe contains one genus—viz., *Trypanosoma sensû stricto*, as defined above, and with *T. rotatorium* Mayer, 1843, as the type.

It is probable that, as constituted, the genus still contains a number of non-defined genera, but these require further investigation, and we therefore divide the species into:—

Section I.: Trypanosomes of Fish.
Section II.: Trypanosomes of Amphibia.
Section III.: Trypanosomes of Reptilia.

SECTION I.: TRYPANOSOMES OF FISH.

In 1841 the first known trypanosome was found by Valentin in the blood of *Salmo fario*, the brown trout.

Since that time a considerable number have been found in fresh- and salt-water fish all over the world. As examples may be mentioned *T. remaki* Laveran and Mesnil, 1901, which exists in two varieties—*parva* and *magna*—and is found in pike; *T. rajæ* Laveran and Mesnil, 1902, in *Raja punctata*,

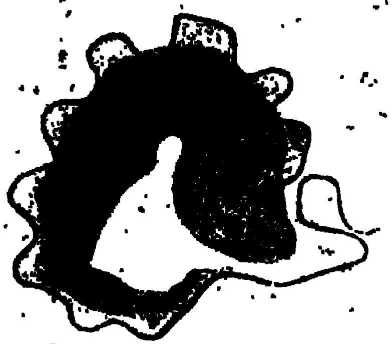

FIG. 94.—*Trypanosoma leschenaultii* ROBERTSON.

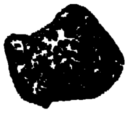

FIG. 95.—*Trypanosoma rajæ*. ROUND FORM, IN THE LEECH.

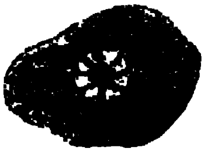

FIG. 96.—*Trypanosoma rajæ*: ROUND FORM, OLDER STAGE.

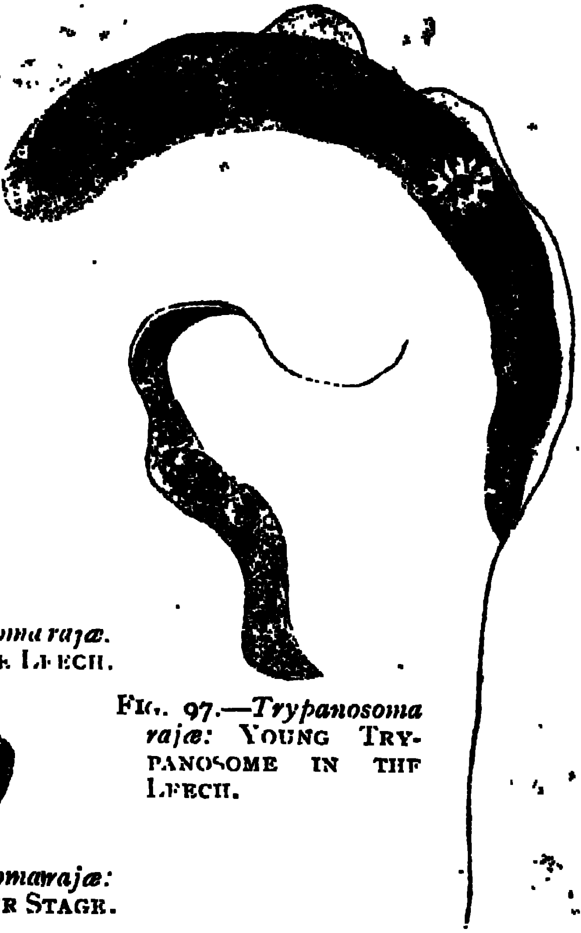

FIG. 97.—*Trypanosoma rajæ*: YOUNG TRYPANOSOME IN THE LEECH.

FIG. 98.—*Trypanosoma rajæ*: POSSIBLY FEMALE FORM, IN THE LEECH.

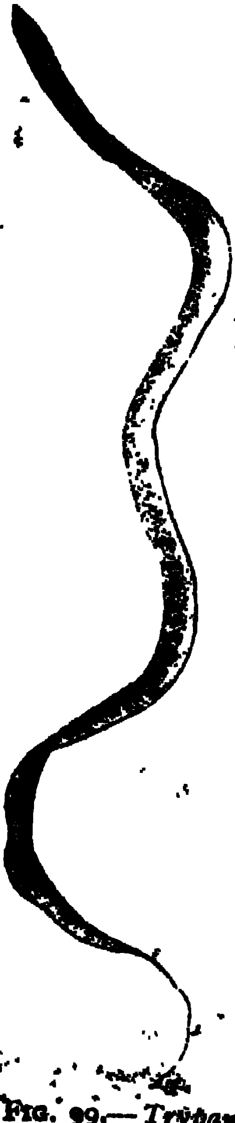

FIG. 99.—*Trypanosoma rajæ*: POSSIBLY A MALE FORM IN THE LEECH.

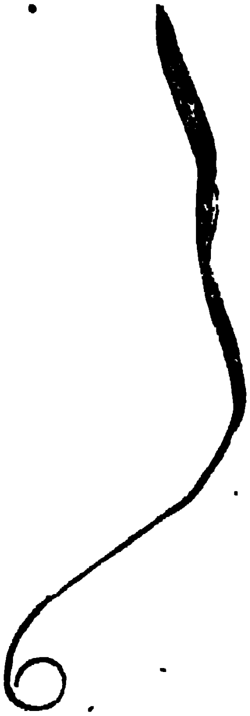

FIG. 100.—*Trypanosoma rajæ*: SLENDER FORM, FROM THE PROBOSCIS OF THE LEECH.

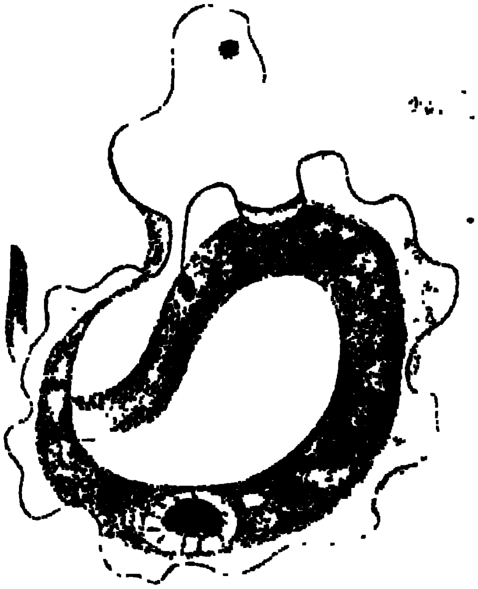

FIG. 101.—*Trypanosoma rajæ*: FULLY DEVELOPED TRYPANOSOME IN THE SKATE.

(All after Miss Robertson.)

and is thought to be spread by a leech—*Pontobdella muricata*; *T. saccobranchi* Castellani and Willey, 1905, in *Saccobranchus fossilis* in the Lake of Colombo, Ceylon.

Trypanosomes have been found in eels. Brumpt in 1906 described a number of new species in different kinds of fish, and Zupitza, in 1909, made a valuable addition to the knowledge of this subject.

Some trypanosomes found in fish are *T. danilewskyi* Laveran and Mesnil, 1904, in *Cyprinus carpis*; *T. carassii* Mitrophanov, 1883, in *Zagassius vulgaris*; *T. tincæ* Laveran and Mesnil, 1904, in *Tinca tinca*; *T. barbæ* Brumpt, 1906, in *Barbus fluviatilis*; *T. elegans* Brumpt, 1906, in *Gobio fluviatalis*; *T. phoxini* Brumpt, 1906, in *Phoxinus lævis*; *T. abramidis* Laveran and Mesnil, 1904, in *Abramis brama*; *T. leucisci* Brumpt, 1906, in *Leuciscus* sp. (?); *T. scardini* Brumpt, 1906, in *Scardinius erythrophthalmus*; *T. squalii* Brumpt, 1906, in *Squalius cephalus*; *T. cobitis* Mitrophanov, 1883, in *Cobitis fossilis*. There are, however, many others described. *T. roulei* Mathis et Léger, 1911, in *Monopteres javanensis*; *T. pellegrini* Mathis et Léger, 1911, in *Macropodus viridi auratus*; *T. chagasi* Horta and Machado, 1911, *T. dorhni* Yakimoff, 1912, in Solea; *T. yakimoffi* in Syngnatis

SECTION II.: TRYPANOSOMES OF AMPHIBIA.

The trypanosomes of frogs were discovered by Gluge as far back as 1842 in the form of the largest trypanosome known—*i.e.*, *T. rotatorium*.

It seems probable that leeches are the carriers of these parasites.

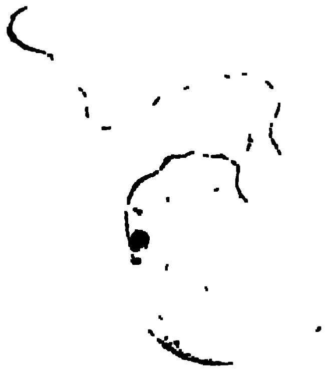

FIG. 102.—*Trypanosoma pertenue* ROBERTSON.

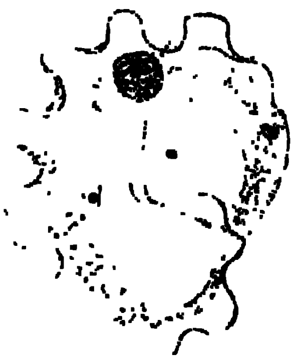

FIG. 103.—*Trypanosoma vittatæ* ROBERTSON SHOWS THE TRYPANOSOME ROLLING UP PRIOR TO DIVISION

(From drawing by Miss Robertson)

Trypanosoma inopinatum Ed. and Et. Sergent, 1904.

Synonyms.—*T. elegans* França and Athias; *T. undulans* França; *T. hendersoni* Patton.

Found in *R. esculenta* L. in Algeria, in *R. hexodactyla* and *R. tigrana* in India. It is very like *T. lewisi*, but is more stumpy. It is spread by the leech, *Helobdella algira*. It gives rise to herpetomonas and crithidial forms and Brumpt has been able to infect frogs by the bite of the infected leeches, and has shown that the infection can be spread by the second generation also—*i.e.*, that it is hereditary. It is also inoculable. The crithidial forms are said to be the infective agent by França.

Trypanosoma nelspruitense Laveran, 1904.

Discovered by Theiler in *R. angolensis* Bocage and in *R. theileri* Macquart.

Trypanosoma somalense Brumpt, 1906.

In *Bufo reticulatus* from Somaliland.

Trypanosoma sp. (?).

Found by Tobey in the American newt, *Diemyctylus viridescens*.

SECTION III.: TRYPANOSOMES OF REPTILIA.

Tortoises.—*Trypanosoma damoniæ* Laveran and Mesnil, 1902, in *Damonia reevesi*, an Asiatic tortoise; *T. vittatæ* Robertson, 1907, in *Emyda vittata* in Ceylon, the intermediate host being a leech.

Crocodilia.—*Trypanosoma grayi* Novy.—This parasite, which was thought to be part of the life-cycle of the *Trypanosoma* of the crocodile, is now known to be a Crithidia.

Lizards.—*T. boueti* Martin, 1907, in *Mabuia raddoni*; *T. leschenaultii* Robertson, 1907, in *Hemidactylus leschenaultii*, in Ceylon; *T. pertenue* Robertson, 1907, in *Hemidactylus triedri leschenaulti*, in Ceylon.

Ophidia.—*T. pythonis* Robertson; Mesnil is doubtful whether this is not a hæmoproteus, while Sambon considers that it is a hæmogregarine, (*H. robertsoni*). *T. erythrolampri* Wenyon, 1909, in *Erythrolampus æsculapii*, *T. primeti* Mathis et Léger in *H. piscator*, *T. najæ* Wenyon, 1909, in *Naja nigricollis*.

SERIES C: TRYPANOSOMES INFECTING WARM-BLOODED ANIMALS.

TRIBE 3: TRYPOCASTELLANELLEÆ.

This tribe may be divided into:—

SECTION I.: TRYPANOSOMES OF AVES. These are but little known, and, pending further study, we must retain the old genus *Trypanosoma sensû lato*.

SECTION II.: TRYPANOSOMES OF MAMMALIA.—They may be classified as follows:—

Series (*a*).—Non-Pathogenic.

1. *Classifiable*:—
   Genus Lewisonella.
   Genus Endotrypanum.
2. *Unclassifiable*:—
   Old genus *Trypanosoma sensû lato* pending further work.

Series (*b*).—Pathogenic.

1. *Classifiable*:—
   Genus Schizotrypanum.
   Genus Castellanella.
   Genus Duttonella.
2. *Unclassifiable*:—
   Old genus *Trypanosoma sensù lato* pending more research.
3. *Little known.*

The classifiable mammalian trypanosomes may be recognized by the characters given in the following table:—

A. With schizogony in the vertebrate host—*Schizotrypanum* Chagas, 1909.

B. Without schizogony in the vertebrate host:—

- I. Enters red blood-corpuscles—*Endotrypanum* Mesnil and Brimont, 1908.
- II. Does not enter red blood-corpuscles.
  - (*a*) Final stage of development in the definitive host is in the hind gut. Infection is contaminative. Aflagellar extremity long drawn out and pointed. Cytoplasm free from granules—*Lewisonella* Chalmers, 1918.
  - (*b*) Final stage of development in the definitive host is in the salivary glands, proboscis, or hypopharynx. Infection inoculative.
    - 1. Polymorphic, with granular cytoplasm, small kinetonucleus, and well-developed undulating membrane. Final stage in the definitive host takes place in the salivary glands—*Castellanella* Chalmers, 1918.
    - 2. Monomorphic, with non-granular cytoplasm, large kinetonucleus, and with or without well-developed undulating membrane. Final stage of development anterior, but not in the salivary glands *Duttonella* Chalmers, 1918.

The type species of these genera are as follows:—

Schizotrypanum cruzi, synonym *Trypanosoma cruzi* Chagas, 1909.

Endotrypanum schaudinni Mesnil and Brimont, 1908.

Lewisonella lewisi, synonym *Trypanosoma lewisi* Kent, 1879.

Castellanella gambiensis Dutton, 1902 (co-type species: *Castellanella castellanii* Kruse, 1903, synonym *Trypanosoma castellanii* Kruse, 1903).

Duttonella vivax, synonym *Trypanosoma vivax* Ziemann, 1905.

SECTION I.: TRYPANOSOMES OF AVES.

In 1845 Gros found trypanosomes in the blood of goat-suckers and cranes which are now known to be very common in birds, but the detection in blood-films is not easy, as the parasites are few and far between. According to Novy and McNeal, the cultivation method is much better.

Laveran and Mesnil summarize them into three types:—(1) Trypanosomes of type of *T. lewisi* in rats (*T. avium minus*), (2) trypanosomes of type of *T. rotatorium* of the frog, (3) long thin trypanosomes without free flagellum—distinct type.

A few examples may be mentioned:—*T. avium* Laveran, 1903, in *Syrnium aluco* L., the wood-owl; *T. confusum* Lühe, 1906, in *Agelaius phœniceus* L., and other North American birds; *T. laverani* Novy and McNeal, 1905, in *Astragalinus tristis* L., North America; *T. paddæ* L. and Mesnil, 1904, in *Padda oryzivora*, the Java sparrow.

Also *T. lagonostictæ* Marullaz, 1914, from *Lagonostictæ senegala*; and *T. Leothricis*, from the Japanese nightingale, *Leothrix luteus*.

SECTION II.: THE TRYPANOSOMES OF THE MAMMALIA

Mammalian trypanosomes may be classified according to Laveran and Mesnil, into:—

Series (*a*).—The non-pathogenic mammalian trypanosomes.

Series (*b*).—The pathogenic mammalian trypanosomes.

This classification is, in our opinion, in accord with evolutionary knowledge.

SERIES A: THE NON-PATHOGENIC MAMMALIAN TRYPANOSOMES.

It is quite beyond the limits of this book to give detailed accounts of these trypanosomes, and all that we can do is to attach a list of the more common with an account of a few.

Classifiable.

Two genera are known—viz.:—

A. Endoglobular forms known—*Endotrypanum*.
B. Endoglobular forms unknown—*Lewisonella*.

Unclassifiable.

C. Little known forms *Trypanosoma sensû lato*.

Genus Lewisonella Chalmers, 1918.

Definition.—Trypocastellanelleæ, found in mammals, non-pathogenic, without endoglobular forms.

Type Species:—*Lewisonella lewisi* Saville Kent, 1880.

We will describe the type species *L. lewisi* Saville Kent, 1880, in greater detail.

Lewisonella lewisi (Saville Kent, 1880).

Synonyms.—*Herpetomonas lewisi* Kent, 1880; *Trichomonas lewisi* Crookshank, 1886; *Trypanomonas lewisi* Labbé, 1891; *Trypanosoma sanguinis* Kanthack, Durham, and Blandford, 1898; *T. rattorum* Borner, 1901; *Trypanomonas murium* Danil, 1899; *Trypanozoon lewisi* Lühe, 1906; *Trypanosoma lewisi* Kent, 1880.

Remarks.—*L. lewisi* was the first mammalian trypanosome to be discovered, for it was seen by Chussat in 1850 in *Epimys rattus* (probably not by Gros in 1845), who thought it was a young nematode, while Lewis, in Calcutta, in 1877, rediscovered it, and recognized that it was a protozoon. It is a typical Lewisonella, and is found in *Epimys rattus* L., *E. norvegicus* Pall, and *E. rufescens* Gray all over the world—in Asia (India, Ceylon, Java, Philippines, Japan), in Europe (England, Ireland, France, Holland, Germany, Russia), in Africa (Uganda, Abyssinia, Gambia, and Cameroons), and in America (United States and Brazil). It is non-pathogenic and restricted to rats, among which it is spread by *Ceratophyllus fasciatus*, the rat-flea.

Morphology.—It is a very active, worm-like little parasite darting about among the corpuscles. It is 24 to 25 μ in length and 1·5 μ in breadth. The anterior end is very pointed, and the whole parasite is thin. The trophonucleus is situated near the junction of the middle and posterior thirds of the body, and the kinetonucleus, which is rod-shaped, is situated anteriorly. There are eight myonemes in the ectoplasm (periplast). Prowazek distinguishes small male forms with a nucleus rich in chromatin, large female forms with clear cytoplasm, and indifferent forms with many granules and poorly defined nucleus.

Life-History—*In the Vertebrate.*—The life-history in the rat has been worked out by Breinl and Hindle (Fig. 89, p. 384). The filament they mention as occurring between the kinetonucleus and the trophonucleus appears to have been also seen by Prowazek. Asexual reproduction may be summarized into reproduction with longitudinal division and reproduction with rosette formation and encystment after some interchange between the kineto- and tropho-nuclei, followed in due course by increased power for longitudinal division. Battaglia describes a process of sporogony with the formation of macro- and micro-gametocytes, and of macrogametes and microgametes, and a similar reproduction has been described by Pricolo. Carini's cyst-like bodies in the lungs are considered by Delinois to be a coccidium, *Pneumocystis carinii*.

In the Invertebrate.—The rat flea, *Ceratophyllus fasciatus*, is the true carrier of *T. lewisi*, as was first demonstrated by Nuttall, and the rare development which may take place in louse *Polyplax spinulosa* is more of the nature of a natural culture than a proper development. The development in the flea has been studied by Swellengrebel and Strickland, and more recently by Minchin and Thompson.

When the flea ingests blood containing the flagellates, they pass directly to the mid-gut, where they enter the epithelial cells, inside which they attain a large size and undergo multiplication in a peculiar manner by forming a large spherical body containing a number of tropho- and kineto-nuclei, and developing flagella, while the original flagellum still remains attached, but is subsequently lost; and then the cytoplasm divides into the daughter trypanosomes, which are now set free, and, passing into the rectum, become crithidial forms by the kinetonucleus travelling past the trophonucleus towards the flagellum. These crithidial forms attach themselves to the wall of the rectum, and shorten into Leishmania-like forms without flagella or without free flagella. These in their turn develop into trypanosome forms, which pass forwards into the mid-gut.

The intracellular stage is at its height about the end of the first day after infection, the rectal stage begins during the second day, the trypaniform types pass into the mid-gut towards the end of the fifth day; and the flea is infective in about six days after its own infective meal.

The 1915 work of Minchin and Thompson may be summarized as follows:—

T. lewisi is transmitted from rat to rat by the rat-flea *Ceratophyllus fasciatus*, but infection does not occur by the flea-bites, but is contaminative by the rat licking from its fur or skin the moist fæces of infective fleas containing the final propagative form, or by eating the fleas.

The cycle of development is as follows —The flea sucks the blood of an infected rat, and so acquires the trypanosomes, which require a minimum of five days to attain the infective stage, which is a small trypanosome which does not penetrate the salivary glands, but remains in the digestive tract, from which it escapes in the fæces, which are taken into the mouth of the rat while licking the fur. The flea remains infective for a long time, but does not pass the germ on to the next generation. After infection some five to seven days elapse before the trypanosome appears in the rat's blood, in which it multiplies till the eleventh to thirteenth day after infection.

In the louse, *Polyplax spinulosa*, the life-cycle has been studied by Prowazek, who finds that the micro- and macro-gametocytes undergo first a reduction of the trophonucleus from sixteen chromosomes to four, and that then the microgametocyte gives rise to only one microgamete, which fuses with the macrogamete, forming an ookinete. This becomes a trypanosome by the separation of the kinetonucleus from the synkaryon. The flagellum projects from the posterior end, which the kinetonucleus now leaves, and, taking the flagellum with it, proceeds towards the anterior end, thus forming the undulating membrane. Gregariniform non-flagellate forms also appear, which penetrate between the epithelial cells. Prowazek failed to infect rats by the bite of the louse, but this has been done successfully since. Swellengrebel and Strickland find that the development in the louse is very irregular and not to be compared with that in the flea.

Cultivation.—Cultural experiments have been carried out successfully by Novy and McNeal on a medium prepared by mixing agar and defibrinated rabbit's blood in equal parts, when forms from 1½ to 60 μ in length may be found, and also rosettes, but the forms are herpetomoniform, with the kinetonucleus at the flagellar end.

Pathogenicity.—Inoculation can only be carried out successfully in rats, in which it is generally non-pathogenic, though some observers have described the rare occurrence of dyspnœa, œdema, and subcutaneous hæmorrhages in intense infections. Some strains may become very pathogenic for rats. These strains show morphological and developmental anomalies—*e.g.*, forms without a blepharoplast—and there is a correlation between virulence and these changes.

Immunity.—Immunity is gained when a rat becomes free from the parasites, and hyperimmunity can be obtained by inoculations. It is thought that the immunity is largely due to phagocytosis, but this is being questioned in many species of trypanosomes. A protective serum is obtainable from hyperimmune rats. Immune serum will agglomerate the trypanosomes.

Hereditary Infection.—The parasites cannot be transmitted from the mother to young, as it appears that they cannot traverse the placenta.

Genus Endotrypanum Mesnil and Brimont, 1908.

Definition.—Trypocastellanelleæ, found in mammals, non-pathogenic, and with endoglobular forms.

Type Species.—*Endotrypanum schaudinni* Mesnil and Brimont, 1908.

Endotrypanum schaudinni Mesnil and Brimont, 1908.

This trypanosome, 13·4 × 3·5 microns, is only known in the endoglobular form in the red blood cells of the sloth, in which it appears as a peg-top-shaped trypanosome with a short flagellum possessing trophonucleus and kinetonucleus. This must be only one stage in its life-history, and as yet the other stages are unknown; and though a free trypanosome was seen in the same animal as the encysted forms, it was considered to be different from the endoglobular forms. In 1914 Darling confirmed these researches, finding the organism in *Cholœpus didactylus* in Panama. No free trypanosomes were seen in the sloth. Free forms only occur after fresh preparations have stood some time.

Unclassifiable.

The following is a list of the unclassifi species, divided according to the classification of the host and nged according to known importance:—

Trypanosomes found in Monkeys.—America: *T. minasense* Chagas, 1909; *T. prowazeki* Gossler, 1908. Asia: *T. rhesii* Terry, 1911; *T. vickersæ* Brumpt, 1909. Africa: A number of unnamed trypanosomes are reported in chimpanzees and species of Cercopithecus.

Trypanosomes of Ungulata.—*Trypanosoma theileri* Bruce, 1902.

Trypanosomes of Rodents.—*T. duttoni* Thiroux, 1905; *T. musculi* Kendall, 1906; *T. grosi* Laveran and Pettit, 1909; *T. microti* Laveran and Pettit, 1909; *T. blanchardi* Brumpt, 1905 (= *T. myoxi* Blanchard); *T. evotomys* Hadwen; *T. peromysci* Watson; *T. criceti* Lühe, 1906; *T. cuniculi* R. Blanchard, 1906; *T. bandicotti* Lingard, 1904; *T. nabiasi* Railliet; *T. leporis sylvatici* Watson; *T. acouchii* Brimont; *T. indicum* Lühe; *T. citelli* Watson; *T. spermophili* Laveran; *T. otospermophili* Wellman and Wherry; *T. petrodromi* Bruce, 1915.

Trypanosomes of Bats.—*T. vespertilionis* Battaglia, 1904; *T. megaderma* Wenyon, 1908; *T. nicolleorum* Ed. and Et. Sergent, 1905; *T. lineatus* Iturbe and Gonzalez, 1916.

Trypanosomes of Insectivora.—*T. talpæ* Nabarro; *T soricis* Hadwen.

Trypanosomes of Edentata.—*T. légeri* Mesnil and Brimont, 1910.

Trypanosomes of Carnivora.—*T. pestanai* Bettencourt and França, 1905.

Trypanosoma duttoni Thiroux, 1905.

Dutton and Todd in 1903 saw a flagellate organism in the blood of mice obtained in a house in McCarthy Island on the Gambia River, but they considered it to be of the type of a *Herpetomonas*; but in 1905 Thiroux described a definite trypanosome in *Mus musculus* L. in Senegal which will only infect mice of all kinds—*e.g.*, *M. minutus* L. (the harvest-mouse)—and it is possible that Dutton and Todd saw one stage of its development.

A number of interesting researches have taken place with this trypanosome. Pricolo found that it could pass through the placenta and multiply in the fœtus, in which he describes latent forms very like those already mentioned in *T. lewisi*—*i.e.*, which resembled Leishmania—having only a rod-shaped kinetonucleus and trophonucleus.

Trypanosomes were found in fleas caught on infected animals, but they did not show any development.

Trypanosoma musculi Kendall, 1906.

This parasite was found in 8 per cent. of the mice examined by Kendall in Panama. It was non-pathogenic, and resembled *T. duttoni*.

Trypanosoma microti Laveran and Pettit, 1909.

Found in *Microtus arvalis* Pallas. It is 25 to 30 μ by 1·5 μ.

Trypanosoma blanchardi Brumpt, 1905.

In *Myoxis glis*, the common dormouse. Like *T. lewisi*, but not inoculable into rats.

Trypanosoma myoxi R. Blanchard, 1906.

Found by Galli-Valerio in *Muscardium* (*Myoxis*) *avellanarius* L., but nothing much is known about the parasite.

Trypanosoma arvicanthidis Delanoe, 1915, from species of Arvicanthus and *T. eburnense* Delanoe, 1915, from Mus concha are varieties of *T. lewisi*.

Trypanosoma criceti Lühe, 1906.

Synonyms. *T. rabinowitschi* Brumpt, 1906.

This trypanosome, which is very like *T. lewisi*, but distinguished by not being transferable to the rat, was found in the hamster (*Cricetus cricetus* L.) by Koch in 1881. A blood-sucking louse has not been found on the hamster, but *Ceratophyllus fasciatus* Bosc is common.

Trypanosoma cuniculi R. Blanchard, 1906.

This trypanosome was found by Jobjet and Nabois in 1891 in the rabbit (*Lepus cuniculus* L.), in which it causes emaciation and perhaps diarrhœa. It is very similar to *T. lewisi*, but smaller. It will not infect white rats and guinea-pigs, but it can be cultivated. It is suspected that *Hæmatopinus ventricosus* Denny and *Pulex goniocephalus* Taschenberg may perhaps have something to do with its life-history.

Trypanosoma bandicotti Lingard, 1904.

This trypanosome is probably not the same as *T. lewisi*, which it resembles in being pathogenic to guinea-pigs. It is found in *Nesokia bandicotti* Bechst in Bombay and the Deccan.

Trypanosoma indicum Lühe, 1906.

T. indicum is found in the Indian squirrel (*Funambulus palmarum* L.) in Madras. It is very like *T. lewisi*, and only slight morphological differences can be found.

Trypanosoma vespertilionis Battaglia, 1905.

Synonym.- *Trypanosoma dionisii* Bettencourt and França, 1908.

Dionisi found a trypanosome in the Italian bat (*Miniopterus schreibersii*) in 1899, and since then numerous bats have been found to carry trypanosomes, and also they can be inoculated with the parasites of surra and mbori, which produce pathogenic effects.

T. vespertilionis has been found in bats from South Italy (Battaglia), Roman Campagna (Sambon), Brazil (Durham), India (Donovan), North Africa (Sergents), and from Portugal (Bettencourt and França). This parasite has been investigated by Battaglia, who has described a process of sporogony, and has shown that the blood filtered through a Kitasato filter is still infectious.

According to Pringault, *T. vespertilionis* is spread by *Cimex pipistrelli*.

Trypanosoma nicolleorum Ed. and Et. Sergent, 1905.

In the blood of *Vespertilio kuhli* Natt and *V. myotis* Bechst in Algeria; not transmissible to mice, rats, or rabbits.

The carrier of the infection is not known. Durham saw trypanosomes in *Stegomyia fasciata* which had fed on a bat, but they might have belonged to the mosquito. Fleas have been examined without success.

Trypanosoma theileri Bruce, 1902.

Synonym. *T. transvaaliense* Laveran, 1902

T. theileri is found in the Transvaal, in Togoland, East Africa, Transcaucasia, and in India. It is of large size, 60 to 70 μ in length and 4 to 5 μ in breadth. A small form is known, 25 to 53 μ in length and 2 to 3 μ in breadth. It moves very rapidly, and has a long flagellum, while the anterior end is pointed and the kinetonucleus is oval. Multiplication is by simple longitudinal fission. A female form has been described by Lühe. It is believed to be spread by species of Hippobosca, and is specific for bovines, not being inoculable into other animals. According to Nocht and Mayer, it is not the cause of gall-sickness or galziekté in cattle in Africa.

Carrier: *Hippobosca rufipes* (Fig. 117, p. 851). An allied species is *T. wrublewskii* Wladimiroff and Yakimoff, 1909.

Similar species are *T. himalayanum*, *T. indicum*, *T. muktesari* Langeard, 1904; *T. franki* Frosch, 1909, *T. americanum* Crawley, 1909; *T. rutherfordi* Hadwen, 1912.

SERIES B: THE PATHOGENIC MAMMALIAN TRYPANOSOMES.

Bruce has classified pathogenic mammalian trypanosomes into groups as follows:—

A. *Polymorphic trypanosomes* with granular cytoplasm, active movements, well-developed undulating membrane, small kinetonucleus. Spread by tsetse-flies, which are the definitive hosts in which development is completed in the salivary glands—*T. gambiense*, *T. brucei*, *T. rhodesiense*, *T. evansi*, *T. equiperdum*. (This group corresponds with the genus *Castellanella*.)

B. *Monomorphic trypanosomes* with non-granular cytoplasm. Spread by tsetse-flies, in which development is confined to the proboscis and hypopharynx. (This group agrees with the genus *Duttonella.*)

  I. Kinetonucleus large and terminal. Undulating membrane poorly developed and simple. Movements very rapid—*T. vivax, T. capræ, T. uniforme.* (Vivax sub-group.)

  II. Kinetonucleus prominent and subterminal. Undulating membrane well developed. Movements active—*T. pecorum* and *T. simiæ.* (Pecorum sub-group.)

Taking into consideration the above, we may arrange the pathogenic mammalian trypanosomes as follows:—

A. Classifiable:—

  I. Genus *Castellanella.*

Genus Castellanella Chalmers, 1918.

Definition.—Trypocastellanelleæ with the definitive host a fly and the intermediate host in a warm-blooded vertebrate. Without reproduction by schizogony in the vertebrate host, in which it is polymorphic, with granular cytoplasm, small kinetonucleus, and well-developed undulating membrane. Final stage in the definitive host is in the salivary glands. Infection is inoculative and transmission is ingestive (see Chapter XXXV., p. 878).

Co-Type Species.—*Castellanella gambiensis* (Dutton, 1902) and *Castellanella castellanii* (Kruse, 1903).

Other Species.—The species of the genus may be differentiated as follows:—

A. *Posteriorly nucleate in rats*:—
  I. Will not infect man. Kills an animal immunized against *C. rhodesiensis*—*C. brucei.*
  II. Infects man. Kills an animal immunized against *C. brucei*—*C. rhodesiensis.*
B. *Not posteriorly nucleate in rats*:—
  I. Infection direct from vertebrate host to vertebrate host during coitus—*C. equiperdum.*
  II. Infection by means of a definitive host:—
    (*a*) Definitive host not a tsetse-fly—*C. evansi.*
    (*b*) Definitive host a tsetse-fly:
      1. Causes chronic and often mild infections in man—*C. gambiensis.*
      2. Causes acute and severe infections in man—*C. castellanii.*

  II. Genus *Duttonella.*

Genus Duttonella Chalmers, 1918.

Definition.—Trypocastellanelleæ with definitive host in a fly and intermediate host in a warm-blooded vertebrate. Without reproduction by schizogony in the vertebrate host, in which it is monomorphic, with non-granular cytoplasm, a large kinetonucleus, which may be terminal or subterminal, with or without a well-developed undulating membrane. Movements active. Final stage in the definitive host is confined to the proboscis and hypopharynx.

Type Species.—Bruce's Uganda strain of *vivax*, which is probably the same as *cazalboui*.

Other Species.—The other species may be recognized as follows:—

(*a*) Kinetonucleus large and terminal. Undulating membrane well developed and simple. Invertebrate host a glossina:—
  1. Rats refractory—*Uniformis*.
  2. Rats susceptible—*Vivax*.
  3. Only equidæ and ruminants susceptible—*Capræ*.

(*b*) Kinetonucleus prominent and subterminal. Undulating membrane poorly developed:—
  1. Small, 8-18 microns; found in cattle—*Pecorum*.
  2. Larger, 14-24 microns; found in monkeys—*Simiæ*.

B. Unclassifiable:—

Genus *Trypanosoma sensû lato*:—

Group 1: Part of the flagellum always free.
Group 2: No part of the flagellum free.
Group 3: Part of the flagellum may or may not be free.
Group 4: Little-known forms.

TRYPANOSOMES OF ANIMALS.

FORMS CLASSIFIABLE.

Genus Castellanella Chalmers, 1918.

Castellanella evansi Steel, 1885.

Synonyms.—*Spirochæta evansi* Steel, 1885; *Hæmatomonas evansi* Crookshank, 1886; and *Trichomonas evansi* Crookshank, 1886. According to Yorke and Blacklock, *T. soudanense* and *T. venezuelense*, according to Bruce, *T. soudanense* Laveran.

Castellanella evansi, discovered by Evans in India in 1880, is the cause of a disease called surra, which occurs in horses, mules, camels, and cattle in India, Burma, Indo-China, Java, Philippines, Mauritius, and North Africa. With regard to cattle, they were supposed to be immune until the outbreak in Mauritius in 1902, which killed from 25 to 100 per cent. of the infected cattle.

Morphology.—This trypanosome, 25 μ in length and 1·5 μ in breadth, has a pointed anterior extremity, a long flagellum, and is actively motile. It reproduces asexually by simple division.

Walker finds that a schizogony takes place in the spleen of the vertebrate host. The trypanosome in the capillary bends round until its two ends meet and fuse, forming a ring, which may become a disc with the flagellum at first attached, but subsequently lost. These bodies measure 2·5 μ in diameter, and possess a kinetonucleus and a trophonucleus. They grow, and their nuclei divide until they reach a size of 10 to 15 μ in diameter, and divide into four to sixteen kineto- and tropho-nuclei, and eventually form mesozoites inside a thin cyst wall. Each mesozoite is 6 to 10 μ in length and 1 to 1·5 μ in width, with two nuclei, but no flagellum or undulating membrane. These mesozoites are believed to develop into trypanosomes. No dimorphism in these bodies has been seen.

Life-History.—Holmes recognizes male and female forms, which he considers conjugate by the anterior extremities only, after which the female divides, forming four amœboid bodies, which, in the liver, spleen, and bone-marrow, develop into trypanosomes. This appears to somewhat resemble the descriptions of Breinl and Hindle of latent forms in *C. castellanii*. *C. evansi* can be cultivated, and appears to develop in certain flies—for example, *Tabanus tropicus*, *T. lineola*, *Stomoxys calcitrans*, *S. geniculatus*, in the stomach of the last of which it has been found. Certainly it can be transmitted to healthy animals by the bites of flies and fleas. It is said that it can also be contracted by eating infected meat.

T. striatus Fabricius, according to Mitzmain, can mechanically transmit surra.

Pathogenicity. The symptoms are fever, remittent or intermittent, emaciation, œdema of the limbs and ventral surfaces, frequently lesions of the eyes and eyelids, great muscular weakness, paralysis, and death. The treatment is by arsenic. A variety, *C. evansi* var. *mborii* Laveran, 1905, is the cause of the disease mborri in dromedaries in Africa.

Castellanella brucei Plimmer and Bradford, 1899.

Synonyms.—Perhaps *T. cani* Blacklock and Yorke, 1913. According to Bruce, *T. rhodesiense* and *T. ugandæ*.

This parasite was discovered by Sir David and Lady Bruce in 1895 in animals suffering from the tsetse-fly disease or nagana (which means 'weakness') in Zululand. At the same time they showed that the tsetse-fly (*Glossina morsitans*) disseminated the disease.

The parasite is widespread throughout Africa, especially in Zululand, Northern Transvaal, and its surrounding countries; also from Pretoria to Lake Nyassa in the basin of the Limpopo, in the basin of the Zambesi, in East Africa, where it causes nagana or the fly disease, and in Uganda, where it is called 'jinja'.

Morphology. The appearance of the parasite is worm like, being 28 to 33 μ in length in horses and donkeys. The length is constant for the given animal, but varies in different hosts, being 26 to 27 μ in rats, mice, guinea pigs, rabbits, and dogs. The anterior end (non-flagellate) is a truncated cone, behind which lies the kinetonucleus as a well-marked rounded mass, posterior to which the flagellum arises. The trophonucleus lies in the middle of the body, and many chromatoid granules may be seen posterior to it, while still further posterior the free whip of the flagellum may be noted. Koch considers *C. brucei* to be identical with *C. evansi*, but the animal reactions clearly show them to be different species.

Life-History.—The life-cycle in the vertebrate host has not been very fully worked out, but the longitudinal division is well known. The kinetonucleus divides first, then the flagellum, then the trophonucleus, and finally the cytoplasm, but, according to Prowazek, division is really a very complicated process. First the blepharoplast becomes thickened, elongated, and dumb-bell-shaped, and then divides. In the trophonucleus the chromosomes behave like the kinetonucleus and the centrosome, and, having divided, the whole nucleus divides. The chromatin granules in the cytoplasm are also said to undergo fission, while a new flagellum develops from the new kinetonucleus. Parasites resembling the latent forms of Breinl and Hindle are known, and are called involution forms.

It is believed by some authorities that the parasite lives in nature in the wildebeeste (*Catoblepas gnu*), the koodoo (*Strepsiceros capensis*), the bush-buck (*Tragelaphus scriptus sylvaticus*), and the hyena, without causing disease. These may form a reserve from which the tsetse-flies *G. morsitans*, *G. pallidipes*, and *G. fusca* can obtain parasites which undergo development in their alimentary canal, during which time they are non-pathogenic, and when fully developed are found in the proboscis, and are again capable of being inoculated into animals, in some of which they are pathogenic. Kleine has proved that the transmission of the trypanosome is not merely mechanical, as suggested by Bruce and others, but also takes place after the trypanosome has undergone development in the fly, which is its true host. Thus, freshly caught *G. morsitans* for the first three days infected cattle, and then, from the fourth to the tenth day the flies were non-infective, but from the eleventh to the forty-fourth day they were very infective. This shows that the parasite must undergo a development in the fly.

Cultivation.—Novy and McNeal have cultivated *C. brucei* in the same manner as *Lewisonella lewisi*, and found some evidence of a toxin, but it only grows exceptionally in the water of condensation from the agar medium which contains half or less than half its volume of blood. Agglomeration takes place under various circumstances—*e.g.*, mixture with immune blood or a few drops of dilute acetic acid, etc.

Pathogenicity.—The disease can therefore be spread by the bites of certain tsetse-flies, particularly *G. morsitans* and perhaps the others mentioned above.

It can, however, be also spread by inoculation and by eating the blood of animals recently dead from the disease. The incubation period is about ten days, and the effects produced in animals vary considerably in the following manner:—

1. It is an acute disease in mice, rats, dogs, monkeys, cats, etc., dogs dying in two to six days, rats in three to six days.

2. It is a subacute disease in rabbits, guinea-pigs, equines, and pigs, a horse dying in fifteen to nineteen days.

3. It is a chronic disease in cattle, goats, geese, and fowls. In cattle it lasts from one week to six months.

Battaglia has succeeded in inoculating bitches by injecting some infected blood *in vaginam*. He has also infected rabbits by inoculating blood on the penis, when a hard, granulomatous nodule, very similar to a human syphilitic primary sore, developed.

Nagana is invariably fatal to the horse, the ass, and the dog, but a small percentage of bovines recover. In these animals it is characterized by fever, by an infiltration of coagulable lymph in the subcutaneous tissue of the neck, of the abdomen, or of the extremities, giving a swollen appearance to those parts; by a destruction more or less rapid of the red corpuscles of the blood, with an extreme emaciation, often blindness; and by the presence constantly in the blood of *C. brucei*.

Very few lesions are found at the autopsy, the most characteristic being:—

1. Enlargement of the spleen.

2. Trypanosomes in the blood.

3. Hypertrophy of the lymphatic glands, but apparently not associated with a development of the parasites in these organs.

4. In horses, the liver and spleen are hypertrophied, and there is yellow serous infiltration under the skin and mucosa and between the muscles, as well as some pleural and pericardial exudations and subpericardial ecchymoses. A gelatinous substance is found at times around the spinal cord.

According to Bradford, Plimmer, Yakimoff, Lanfranchi, Rondoni, Goretti and others, the spleen has a trypanolytic action, but this is denied by Laveran, Thiroux, Massaglia, and others.

The best treatment is arsenic in some form. Trypanroth, a benzine colour, and serum treatment have not proved of great service.

Castellanella equiperdum Doflein, 1901.

Synonym.—*T. rougeti* Laveran and Mesnil.

C. equiperdum is the cause of the disease called dourine or mal du coït in horses in Europe, India, North Africa (Algeria), and North America.

Morphology.—It is about 25 to 28 μ in length, and has no chromatic granules in the cytoplasm. It is difficult to find in naturally infected animals, being best obtained from the plaques of the eruption. Salvin-Moore and Breinl reported the presence of latent bodies in inoculated rats.

Life-History.—It does not appear to be spread by a fly, but by coitus between stallion and mare. Hence the disease resembles syphilis, and proves that a trypanosome is capable of penetrating a mucous membrane. The incubation is from eleven to twenty days.

Stage 1, *or the Period of Œdema.*—The genital organs begin to show signs of œdema, generally painless and not inflammatory, though there is some fever. In about a month the œdema disappears, and weakness and emaciation begin.

Stage 2, *or the Period of Eruption*, is characterized by the appearance in about forty to forty-five days (or two months) after infection of an eruption,

characterized by circular œdematous areas about the size of a two-shilling piece, generally under the skin of the sides and hind-quarters, but sometimes also under that of the neck, shoulders, and thighs. This eruption is very variable, and may appear in the morning and disappear at night, but generally it lasts a week, and leaves the animal in a feeble condition. There is also synovial engorgement of the joints and tendon-sheaths, and enlargement of the lymphatic glands, particularly the inguinal. The temperature is often raised to 39° C. (102·2° F.) in the evening, and falls to 38·5° C. (101·4° F.) in the morning.

Stage 3, or the Period of Anæmia and Paralysis.—The animal now becomes very anæmic, with pale mucosæ, and emaciation is marked. There are often superficial abscesses which do not heal, and some conjunctivitis and ulcerative keratitis. Micturition is difficult, and the urine is thick. Sensibility is diminished, and paralysis comes on, due to softening of the cord, and in from two to eighteen months the animal dies. The disease is said to be always fatal.

The above is the usual type of the disease, and may be called chronic dourine, but in addition there is an acute type, in which the animal dies after the first stage from acute paralysis, which comes on suddenly a few days after the appearance of the eruption.

The post-mortem lesions are in the spinal cord and the lymphatic glands. In the cord there is gelatinous exudation around the lumbar area, and cervical enlargement with intense chronic inflammation of the posterior spinal ganglia, with degeneration of the perikarya and their associated neurones, causing degeneration of the posterior roots and columns, as in tabes dorsalis.

The grey matter of the cord also shows chromolytic changes, with capillary hæmorrhages due to chronic inflammation. Mott says that the infiltration and thickening of the septa of the cord, the infiltration of the nerve roots and the vessel walls with lymphocytes, is like a syphilitic meningitis. The membranes at the base of the brain may also be affected. The lymphatic glands are enlarged, congested, and softened. The disease appears to begin by inoculation, and then to spread to the inguinal glands, and then to the pelvic lymphatics, and from them to the posterior lumbo-sacral roots, and thus the cord becomes affected. Other lesions are gelatinous exudation under the skin, serous effusions into the pleural and peritoneal cavities, wasting and pallor of muscles, with fatty degeneration and an interstitial keratitis.

Genus Duttonella Chalmers, 1918.

Duttonella vivax Ziemann, 1905.

Synonym. *Trypanosoma vivax* Ziemann, 1905.

This trypanosome was found by Ziemann in 1905 in the blood of cattle, sheep, and goats, suffering from 'souma' in the Cameroons. Morphologically it closely resembles *T. cazalboui*, but it differs in the following:—

1. Rats are susceptible to *T. vivax*, but not to *T. cazalboui*.
2. Cross immunity experiments indicate distinct differences.

Bruce's *T. vivax* is *T. cazalboui*, because rats are not susceptible to Bruce's Uganda strain. It is possible that a strain allied to *D. vivax* has been found by Macfie in human blood (*vide* p. 430).

The flagellate is very rapid in its movements. A large kinetonucleus and clear cytoplasm are present. It measures 16-31 × 2-3 microns, and has its flagellum always free. It is pathogenic for equidæ and ruminants. The development is anterior in the tsetse-fly, being confined to the proboscis.

Duttonella capræ Kleine, 1910.

Synonym. *Trypanosoma capræ* Kleine, 1910.

Found in sick goats near Tanganyika, it is capable of passing through its cycle of development in *G. morsitans* in some nineteen days after infection. Development only takes place in the proboscis. The final stage is in the hypopharynx, where the trypanosomes revert to the blood form and become infective.

It is a heavily built trypanosome, with very rapid movements, measuring

18-32 × 1·75-4·25 microns, and having the flagellum always free. It is pathogenic for equidæ and ruminants only.

Duttonella uniformis Bruce, Hamerton, Bateman, and Mackay, 1911.

Synonym.—*Trypanosoma uniforme* Bruce, Hamerton, Bateman, Mackie.

It is very like *T. cazalboui*, but smaller, and causes a very fatal disease in cattle. It is a small active trypanosome 16 × 1·5-2·5 microns, with the free part of the flagellum some 1-5 microns in length. There is no narrowing opposite the trophonucleus. It is spread by *Glossina palpalis*, which becomes infective in twenty-seven to thirty-seven days. The development is anterior, being confined to the proboscis.

Duttonella pecorum Bruce, Hamerton, Bateman, Mackie, 1910.

Synonym.—*Trypanosoma pecorum.*

This term probably includes *Trypanosoma dimorphon*, *T. congolense*, and *T. confusum*, Dr. Edington's Zanzibar trypanosome, the trypanosomes from Chai-Chai and from Southern Rhodesia.

It is found in cattle. It measures 8·0-18·0 microns, and is capable of passing through a cycle of development in *G. morsitans*, which becomes infective after twenty days. Development takes place like *T. simiæ* first in the gut, then in the labial cavity, and finally in the hypopharynx, where it becomes infective.

Duttonella simiæ Bruce, Harvey, Hamerton, Davey, and Lady Bruce, 1912.

Synonym.—*Trypanosoma ignotum* Kinghorn and Yorke, 1902.

It causes a rapidly fatal disease in monkeys and a chronic disease in goats. It is abundantly present in *Glossina morsitans* in Nyassaland and North-Eastern Rhodesia. It measures 14-24 × 1-2·75 microns, and is monomorphic. Its natural host appears to be *G. morsitans*, and the monkey seems to be a new host. The development is completed in the proboscis and hypopharynx.

FORMS UNCLASSIFIABLE.

Genus Trypanosoma *sensû lato.*

GROUP I: PART OF THE FLAGELLUM ALWAYS FREE.

They may be separated from one another according to the following scheme, based upon the invertebrate host, the pathogenicity, and the serum reactions:—

- A. *No invertebrate host*, spread directly from male to female by coitus:—
  - Kinetonucleus near aflagellar end and easily seen. Habitat America—*Hippicum*.
- B. *Invertebrate host not a Glossina*:—
  - I. Kinetonucleus very insignificant. Habitat, South America—*Equinum*.
  - II. Kinetonucleus ordinary. Parasite monomorphic. Habitat, various. Animal immune to *C. evansi* becomes infected with *T. togolense* and *T. soudanense*.
    - (*a*) Animal immune to *T. togolense*, infective by *C. evansi* and *T. soudanense*—*Togolense*.
    - (*b*) Animal immune to *T. soudanense* becomes infective by *C. evansi* and *T. togolense*—*Soudanense*.

C. *Invertebrate host a Glossina* :—
  Rats refractory. Large forms, 24 microns—*Cazalboui*.
D. *Invertebrate host unknown* :—
  I. Attacks horses :—
    (*a*) In Venezuela—*Venezuelense*.
    (*b*) In Morocco, separated by cross immunity—*Marocanum*.
    (*c*) In Algeria, separated by cross immunity—*Berberum*.
  II. Attacks horses and cattle :—
    In Annam—*Annamense*.
  III. Attacks cattle :—
    In Italian Somaliland—*Cellii*.

Trypanosoma equinum Vosges, 1901.

Synonym.—*T. elmassiani* Lignières.

T. equinum, discovered by Elmassian, is the cause of mal de caderas in horses and dogs in South America.

Morphology.—This parasite closely resembles *T. brucei* and *T. evansi*. In length it is 22 to 24 μ, and in breadth 1·5 μ, and it has the same measurements in different species of animals. It is very active, but its principal characteristic is that the kinetonucleus is very insignificant.

Life-History.—Multiplication is by equal binary division. It agglomerates, and has been cultivated by Thomas and Breinl on a rabbit's blood and chicken-broth agar medium.

It can be inoculated into the ordinary laboratory animals. Its mode of propagation is not well known, but Migone has shown that it is the cause of a disease which kills the capybara (*Hydrochœrus capybara*), which appears to be the reservoir for the parasite, as monkeys inoculated from a sick *Hydrochærus* died in seventeen days. How the disease spreads from the Carpinchós (*Hydrochærus*) to the horses is not clear. Dogs may be infected by eating diseased animals, and then from the dog the infection may be spread to the horse by fleas, because they have been found to infect rats. Some authorities consider that it may be spread by members of the Tabanidæ (Chrysops ?) and by *Stomoxys*, but Neiva has infected *Triatoma infestans* Klug, and its fæces produced the disease in guinea-pigs when placed on the conjunctiva.

Pathogenicity.—Mal de caderas is a very fatal disease among the horses of South America. The first sign of the disease is weakness, which makes rapid progress, though the appetite remains good. The temperature is febrile, and after a variable period the hind-quarters become paralyzed and the horse drags its limbs, the hoofs scraping the ground. As it walks it staggers, the hind-quarters oscillating from right to left, which characteristic gives the disease its name of mal de caderas, the disease of the hind-quarters. In the stable it can support itself against the walls, but in the open air it staggers and falls. There may be albuminuria and hæmaturia, and an eruption on the neck, shoulders, and hind-quarters. The eyelids show conjunctivitis and chemosis. The horse lives about two months after the paralysis sets in.

Congestion and enlargement of the spleen and mesenteric glands are seen in post mortems. The kidneys are affected, nephritis and interstitial hæmorrhages being noted. There are also serous exudations into the peritoneum, the pleura, the pericardium, and the spinal canal.

Trypanosoma soudanense Laveran, 1907.

Type of *Trypanosoma evansi* causing tahaga in dromedaries in the Upper Niger, el debab in Southern Algeria, and the zousfana in horses in Southern Algeria. Carriers Tabanidæ. Yorke and Blacklock consider this to be the same as *Castellanella evansi*.

Trypanosoma togolense Mesnil and Brimont, 1909.

Type of *Castellanella evansi*, parasitic in horses and cattle, and the cause of nagana in Togoland.

Trypanosoma (Duttonella) cazalboui Laveran, 1906.

This organism, which should be placed in the genus Duttonella, was found by Cazalbou in 1904 in 'souma,' a form of cattle trypanosomiasis in Upper Nigeria. The disease is known in West Africa, in Uganda, the French Congo, the Congo, and Rhodesia. It affects cattle, horses, mules, and donkeys, the incubation being seven days and the disease acute, subacute, or chronic. Cattle may die in eight days, two months, or more than twelve months. It is monomorphic, 24 × 1·5-2 microns, with an oval trophonucleus situate about the middle of the body, and a spherical kinetonucleus lying near the aflagellar extremity. The undulating membrane is not markedly folded, and the flagellum always becomes free. In the vertebrate there is the usual longitudinal division. Trautmann records the successful inoculation of *Cercopithecus patas*. It may develop in *G. palpalis*, *G. tachinoides*, *G. longipalpis*, or *G. morsitans*, and may be directly conveyed by stomoxys. *G. palpalis* is the usual carrier. The development is anterior, being restricted to the proboscis. The first three carriers become infective in six to seven days, and *G. morsitans* in eight to ten days, but in Uganda it may require eleven to thirty-five days to become infective in a fly, which difference may be due to climate. In the proboscis the trypanosome passes through leptomonas or crithidial forms, and becomes attached to the walls of the labrum and multiplies. Under the influence of the salivary secretion these forms become small, actively motile trypanosomes, which are the infective agent, and apparently remain in the fly for the remainder of its life.

Trypanosoma hippicum Darling, 1910.

This trypanosome causes a disease called murrina among mules, and was first described in some animals imported from the United States via New Orleans to Panama. The trypanosome resembles *Castellanella evansi*, being 18 to 28 μ in length, with a width of 1·5 to 3 μ. The trophonucleus is oval and median. The kinetonucleus, which is near the aflagellar end, is very easily seen, which is a characteristic feature of the parasite. The undulating membrane is not much folded. It divides longitudinally in the blood. It is spread by coitus, and can also be spread mechanically by species of *Musca*, *Compsomyia*, and *Sarcophaga* sucking wounds in the diseased and the healthy. The essential pathology of murrina is an intoxication resulting in cellular degeneration and necrosis. These toxins produce endotheliolysis, lymphocytosis, auto hæmagglutination, phagocytosis of erythrocytes and trypanosomes, hyperplasia of the spleen, bone marrow, and lymph glands, and cellular exudations into the kidney, liver, etc. Owing to the destruction of the endothelium there is considerable amount of ecchymosis in various regions.

Trypanosoma venezuelense Mesnil, 1910.

Type of *Castellanella evansi*, and considered by Yorke and Blacklock to be identical. Attacks horses in Venezuela; carrier unknown.

Trypanosoma annamense Laveran, 1911.

Type of *Castellanella evansi*; causes disease in horses and cattle in Annam. Carriers: Tabanidæ and Hippoboscidæ.

Trypanosoma cellii Martoglio, 1911

This trypanosome is pathogenic for cattle in Italian Somaliland, causing a disease called 'gobiat.' Pathogenic for dogs, rabbits, rats, and mice.

In bovines there are the following types: (1) Irregularly rounded, with short flagella inside some; (2) Leishmania-like forms; (3) Trypanosomes.

Trypanosoma marocanum Sergent, Lhéritier, and Belleval, 1915 (16-21 × 1·5-2·5 microns), is the cause of a disease of horses at Casablanca in Morocco. Morphologically it is identical with *T. berberum*, the cause of debab, but crossed immunity experiments separate it from this organism and from *T. equiperdum* and *T. soudanense*. Laveran says that there are two trypanosomes at work on Moroccan horses, one monomorphic and one polymorphic.

Trypanosoma berberum Edmond and Et. Sergent, and Lheritier, 1912, is the cause of debab in Algerian horses.

Group 2: No Part of the Flagellum Free.

Trypanosoma congolense Broden, 1904.

Synonyms.—According to Blacklock and Yorke, *T. dimorphon* (*sensû* Laveran and Mesnil); *T. confusum* (Montgomery and Kinghorn); *T. pecorum* (Bruce); *T. nanum* (Laveran).

This trypanosome causes disease among horses, cattle, sheep, and dromedaries in the French and Belgian Congos and in North-East Rhodesia. It is 10 to 17 μ long and 1 to 2 μ broad. Carrier, *Glossina morsitans*, which is infective twenty-three days after a feed thereon. The alimentary canal is full of parasites, and the labrum contains the Leptomonas type, while the small infective trypanosomes are in the hypopharynx.

Trypanosoma dimorphon Laveran and Mesnil, 1904.

This trypanosome was discovered by Dutton and Todd in 1904 in horses on the Gambia, and is now known to exist in several parts of Africa, where perhaps a wide equatorial belt across the continent is affected. It is also found in cattle, dogs, pigs, sheep, and goats.

Morphology.—It exists in three forms:

1. *Tadpole Form.*—Found in the early stage of the disease, 11 to 13 μ long and 0·18 μ broad.

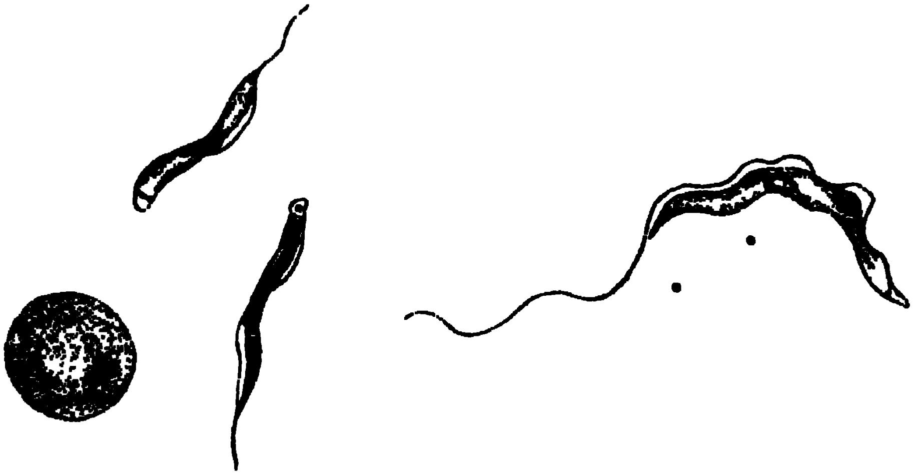

FIG. 104.—*Trypanosoma dimorphon* LAVERAN AND MESNIL.
(After Dutton and Todd.)

2. *Stumpy Form.*—Seen when the disease is not too far advanced, and characterized by a short thick body and a short flagellum. Length 16 to 19 μ, breadth 3·4 to 3·5 μ.

3. *Long Form.*—With long thin body and long flagellum, found a few days before death. Length, 26 to 30 μ; breadth, 1·6 to 2 μ.

These may be respectively indifferent, female, and male forms of the parasite, a view supported by Hindle.

It has been cultivated, and it can be inoculated into rats, mice, guinea-pigs, and rabbits, as well as horses.

Life-History.—Hindle's observations show that the indifferent forms give rise to latent bodies or cysts which gather in the spleen, where they lie dormant for a time, and finally develop again in trypanosomes. It apparently can undergo development in *Glossina palpalis*, as Bruce and Hamerton have shown that it is a carrier, while Bouet and Roubaud have shown that *G. tachinoides* and *G. longipalpis* can also transmit the parasite as in *G. morsitans*. The development is by multiplication in the intestine, and then in the form of Leptomonas or Crithidia in the proboscis, after which the fly becomes infective in about eighteen days from the date of the infective feed.

Pathogenicity.—The symptoms in the horse begin with loss of vigour, followed in two to three weeks by fever. During the next month the weakness is more marked and the abdomen swells, the testicles hang down and are œdematous, the coat becomes staring, the animal looks apathetic, and death ensues in about a year.

The post mortem shows œdema of the abdominal wall and a coloured fluid in the pleura and pericardium, with hypertrophy of the lymphatic glands, fatty liver, and congestion of the lungs. The spleen is normal.

Trypanosoma frobeniusi Weissenborn, 1911.

Allied to *T. dimorphon* and *T. congolense*, and found in horses in Togoland.

Trypanosoma nanum Laveran 1905.

Balfour in 1904 discovered this parasite in cattle, which appeared to be ill, on the White Nile. The parasites are small (10 to 14 μ by 1·5 to 2 μ), with no free flagellum, and are non-pathogenic for dogs, rabbits, and monkeys. Amœboid forms were found in the cerebro-spinal fluid. Duke in 1912 showed that it was transmitted by *Glossina palpalis*, in which it developed in the hind gut, and from thence forwards to the œsophagus, but did not infect the salivary glands. Development according to Miss Robertson, takes place in *G. palpalis*, and is like *Castellanella castellanii*, but with crithidial phase in proboscis, not in salivary glands. The parasite develops in the hind intestine and reaches the proventriculus on the twentieth day, and the proboscis on the twenty fifth, where they become crithidial forms, and finally trypanosomes which, however, may only be developed in the hypopharynx.

GROUP 3: PART OF THE FLAGELLUM MAY OR MAY NOT BE FREE.

Trypanosoma pecaudi Laveran, 1907.

In the French Sudan, in addition to m'bori and souma, there is a third disease, baleri, in Equidae caused by *T. pecaudi*, with two forms like *T. dimorphon*: (1) long and slender (25 to 35 μ by 1·5 μ), (2) short and broad (14 to 20 μ by 3 to 4 μ). Carriers: *Glossina longipalpis*, rarely *G. palpalis* and *G. tachinoides*.

The incubation in *G. longipalpis* is about twenty three days. The trypanosomes multiply in the intestine, and in seven to nine days invade the whole intestine and pharynx. The parasites now enter the proboscis and pass through crithidial and leptomonas stages. Finally, some reach the hypopharynx, where they assume the '*salivary trypanosome form*' and become infective.

LITTLE KNOWN TRYPANOSOMES

Trypanosoma elephantis Bruce, Hamerton, and Mackie, 1909, has been found in the elephant in Uganda; it resembles *T. soudanense*.

Trypanosoma ingens Bruce, Hamerton, and Mackie, 1909, has been found in the reed buck and ox in Uganda, it is of large size (72 to 122 μ by 7 to 10 μ).

Trypanosoma giganteum Lingard was found twice in cattle suffering from symptoms similar to those found in surra.

Trypanosoma bovis Kleine was found in sick cattle near Tanganyika

THE TRYPANOSOMES OF MAN.

There is evidence that man is infected with a variety of trypanosomes, the number of which is likely to be increased in the near future. Those described in man are:

1. *Trypanosoma gambiense* Dutton, 1902.
2. *Trypanosoma castellanii* Kruse, 1903.
3. *Trypanosoma vivax* Ziemann, 1905, varietas *macfiense.*
4. *Trypanosoma cruzi* Chagas, 1909.
5. *Trypanosoma rhodesiense* Stephens and Fantham, 1910.
6. *Trypanosoma nigeriense* Macfie, 1913.
7. *Trypanosoma gambiense* varietas *longum* Da Costa, St. Anna, Dos Santos, and Alvares, 1915.

When a classification is desired it is always necessary to attempt to discover the characters of the original species, which in this case is *T. gambiense* Dutton, 1902. Sixteen years have passed since the slides containing the original specimens of Dutton and Todd were made, and, therefore, as the original strain has long been lost, the only method of comparing other organisms with the original specimens is morphological. Chalmers and O'Farrell have made this comparison by measuring one thousand non-dividing forms in the original slides. As far as measurements go, these strains are very similar, but, as we have repeatedly insisted, morphology often may not help in separating closely related but perhaps quite distinct species, which require to be studied serologically and with regard to animal pathogenicity, and, in cases of human infection, with regard to the nature of the disease in man. Thus Stephens has pointed out that *T. lewisi* and *T. rabinowitschi*, *T. brucei* and *T. evansi*, *T. pecaudi* and *T. ugandæ*, *T. rhodesiense* and *T. pecaudi* are indistinguishable morphologically, but are distinct biologically.

We mention these points in order to make clear to the reader the necessity of comparing human trypanosomes by means of the clinical features of the disease in man, the serum reactions and animal experiments, as well as by morphological characters, and we have suggested for years that the name *T. gambiense* covered a number of different forms, which at the present time is generally admitted with regard to *T. rhodesiense*. And why not? Are there not a number of different trypanosomes in wild animals in Africa, and is it impossible that man should from time to time become infected by one of these, even if it does not appear in epidemic form in the human race? To exemplify we draw attention to an organism resembling *T. vivax* found by Macfie in man.

Sir David Bruce believes that *T. rhodesiense* Stephens and Fantham, 1910, is the same as *T. brucei* Plimmer and Bradford, 1899, but this can hardly be so, because Laveran and Nattan-Larrier have immunized a ram against *T. brucei*, and then infected it with *T. rhodesiense*, an acutely lethal infection ensuing. The serological experiments of Chalmers and O'Farrell *in vitro* and *in vivo* also show the same marked differences between *T. rhodesiense* and another posterior nucleate trypanosome. These experiments, to our mind, are more important than measurements, and more important than finding that the development in *Glossina morsitans* is very similar in both variants. *T. rhodesiense* may have been derived in recent times from *T. brucei*, but its altered environment in man has changed its physiological characters. As the fly remains the same, one would expect this portion of the life-cycle to be similar in the two trypanosomes.

We look upon *T. nigeriense* and *T. gambiense* var. *longum* as belonging to *T. gambiense*, because, apart from the morphological similarity, to which we do not assign importance, their pathological action in man and the lower animals appears to be identical.

As a result of these considerations, and changing the names so as to agree with the new nomenclature, we recognize the following parasites of man:—

A. *Belonging to the genus Castellanella*:—
  1. *Castellanella gambiensis* (Dutton, 1902).
  2. *Castellanella castellanii* (Kruse, 1903).
  3. *Castellanella rhodesiensis* (Stephens and Fantham, 1910).
B. *Belonging to the genus Duttonella*:
  4. *Duttonella vivax* (Ziemann, 1905), var. *Macfiensis* (Castellani and Chalmers, 1918)
C. *Belonging to the genus Schizotrypanum*:—
  5. *Schizotrypanum cruzi* Chagas 1909.

These five species may be differentiated as follows:—

A. With schizogony—*S. cruzi*.
B. Without schizogony:—
  I. Monomorphic—*D. vivax*.
  II. Polymorphic:
    (*a*) Posteriorly nucleate *C. rhodesiensis*.
    (*b*) Not posteriorly nucleate.—
      1. Animal infections chronic and comparatively mild. Common North-West Africa—*C. gambiensis*.
      2. Animal infections severe. Common Equatorial Africa—*C. castellanii*.

Castellanella gambiensis (Dutton, 1902).

Usual old name *Trypanosoma gambiense* Dutton, 1902.

Synonyms.—*T. nepveui* Sambon, 1903; *T. hominis* Manson, 1903; *T. fordii* Maxwell, 1903; *T. nigeriense* Macfie, 1913; *T. gambiense* var. *longum* Da Costa, St. Anna, Dos Santos, and Alvares, 1915.

Definition.—Castellanella without schizogony, polymorphic, trophonucleus not situate close to aflagellar end. Infections chronic.

History.—This trypanosome was first noticed by Ford in a case of peculiar fever on the Gambia. He showed the parasite to Dutton, who, recognizing it to be a trypanosome, described and named it; and they considered it to be the cause of Gambia fever, which was never thought by them to be connected with sleeping sickness. The organism had, however, been previously seen in the blood of man and imperfectly described by Nepveu. We consider it to be the same organism as that described by Scott Macfie in 1913 as *T. nigeriense*. Yorke and Blacklock in 1915 consider that man is the chief reservoir of this parasite in Sierra Leone, where sleeping sickness is very chronic and difficult to recognize. A secondary reservoir is in cattle. They record two cases with very mild symptoms. Sartory, Lasseur, and Brissaud record *C. gambiensis* trypanosomiasis in a French soldier who had left Africa for eight years, and had never been in a tsetse-fly area. In Africa he lived in Algiers, at El Golea, and went to Timimoun. Bagshawe draws attention to Nepveu's 1888 and 1890 observations, which have never been explained.

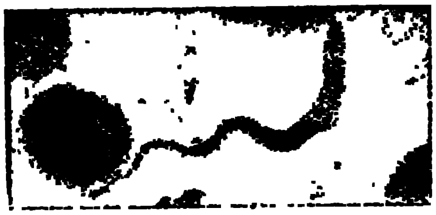

Fig. 105.—*Castellanella gambiensis* (Dutton, 1902). (× 1,200 Diameters.) Long form from the original Gambia fever case (Mr. K.) discovered by Dutton. (Photomicrograph.)

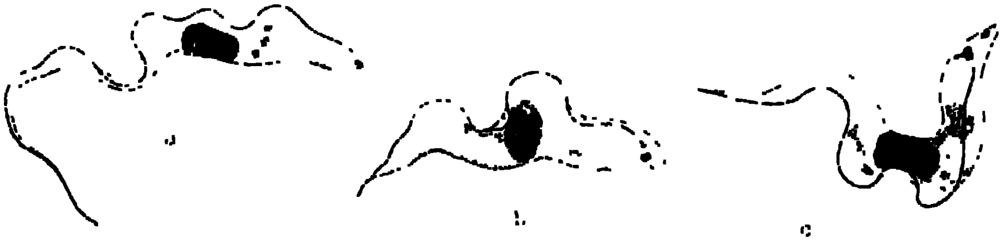

Fig. 106.—*Castellanella gambiensis* (Dutton, 1902). (× 1,200 Diameters.) Original Gambia specimens from a rat inoculated from the second case of Gambia fever, showing polymorphism [illegible], long, intermediate, and short forms.

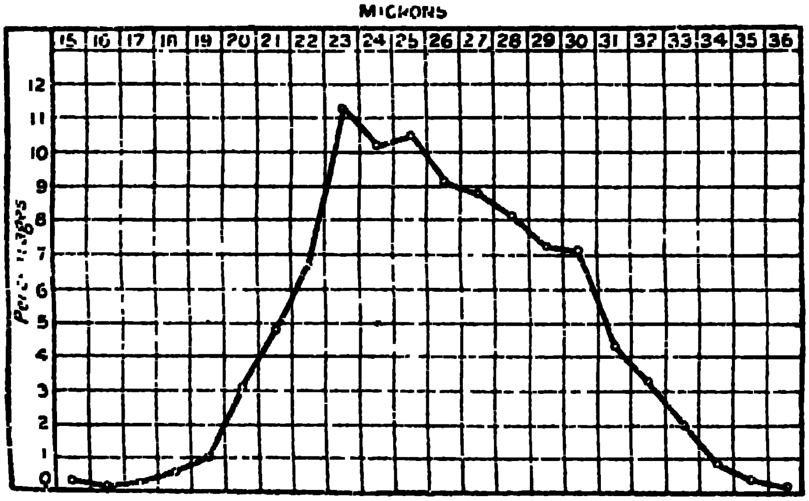

Fig. 107.—*Castellanella gambiensis* (Dutton). Chart of Lengths.

Morphology.—It is a polymorphic trypanosome, and morphologically does not differ essentially from *C. castellanii*, of which a detailed description is given below.

Life-History. This has not been fully studied, and it is not definitely known whether it takes place in *Glossina palpalis* or in some allied tsetse-fly.

Serum Reactions.—These reactions require to be studied in detail.

Pathogenicity. It causes a form of sleeping sickness, which apparently is more chronic than that produced by *C. castellanii*, while the symptoms are often less severe, though the termination is fatal without treatment, to which it appears to be more amenable.

Castellanella castellanii (Kruse, 1903).

Usual old name *Trypanosoma castellanii* Kruse, 1903.

Synonym.—*T. ugandense* Castellani, 1903.

C. castellanii was first seen in the cerebro-spinal fluid of cases of sleeping sickness by Castellani in 1902, and reported by him as the cause of the disease in 1903; he asserted also the probable plurality of species of the trypanosomes affecting man, in analogy to what takes place in the lower animals, such as horses and cattle. Bruce and Nabarro demonstrated the fact first suggested by Sambon and Brumpt that it could be spread by a tsetse-fly, *Glossina palpalis*; and Kleine has demonstrated that the transmission is not merely mechanical, but also takes place after a period during which the fly is non-infective, the deduction being that the trypanosome must undergo a development in the fly which acts as a true host. Finally Miss Robertson worked out the life cycle in the tsetse-fly.

FIG. 108.—*Castellanella castellanii* (KRUSE, 1903).

The original trypanosome found by Castellani in cerebro-spinal fluid of a case of sleeping sickness in Uganda. (Photomicrograph.)

Morphology.—*C. castellanii* measures from 14 to 33 μ in length and from 2 to 2·5 μ in breadth (Laveran and Mesnil give 17 to 28 μ in length and 1·4 to 2 μ in breadth); but, as already stated, it is very polymorphic, having short forms 14 to 20 μ, medium forms 20 to 24 μ, and long forms 23 to 33 μ. The anterior end is variable and sometimes rounded; the kinetonucleus is an oval body, behind which is often seen a vacuole. The trophonucleus is oval in shape, and situated about the middle of the body, behind which there may be some chromatic granules in the cytoplasm, which at the posterior end runs along the flagellum for a considerable distance.

Asexual Reproduction.—The life-history of the parasite in the human body is not accurately known. It can often be obtained from the peripheral blood, but sometimes the most prolonged search fails to demonstrate it. It can then be found by puncturing the enlarged lymphatic glands, by scarification of the eruption, or by puncture of the spinal canal, if the case is one of sleeping sickness.

Salvin, Moore, and Breinl have, however, investigated the life-cycle in the rat, in which, after inoculation, the parasites increase to a maximum in the peripheral blood, and then decline gradually to nil, at which they remain for a period—the latent period—and then increase again in numbers and reappear in the peripheral blood.

Their investigations give the following results: The parasite may grow to a fair size, and then divide into two by simple fission, and this may be repeated till the blood is swarming with them. When this is the case, a relatively thick band, said by Swellengrebel to be composed of metachromatic or volutine granules (axial filament), such as that described by Miss Robertson in *T. rajæ* and by Prowazek in *T. lewisi*, grows from the kinetonucleus down the endoplasm till it reaches or even passes the nucleus, or it may coil on itself, but eventually is connected with the trophonucleus.

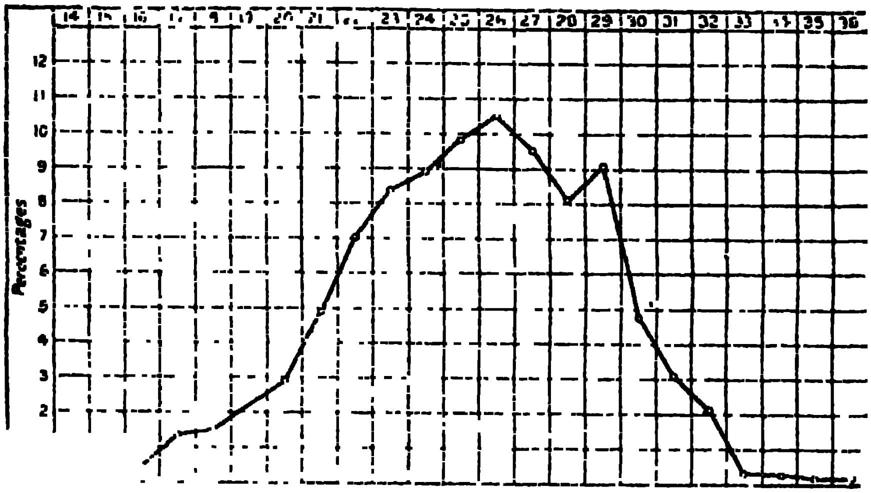

FIG. 109.—*Castellanella castellanii.* CHART OF LENGTHS.

The trypanosomes now decrease in numbers in the peripheral blood, and are found in the lungs, spleen, and bone-marrow. In these organs the protoplasm becomes detached from the periphery of the nucleus, which lies in a clear space. The nucleus contracts, and a large clear vesicle forms in connection with it, and around both a cytoplasmic sheath is formed. The rest of the cell body now disintegrates, and the flagellum with the kinetonucleus may be seen lying detached. These bodies now become lodged in the spleen and bone-marrow, where they remain intact for a period of ten days or more—through the whole of the negative or latent period when the trypanosomes are missing from the blood of the infected rat. Moore and Breinl, therefore, call them latent bodies. They consist of a flattened nucleus, containing a centrosome, and attached to a vesicle, the whole being surrounded by a ring of cytoplasm. This latent phase has been confirmed by Fantham.

Just before the reappearance of the trypanosomes in the peri-

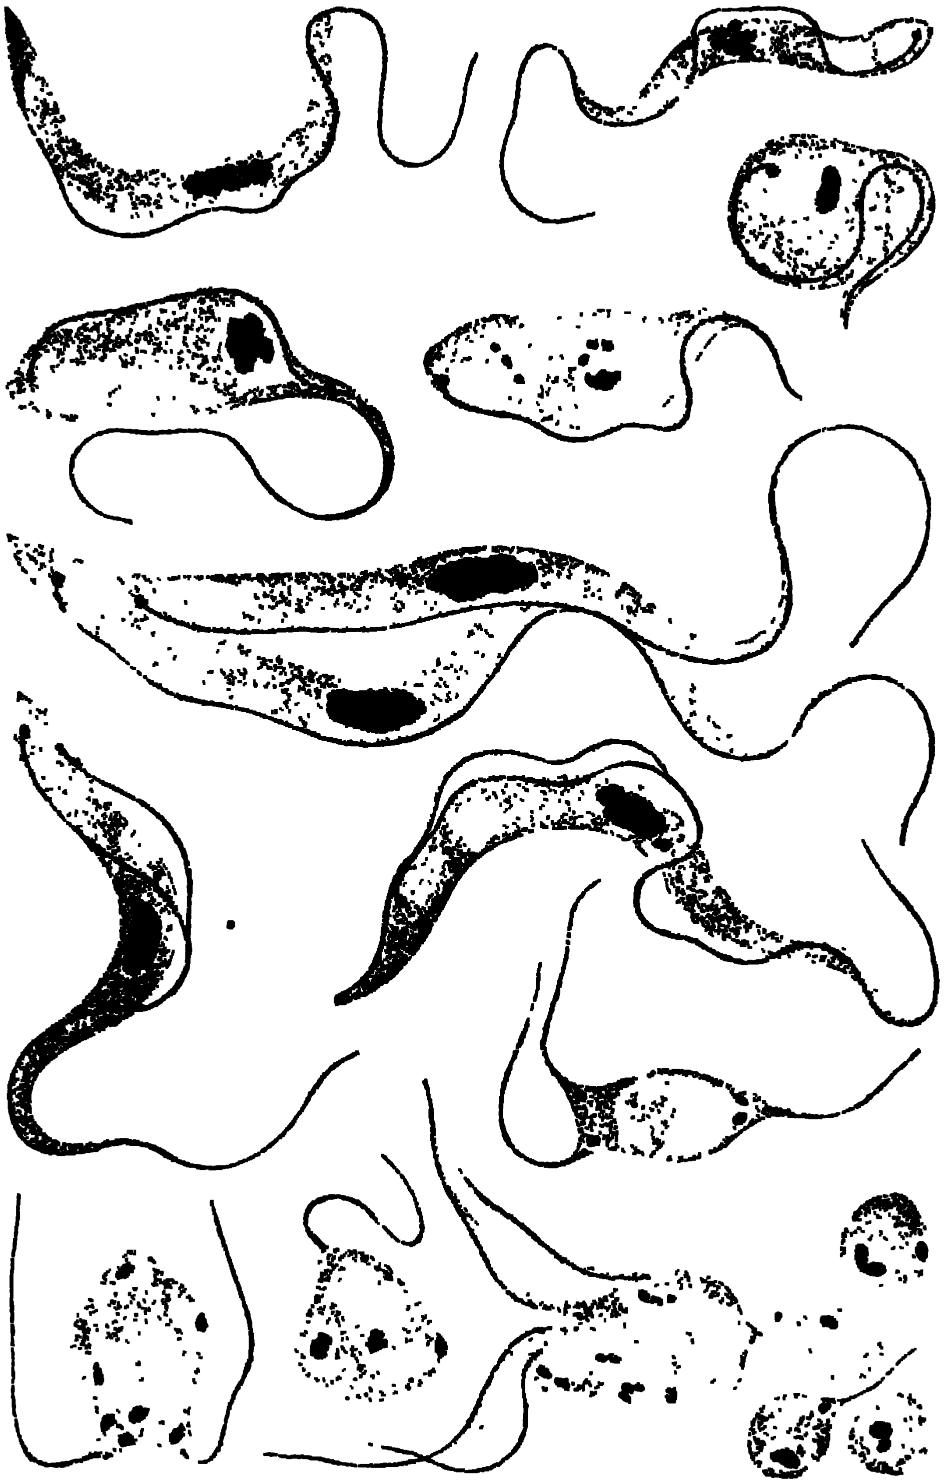

FIG. 110 *Castellanella castellanii* (KRUSE, 1903).

(Forms found in the cerebro-spinal fluid.)

The figures in the top row show the ordinary forms; in the second row the stumpy forms; in the third and fourth rows longitudinal division. The lowest row shows multinucleate and polyflagellate forms (Rabinowitsch-Kempner forms), and small round flagellate and non-flagellate forms (Plimmer-Bradford and Castellani's forms). (From Castellani's report in Reports of the Royal Society on Sleeping Sickness.)

pheral blood the centrosome inside the nucleus divides, and the new centrosome, escaping from the nucleus, becomes the kinetonucleus, and lies in the cytoplasm, which has now increased in amount. The vesicle has gradually disappeared. A new flagellum now appears, and gradually the latent body becomes a trypanosome. The rounded bodies with one or two nuclei, with or without the small flagella, are probably identical with the forms found by Castellani several years ago in the cerebro-spinal fluid of cases of sleeping sickness, and described by him under the term 'amœboid forms.'

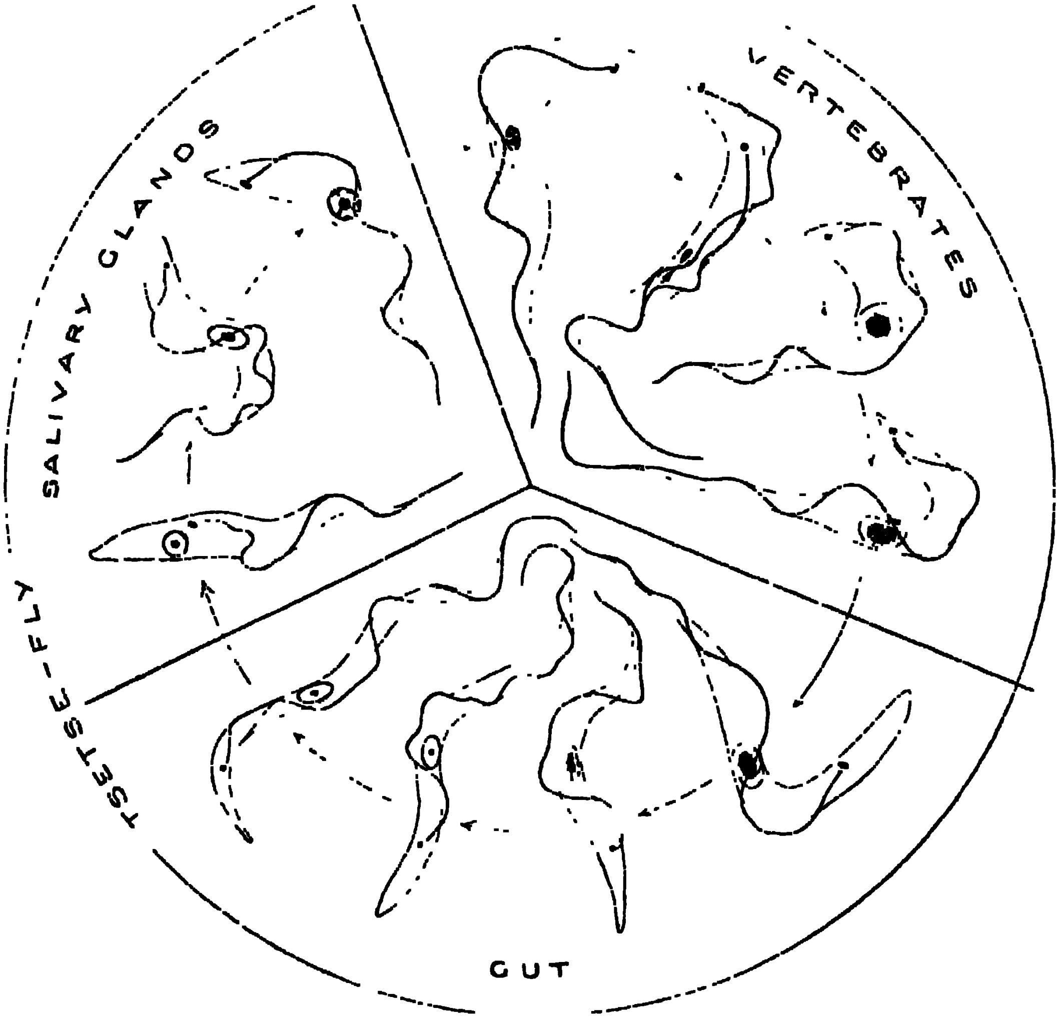

FIG. 111.—*Castellanella castellanii.* Life-Cycle.

Reproduction in the Fly. The researches of Kleine, Taute, Bruce, Hamerton, Bateman, and Mackie have shown that, after ingestion at a correct period (as demonstrated by Miss Robertson), the trypanosomes enter the stomach of the fly, and in twenty-four hours lose their infectivity, as demonstrated by inoculation. According to Miss Robertson, the trypanosomes multiply in the posterior part of the mid-gut, and after the tenth or twelfth day give rise to long forms which move forwards into the proventriculus between the twelfth and twentieth day, after which they pass along the hypopharynx into the salivary glands. Here they become attached to the walls and are converted into crithidial forms, which divide, forming small trypanosomes similar to those found in the blood of the vertebrate. The salivary gland development requires two to five days before the fly becomes infective, which only happens in about 8 per cent. of flies. The duration of the life cycle in the fly depends upon the air temperature.

Vertebrate Reservoir.—Duke considers that he has proved that the Sitatunga antelope is a reservoir for this trypanosome, and considers that the infection of two boys working on the uninhabited islands of Victoria Nyanza and constantly exposed to bites of *G. palpalis* is confirmatory.

Pathogenicity.—It is the cause of one form of sleeping sickness.

Castellanella rhodesiensis (Stephens and Fantham, 1910).

Synonym. *Trypanosoma rhodesiense* Stephens and Fantham, 1910.

History.—In 1910 Stephens and Fantham advanced the view that the trypanosomes found in cases of sleeping sickness in the Luangwa Valley in Rhodesia belonged to a new species, because the trophonucleus of a certain percentage of short forms was situate either close to or even on the aflagellar side of the kinetonucleus. This view is at the present time accepted by the majority of authorities, although there are some who maintain that it is a variety of *C. brucei*, in which similar forms have also been seen. The animal reactions of the new trypanosome were studied by Yorke in 1910, Bevan in 1911, and more recently by other observers. In 1912 Kinghorn and Yorke showed that this trypanosome was transmissible by *Glossina morsitans*, in which it underwent development. They demonstrated that it occurred in waterbuck, hartebeest, impala, and wart-hogs, as well as in native dogs, and they further showed the importance of atmospheric temperature on the length of time required for the cycle of development in the fly.

Morphology.—*C. rhodesiensis* closely resembles *C. castellanii* in general appearance. It has a length varying from 12 to 31 μ, with an average of 21·5 μ, and shows the usual pleomorphic forms—*e.g.*, short stumpy forms varying from 13 to 21 μ in length; intermediate forms, 22 to 24 μ in length; and long, slender forms 25 μ or more in length. The most common are the long, slender forms. The position of the trophonucleus is variable, but it is usually situate towards the aflagellar end of the parasite, and in the short stumpy forms is often close to the kinetonucleus, or even on its aflagellar side.

Life-History.—(*a*) *In the Vertebrate* longitudinal division can take place as in *C. castellanii*. About the time that trypanosomes are most numerous in the blood the researches of Fantham show that some forms in the lungs become converted into latent bodies by disintegration and loss of the flagellar end, followed by a migration of the kinetonucleus towards the trophonucleus, and a subsequent casting off of the aflagellar end with the remains of the flagellum. The result of this posterior and anterior reduction in length is to produce a rounded body, with a trophonucleus and a kinetonucleus, which surrounds itself with a capsule and forms the latent body or *the post-flagellate stage* of the life-cycle. These cysts are about 2 to 4 μ in diameter.

After a time these bodies become the *preflagellate stage*, increase in size and length, and eventually a flagellum grows out from the kinetonucleus and gives rise to the undulating membrane, and thus again forms the usual *flagellate stage*.

(*b*) *In the Invertebrate.* *Glossina morsitans*, when fed upon infected animals, is capable of spreading the infection mechanically for about twenty-four hours, after which period it ceases to be infective, and remains non-infective for at least fourteen days, after which about 5 per cent. of flies become again infective, when trypanosomes can be demonstrated in its alimentary canal and in its salivary glands.

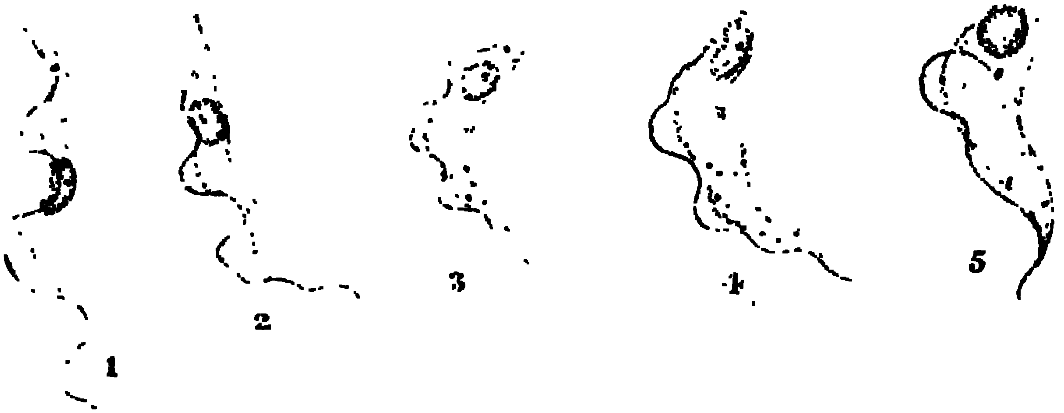

FIG. 112.—*Castellanella rhodesiensis* (STEPHENS AND FANTHAM).
(After Stephens and Fantham.)
1, Long narrow form; 2-4, nucleus passing to aflagellar end; 5, nucleus at the aflagellar end.

Zoological Distribution.—As mentioned above, this parasite occurs not merely in man and domestic animals, but also in big game.

Specificity.—The question now arises, Is it a good species or not? First of all, is it *T. castellanii*?

(*a*) *Sero Diagnosis.*—(1) Attachment experiments are very inconstant, and do not distinguish between the two.

(2) Trypanolysis does not help, being also inconstant.

(3) *C. castellanii* is resistant to human serum. *C. rhodesiensis* is less resistant.

(*b*) *Crossed Immunity.*—An animal having an immunity against *C. castellanii* can be infected by *C. rhodesiensis*. The reverse experiment has not yet been conducted.

We may therefore conclude that *C. castellanii* and *C. rhodesiensis* are different species.

Is *C. rhodesiensis* a variety of *C. brucei*? The answer is No, because Laveran has shown that animals immunized against

C. brucei are susceptible to *C. rhodesiensis*. Is *C. rhodesiensis* a variety of *T. pecaudi ?* No, because the former is more virulent than the latter to animals, and because sleeping sickness is unknown in the region where 'baleri' is intense, and, finally, because an animal immunized against *C. rhodesiensis* is not immune against *T. pecaudi*.

We may therefore conclude that *C. rhodesiensis* Stephens and Fantham, 1910, is a good species.

Cultures.—Thomson has cultured it with partial success on a modification of the Novy-McNeal-Nicolle medium.

Vertebrate Reservoir.—It is claimed that the larger game animals are the reservoir of this trypanosome.

Pathogenicity.—*C. rhodesiensis* is the cause of one form of sleeping sickness.

Schizotrypanum cruzi Chagas, 1909.

Synonym.—*Trypanosoma cruzi* Chagas, 1909.

History.—This trypanosome was discovered by Chagas in the intestine of *Lamus megistus* Burmeister in Brazil, and later it was found in the blood of a child suffering from irregular fever, progressive anaemia, and enlargement of various groups of lymphatic glands. The trypanosome was characterized by the presence of a large kinetonucleus, and by the facility with which it could be cultivated on blood agar. In 1910-11 Chagas published a series of papers upon the life-history of the parasite and the symptomatology of the disease which it produces. In 1911 Vianna studied the pathological anatomy, while further studies on the parasite were made by Brumpt, Martin Mayer, Rocha-Lima, and others.

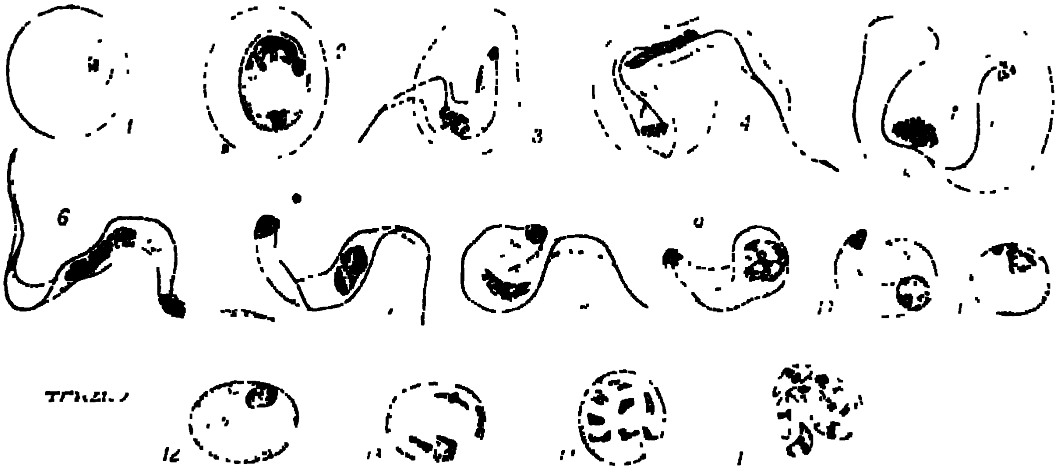

FIG. 113.—SCHIZOGONY OF *Schizotrypanum cruzi* CHAGAS. (After Chagas.)

1, Merozoite in red blood cell; 2, parasite totally enclosed in red cell, no flagellum or undulating membrane; 3-5, parasites partially enclosed in red cell; 6, 7, parasites in human blood; 8-11, parasites in the lungs of Callithrix; 12, 13, initial forms of schizogony; 14, 15, schizogony in the lungs of Callithrix.

Morphology.—In the peripheral blood of man *S. cruzi* appears in two forms—either free or in the red blood-corpuscles.

The free forms are also differentiated into two forms—viz., one with a large egg-shaped kinetonucleus, with a chromatic appendage, and with an oval or band-like trophonucleus with a centrosome. The flagellum starts from the kinetonucleus or from its chromatic appendage.

In the second free form the kinetonucleus is round and smaller than the first, and has, as a rule, no chromatic appendage. This form is broader than the one previously described. Whether this is a sexual differentiation or not is unknown.

The intraglobular forms may be completely or partially enclosed in the red cell, or merely attached by the aflagellar end.

Measurements of these forms were not originally given by Chagas, but it would appear as though the average length was 20 μ, with a certain amount of variation.

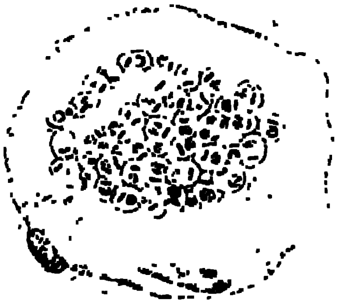

FIG. 114. TRANSVERSE SECTION OF A STRIATED MUSCLE CONTAINING *S. cruzi* CHAGAS IN THE CENTRAL PORTION (× 1,300.)

(After Vianna.)

Life-History.—*Schizogony.*—*S. cruzi* is remarkable in that it is not known to undergo longitudinal division either in the peripheral blood or the internal organs of its host. According to Chagas, there is a regular cyclic development, the parasite entering the capillaries of the lungs, where it loses its flagellum and undulating membrane, while the trophonucleus moves nearer the flagellar end, and the whole parasite becomes curved, first into a half-moon, and finally so much that the two ends fuse, forming a ring and finally a disc. In some instances the kinetonucleus disappears, while in others it fuses with the trophonucleus, after which the nucleus divides into eight, and eventually gives rise to eight merozoites lying inside the periplast, which acts like a cyst wall. The merozoites with kinetonuclei are considered to be microgametes, and those without kinetonuclei to be macrogametes. The merozoites escape from the periplast wall singly, and, entering the red blood cells, become flagellates, and, finally leaving the red cell, become free in the liquor sanguinis, thus completing the cycle of gametogony, or differentiation and multiplication of gametes.

Agamogony, or asexual reproduction, takes place in the cells of various organs—*i.e.*, in hypertrophied endothelial cells in the lungs, in the cardiac muscle, in the neuroglia of the central nervous system, and in striped muscle. In these situations the parasite appears as a rounded body with trophonucleus and kinetonucleus, but without flagellum or undulating membrane. Agamogony increases the number of parasites in the host, and is responsible for the production of the symptoms, while gametogony differentiates the sexual forms, and presumably lays the basis for the infection of the invertebrate host. This form of development is confirmed by Brumpt.

In the Invertebrate.—The further development takes place in the bug *Lamus megistus* (*Triatoma megista*) and allied forms, in which Chagas notes two forms of development: the first is considered to be sexual, and the second to be asexual.

The sexual method is as follows: In about six hours after the ingestion of blood the kinetonucleus moves close to the trophonucleus, with which it possibly blends; the flagellum and undulating membrane are now usually lost, but some forms retain the flagellum. The parasite now becomes rounded, and multiplies rapidly by division, but after this has ceased it becomes pear-shaped, develops a flagellum, and becomes a crithidial form, and then passes into the cylindrical portion of the intestine in which it can be seen in about twenty-five hours after the ingestion of blood. These crithidial forms can also be found in the rectum and in the fæces. The final stage is a small trypaniform type—*i.e.*, long, slim forms, with band-like trophonucleus and large kinetonucleus. These are found in the hind-gut in the body cavity, and in the salivary glands, and are the forms by which the parasite is transmitted to a new vertebrate host. The development in the bug requires at least eight days for its completion.

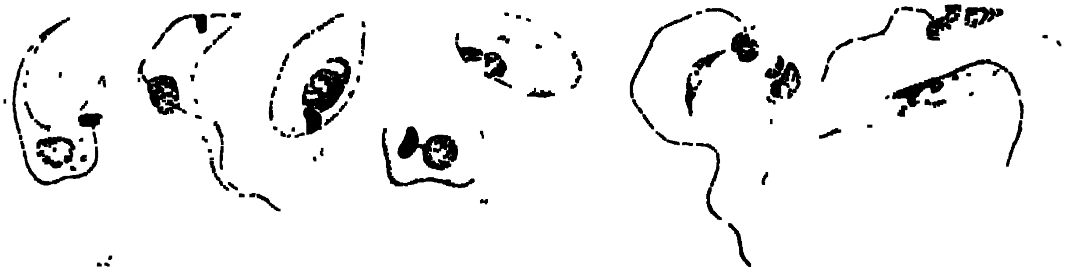

FIG. 115. *Schizotrypanum cruzi* CHAGAS: DEVELOPMENT IN *Lamus megistus* (*Triatoma megista*).

(After Chagas.)

1-6, Forms found in the mid-gut of *Lamus megistus*; 7, flagellate forms found in the posterior segment of *L. megistus*.

FIG. 116. *Schizotrypanum cruzi* CHAGAS.

(After Chagas.)

Forms found in the salivary glands of *Lamus megistus* (*Triatoma megista*)

The asexual method is a constant process, and resembles the growth seen in artificial cultures, and is a simple multiplication, giving rise to crithidial forms which are found principally in the hind-gut.

Brumpt finds that the parasite lives well in *Clinocoris lectularius*, *C. rotundatus*, *Clinocoris boueti*, and *Ornithodorus moubata*. His account of the cycle of development is as follows:—Starting with the trypanosome in the posterior part of the intestine, when this is inoculated into the vertebrate, it enters the cells of the body, and becomes Leishmania-like bodies, which eventually develop into free-swimming trypanosomes, from which the form capable of continuing the infection in the vertebrate or invertebrate is produced. In the invertebrate these become crithidia-like forms, and eventually trypanosomes capable of infecting vertebrates, and thus completing the cycle of life history.

Brumpt and Gonzalez-Lugo have found the parasite in the fæces of *Rhodnius prolixus* two months after infection. *Triatoma vitticeps* and *T. dimidiata* are also carriers, as is *T. sordida* Stal and *Rhipicephalus sanguineus*.

Culture.—*S. cruzi* is easily cultivated upon the Novy-McNeal medium, when the first changes begin in about six hours, and closely resemble those already described in the bug.

Pathogenicity.—Two to three days after an infective feed the larvæ of *Lamus* cease to be infective to vertebrates, and first become so on the eighth to the tenth day, after which they remain infective for a long period. The parasites so introduced into man give rise to American trypanosomiasis.

Reduction in Virulence.—*S. cruzi*, when repeatedly passed through animals of the same species, become weakened in virulence, but regain this when transmitted to a fresh species.

Infectivity.—The infected monkey is infective for the bug, while the infected guinea-pig is not.

Duttonella vivax Ziemann, 1905, var. macfiensis.

Synonym.—*Trypanosoma vivax* (Ziemann, 1905) *pro parte*.

In 1917 Macfie described a monomorphic trypanosome very closely resembling *T. vivax*, but slightly smaller, with the crest in curves of measurements at 21 instead of at 23 microns. It is said to be intermediate between *T. uniforme* and *T. vivax*.

It was found in the blood of a man suffering from trypanosomiasis on the Gold Coast, where *T. vivax* is common in the humpbacked cattle at Accra. The maximum length was 24 microns, the minimum 18 microns, and the average 20·7 microns.

It is monomorphic, with abrupt narrowing of the body immediately anterior to the trophonucleus. The posterior (aflagellar) end is blunt, and the large rounded kinetonucleus is terminal or nearly so. The undulating membrane is narrow, and there is always a long free flagellum.

Castellanella nigeriensis Macfie, 1913.

This trypanosome was found in cases of human trypanosomiasis from the Eket district of Southern Nigeria, by Macfie, where it was common in young people. It appears to give rise to a not very virulent, non epidemic form of trypanosomiasis. It is polymorphic, and in our opinion is the same parasite as the original *C. gambiensis*, of which it appears to be merely a variant. We have placed it as a synonym of *C. gambiensis*.

Castellanella lanfranchii Lanfranchi, 1915.

It approximates to *C. evansi*, and is the organism with which Lanfranchi accidentally inoculated himself. As regards precipitating and complement fixation power is very similar to *C. evansi*, but as regards trypanolytic action of the serum it approximates more *C. castellanii*.

APPENDIX: INCERTÆ SEDIS.

In this addendum to the Trypanosomidæ we include the genus Leucocytozoön and the Spirochætacea. With regard to the former—*Leucocytozoön* Danilewsky, 1889—a number of species have been described of which the life-history is but imperfectly known, except in the case of *L. ziemanni*, which has been studied by Schaudinn, and partly in *L. lovati*, which has been carefully studied by Fantham. They are only definitely known to occur in birds, and must be distinguished from the Hæmogregarines of mammals.

Leucocytozoön Danilewsky, 1889.

Synonyms.—*Hæmamœba* Laveran, 1903; *Spirochæta* Schaudinn, 1904; *Trypanomorpha* Woodcock, 1906.

The leucocytozoa were first described by Danilewsky between 1884 and 1886 in the blood of the wood-owl (*Syrnium aluco*) and other Strigidæ.

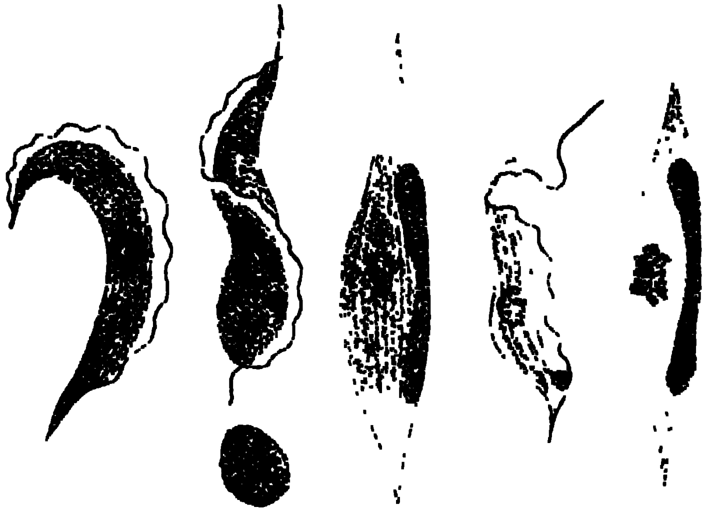

FIG. 117.—*Leucocytozoön danilewskyi* Ziemann.
(After Schaudinn.)

From the left to the right, a macrogametocyte free, same attached to a blood cell, same enclosed in a blood cell; a free microgametocyte, same enclosed in a blood cell.

He described them as spherical or oval, slightly granular bodies contained in a delicate transparent homogeneous capsule, which possessed a large elongated nucleus, compressed in the middle, and broadened at the extremities. This capsule he believed to be a degenerated leucocyte, but later he held it to be an erythrocyte. He also described macrogametes and motile oökinetes, and later he described the microgametocytes. In 1893 Sakharoff confirmed these observations and described new species in ravens, rooks, and magpies. In 1895 Theobald Smith discovered a leucocytozoön in *Meleagris gallapavo domestica* (the turkey); and in 1898 Ziemann described another specimen in *Glaucidium noctuæ* (the little owl) from Crema, in Italy. In 1902 and 1903 Laveran described forms in birds with mixed infections, and stated that he considered that they were contained in red blood cells. In 1904

Berestneff described several forms in owls, ravens, and magpies, but noted that they were in leucocytes, and in the same year came Schaudinn's paper on the development of *Leucocytozoon ziemanni*, which is given in detail later on. The Sergents, in studying the parasite in the little owl in Algeria, supported Schaudinn. In 1905 Laveran and Lucet studied Theobald Smith's parasite, and concluded that it was enclosed in a leucocyte. In 1906 Neave described a parasite in *Numida ptilorhyncha*, and in 1907 Sambon and Seligmann described one in *Lagopus scoticus* (the red grouse); and Dutton, Todd, and Tobey another in *[illegible]* (the Congo grey hawk); and lastly Sambon has reviewed the whole genus in a singularly able manner, and has described species from the capercailzie (*Tetrao urogallus*) and the pheasant (*Phasianus colchicus*). Important work has been done by Fantham, who demonstrated schizogony in *L. lovati* Sambon and Seligmann, 1907. E. H. Ross has suggested that Kurloff bodies may be Leucocytozoa, and may produce a spirochaete-like organism.

Leucocytozoon danilewskyi Ziemann, 1898.

Synonyms. *Haemamoeba ziemanni* Laveran, 1902; *Spirochaeta ziemanni* Schaudinn, 1904; *[illegible]* Blanchard, 1905; *Leucocytozoon*

FIG. 118.—INTRACELLULAR FORM OF *Leucocytozoon lovati*. (After Sambon.)

FIG. 119.—INTRACELLULAR MICROGAMETOCYTE OF *Leucocytozoon lovati*. (After Seligmann and Sambon.)

FIG. 120.—INTRACELLULAR MACROGAMETOCYTE OF *Leucocytozoon lovati*. (After Seligmann and Sambon.)

ziemanni Lühe 1906. *L. danilewskyi* is found as a parasite in the haematoblasts (or according to other authors, in the leucocytes) of the little owl, *Glaucidium noctua* (*Athene noctua* Retz.), and the wood owl, *Syrnium aluco* L.

The history of the life cycle, according to Schaudinn, may be begun with the biting of the owl by *Culex pipiens* L., and the sucking of blood containing micro- and macro-gametocytes.

Microgametocyte.—The microgametocyte may attain dimensions much larger than a leucocyte, and exists in the blood of the owl in two conditions: (1) a free active stage in the liquor sanguinis; (2) endocellular resting stage in a blood cell; and, later, when the parasite has become too large to penetrate a host cell, free in the blood stream. In this condition the parasite may engulf the cells which formerly served it for food and shelter.

(1) *Free Active Stage.*—This is the trypanosome stage (*T. ziemanni*). The anterior end is sharp-pointed, with a kinetonucleus just at its base, from which the flagellum arises, passing posteriorly along the body and projecting some distance from the posterior end. There is a well-defined undulating membrane, with sixteen myonemes arranged in four double rows or pairs on each side. The trophonucleus is well developed, and situate near the centre of the trypanosome.

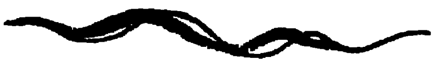

FIG. 121.—*Leucocytozoön danilewskyi* ZIEMANN: MICROGAMETE. (After Schaudinn.)

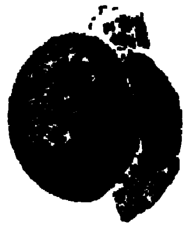

FIG. 122.—*Leucocytozoön danilewskyi* ZIEMANN: MACROGAMETE. (After Schaudinn.)

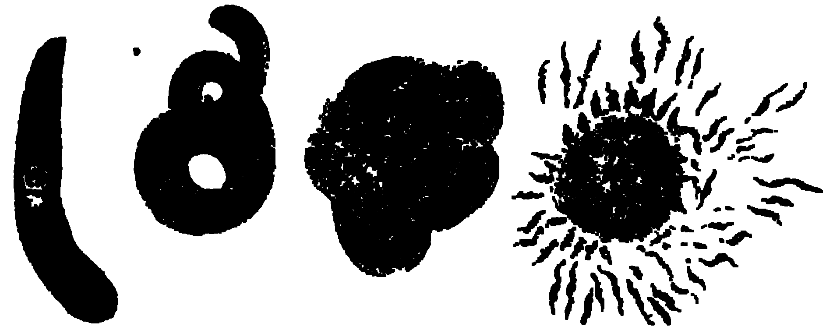

FIG. 123.—*Leucocytozoön danilewskyi* ZIEMANN: THE DEVELOPMENT OF THE OÖKINETE AND THE FORMATION OF SMALL TRYPANIFORM BODIES. (After Schaudinn.)

(2) *Endocellular Resting Stage.*—In the intracellular stage the parasite is quite spindle-shaped, the ends being composed of ectoplasm, while the endoplasm forms a dark oval central mass containing the trophonucleus, close to which the kinetonucleus is situated. The flagellum has disappeared, but the myonemes of the ectoplasm can still be seen.

Macrogametocyte.—This has also two stages—(1) free, (2) endocellular.

(1) *Free Active Stage.*—The free stage differs from the microgametocyte in being larger, in having no free projection of the flagellum, and in having smaller tropho- and kineto-nuclei, and in the myonemes not being arranged in pairs.

(2) *Resting Stage.*—This differs from the microgametocyte in being large, with smaller nuclei.

These gametocytes, called 'leucocytozoön' by Danilewsky and 'hæmamœba' by Laveran, being found in the peripheral blood of the owl, are sucked into the stomach of *Culex pipiens*, and then proceed to conjugation.

Microgamete.—The microgametocyte escapes from the capsule-like periplast, and its nucleus breaks up into eight double chromosomes, which are reduced to eight single chromosomes. These travel to the periphery, and form microgametes in the manner described for *Hæmoproteus noctuæ*, microgametes which they are said to resemble.

Macrogamete.—The macrogametocyte escapes from its enclosing cell, and the process of development of the macrogamete is the same as in *Hæmoproteus*.

Fertilization.—This is the same as in *Hæmoproteus*.

Oökinete.—There are the same three kinds of oökinetes as in *Hæmoproteus*—viz., the indifferent, the male, the female.

The ookinete, however, differs by growing in size and multiplication of its nuclei, and at the same time coiling upon itself so as to form a skein. This skein contains a large number of nuclei uniformly distributed.

Around each of these, small portions of protoplasm gather, and become finally separated off, to form small indifferent trypanosomes in the case of the indifferent ookinete, male trypanosomes from the male ookinete, female trypanosomes from the female ookinete. A large mass of residual protoplasm is left.

These trypanosomes, especially the male, are very minute, and reproduce by longitudinal division, during which they do not separate at once, but remain attached posteriorly. Couples attached to one another may extend into the same straight line, thus giving rise to a spirochæte-like form, and while in this position may undergo longitudinal division. The spirochæte forms may become pear-shaped resting forms.

In the Owl.—On entering into the owl, the indifferent forms pass through alternate endocellular and free stages. In the former there is growth, and in the latter there is division into smaller forms. After some time micro- and macrogametocytes are formed in increasing numbers.

This life-history has been doubted, but Sambon has seen forms in which a coiled trypanosome body can be detected in the blood cells.

The Enclosing Cell.—There has been great doubt as to the character of the body enclosing a leucocytozoon.

1. Ziemann, Schaudinn, Dutton, Todd, and Tobey believe that it is a portion of the parasite itself—*i.e.*, the periplast—and that it may enclose a red blood cell.

2. Danilewsky considers it to be a leucocyte, but derived his red cells from leucocytes. In considering it to be a leucocyte, he is supported by Laveran, Lucet, Sakharoff, and Berestneff, and most recent observers.

3. Laveran in his earlier observations believes it to be a red cell, and this Sambon supports, as do Keysselitz and Mayer.

It may be taken to be a much-enlarged dehæmoglobinized hæmatoblast or red cell, the spindle shape of which may be explained by the fusiform shape of the hæmatoblasts, and by the pseudopodia of the young parasites protruding into the long ends of the host cell. When the parasite contracts, these ends shrivel up, giving rise to the usual appearance.

The Spirochætes.—At first Schaudinn, after tracing out the life-history described above, thought that all spirochætes would be found to be allied to true trypanosomes; but in 1905 he stated that the spirochæte-like forms which he found in the little owl were far removed from true spirochætes, and that the relationship was only phylogenetic, and very distant at that.

E. H. Ross has brought evidence to show that Kurloff's bodies (*i.e.*, clear spherical vacuoles in the large lymphocytes of guinea-pigs) are intracorpuscular stages in the life-history of a Leucocytozoon (*Lymphocytozoön cobayæ* E. H. Ross, 1912) which ultimately give rise to spirochæte-like bodies, the development of which he traces, and which he considers to be the gametes. Later he and McDonagh described a similar origin for *Treponema pallidum*.

Recent work has tended to confirm the doubts thrown on Schaudinn's work, but the general appearance of a Leucocytozoön in its cell is sometimes remarkably similar to a trypanosome. It is possible that there may be

different parasites confused under the term Leucocytozoön, and their life-histories may be different, as Fantham's work, presently to be described, is opposed to Schaudinn's work.

Leucocytozoön lovati Sambon and Seligmann, 1907.

This leucocytozoon was discovered by Sambon and Seligmann in the red grouse (*Lagopus scoticus*), and has been recently restudied by Fantham. The microgametocyte and macrogametocyte are depicted in Figs. 119 and 120 on p. 432, and were till recently the only forms known, but Fantham has now found the schizonts, and described the process of schizogony.

Sporogony.- The microgametocytes measure 13 to 17 μ in length by 6 to 12 μ in breadth, and possess hyaline pale staining cytoplasm with a large, rather granular nucleus. The macrogametocyte measures 14 to 20 μ in length by 10 to 16 μ in breadth, and has a granular somewhat alveolar cytoplasm with a central nucleus with a karyosome. Their further development is unknown, but Fantham has found vermicules in *Ornithomyia lagopodis*, the grouse-fly, which may be the agent of transmission.

Schizogony.- The schizont is found in the spleen in cells which they almost fill and absorb, and which they do not elongate in the way in which the gametocytes deform their host cells. The schizont measures 11 to 14 μ by 8 to 11 μ, and is therefore of an oval shape, with a nucleus resembling that of the microgametocyte, and a cytoplasm like that of the macrogametocyte

The nucleus divides by rapid binary fission into some 12 to 20 small nuclei and then the cytoplasm divides, giving rise to 12 to 20 merozoites, which are small vermicules measuring 7 to 8 μ by 1 to 1·5 μ There is some residual cytoplasm after division. The merozoites now escape from the parasite and cell, and for a very brief period become free, swimming in the liquor sanguinis, and then quickly re-enter leucocytes or immature erythrocytes, and ultimately differentiate into gametocytes or schizonts.

Remarks. This process of schizogony may explain the periodical increase in the gametocytes in the blood noted by Mathis and Léger in *L. caulleryi* in Tonkin. Fantham very carefully points out that the above life-history may not take place in all Leucocytozoidæ, but, notwithstanding this, Fantham's results do not support Schaudinn's researches.

Species. Some of the species described are: *Leucocytozoön majoris* Laveran, 1902, in the great tit (*Parus major*); *L. sakharoffi* Sambon, 1908, in the raven (*Corvus corax*); *L. berestneffi* Sambon, 1908, in the magpie (*Pica pica*); *L. danilewskyi* Ziemann, 1898, in the little owl (*Athene noctua*); *L. toddi* Sambon, 1907, in the Congo grey hawk (*Asturinula monogrammica*); *L. mansoni* Sambon, 1908, in the capercailzie (*Tetrao urogallus*); *L. lovati* Sambon and Seligmann, in the red grouse (*Lagopus scoticus*); *L. macleani* Sambon, 1908, in the common pheasant (*Phasianus colchicus*); *L. smithi* Laveran and Lucet, 1905, in the domestic turkey (*Meleagris gallopavo domestica*); *L. neavei* Balfour, 1906, in the Abyssinian guinea-fowl (*Numidia ptilorhyncha*); *L. caulleryi* Mathis and Léger, 1911, *L. sabrazesi* in *Gallus ferrugineus*, *L. martini* Mathis and Léger in *Pavo cristatus*; *L. marchouxi* Mathis and Léger in *Turtur humilis*, and *L. leboeufi* Mathis and Léger in *Querquedula crecca*.

Spirochætacea Fantham, 1908.

Synonyms.- *Proflagellata* Doflein; *Spiroschaudinnidæ* Sambon, 1907; *Spiroflagellata* Krzysztalowicz and Siedlecki, 1907.

Definition.- Plasmodromata, generally parasitic, in form narrow, wavy, and thread-like, with or without an undulating membrane. The cytoplasm is divided into endoplasm and ectoplasm, and is bounded by a flexible, chitinous periplast. The nucleus consists of a spiral achromatic filament, on which are arranged transverse bars or rodlets of deeply staining chromatin.

Remarks.—The Spirochætacea are closely related to the Binucleata, and especially to the Trypanosomidæ.

The Treponemata are joined to the spirochætes because of their general resemblance, though it must be admitted that no nucleus of the nature of the spirochæte nucleus has yet been described, and the spirals are apparently not due to movement.

The Spirochætacea are potent factors in the production of disease, for *S. recurrentis* is the cause of one type of relapsing fever, *S. carteri* of another, *S. duttoni* of another, and *S. novyi* of yet another, while the Treponemata are the cause of syphilis and yaws.

The Spirochætacea may be divided into two families:—

1. With undulating membrane: Spirochætidæ.
2. Without undulating membrane: Treponemidæ.

Spirochætidæ Ehrenberg, 1883.

Definition.—Spirochætacea with an undulating membrane. Body may be ribbon-shaped on transverse section.

Type Species.—*Spirochæta plicatilis* Ehrenberg, 1833.

Remarks.—There is a difference of opinion as to whether these organisms are protozoa or bacteria. At first they were universally regarded as bacteria, but in 1904 Schaudinn's paper on the leucocytozoon in the little owl indicated that this body, after fertilization in the gut of *Culex pipiens* and subsequent asexual division, produced a large number of minute forms which he at the time considered to be spirochætes, and he further concluded that in all probability all spirochætes were stages in the life-history of intracellular parasites. In 1905, however, he came to the conclusion that the spirochæte forms which he had seen develop from *T. ziemanni* were trypanosomes. In fact, there is one great point of difference—the forms which he described possess a distinctly consolidated nucleus, whereas spirochætes do not. After this the view that spirochætes were bacteria was revived, particularly by Novy and Knapp, on the following grounds:—

1. Absence of trophonucleus.
2. Transverse division.
3. Rapid multiplication.
4. Absence of plasmolysis with distilled water.
5. Persistence of form when acted upon by heat.
6. The production of active immunity.
7. The absence of aerotropism—*i.e.*, the tendency to mass round a bubble of air.

Dobell, as a result of his prolonged inquiries, came to the conclusion that they are Schiophyta (bacteria + Cyanophyceæ), and not protozoa. He also concludes that they belong to the bacteria, and probably constitute a group of the same systematic status as the cocci, the bacilli, and the spirilla.

On the other hand, there is a growing feeling among biologists that spirochætes are really protozoa—*e.g.*, Doflein, Minchin, Sambon, Nuttall, Fantham, and Krzysztalowicz and Sisdlecki. Fantham points out that the strongest arguments in favour of their being bacteria are:—

1. Diffuse character of nucleus somewhat like *Bacillus bütschilii.*
2. The possible occurrence of transverse fission.
3. The absence of a typical kinetonucleus.

While the points in favour of their belonging to the protozoa are:—

1. The possession of an undulating membrane.
2. The occurrence of longitudinal division (denied by Schellach).
3. The non-plasmolysis.
4. Difficulty to find artificial media on which they can grow.

We consider that they are protozoa, and, further, that they are related to the trypanosomes. Spirochætes are, however, distinctly peculiar, particularly with regard to their diffuse nucleus; but there appears to be almost a series from the diffuse nucleus of the bacteria through the achromatic spiral, with its attached chromosomes of the spirochætes, to the condensed nucleus of the higher protozoa. Schellach derives them phylogenetically from the oscillatory cyanophees, genus *Spirulina.*

Morphology.—Spirochætes vary much in size, from *Spiroschaudinnia recurrentis*, which is 8 μ in length, to *Cristispira balbianii*, which may be 150 μ in length and 2 to 3 μ in thickness. The type species *Spirochæta plicatilis* was found in muddy water by Ehrenberg in 1833, and was said by Schaudinn in 1905 to possess an undulating membrane. Sambon, however, considers that this so-called type species is quite different from *S. recurrentis*, and should be placed in a different group therefrom. The most carefully studied types are *Cristispira balbianii* Certés, 1882, found in oysters, and *Cristispira anodontæ* Keysselitz, 1906, emended Schellach, 1909, both of which have been the subject of research by Fantham, whose results are here followed. These organisms are long, wavy, and thread-like, composed of cytoplasm, which can be differentiated into an ectoplasm, which is generally converted into a thin, flexible, chitinous membrane, the periplast. This is continued laterally into a spirally arranged membrane, the crista, containing longitudinally arranged fibrillæ, and having a thickened border composed of chromatin. The longitudinal fibrillæ are composed of eight to nine principal and numerous secondary fibrillæ, which are contractile, and are called 'the myoneme fibrillæ' (Fig. 124). The membrane, or crista, which does not markedly undulate, helps in locomotion, which is rapid, and takes place by a wave-like flexion of the body, which causes forward movement, and a corkscrew motion, produced by the spiral winding of the membrane, enabling the parasite to bore its way through the débris amidst which it may be living. A spirochæte can move backwards or forwards indifferently.

The endoplasm is slightly more granular than the ectoplasm, and contains a diffuse nucleus, which appears to consist of an achromatic filament with bars of chromatin.

In addition to this nucleus there is a dot of chromatin (basal granules) at each end of the periplast in *C. balbianii*, and only at one end in *C. anodontæ*; in the latter a short, stiff process of periplast projects from it, which is considered by some observers to be a flagellum.

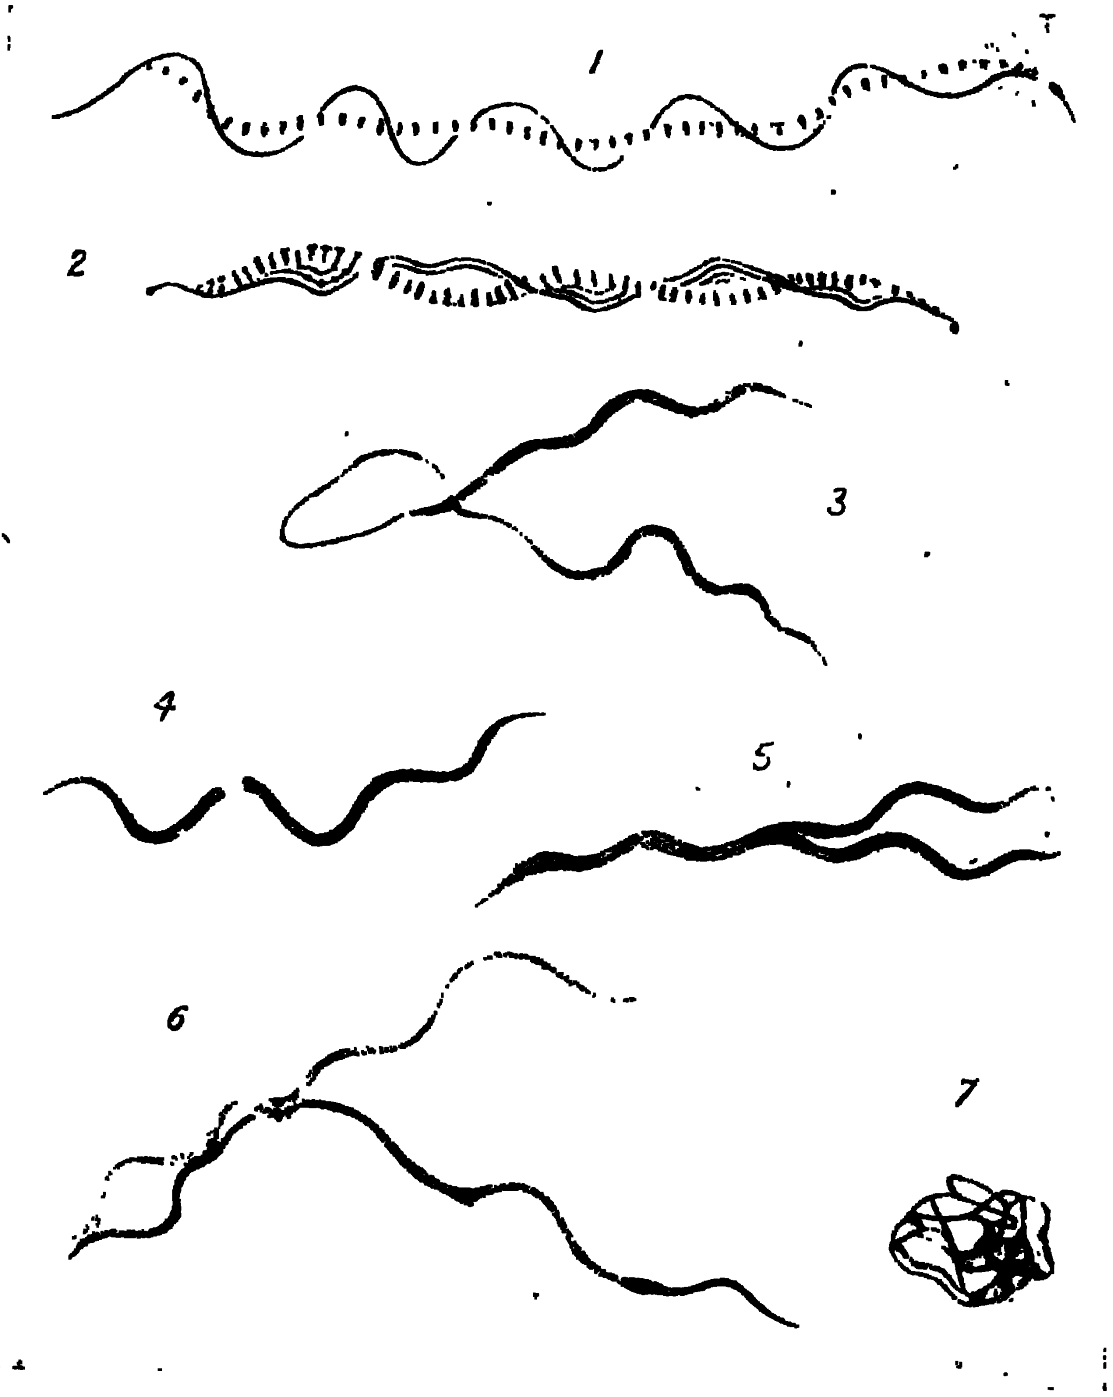

FIG. 124 – SPIROCHÆTES.

1. *Cristispira anodontæ*, showing the undulating membrane and chromatic bars (after Fantham, *Quarterly Journal of Microscopical Science*); 2, *C. balbianii*, showing fibrillæ in undulating membrane (after Fantham); 3-7, *Spiroschaudinnia duttoni* (after Breinl, *Annals of Tropical Medicine and Parasitology*); 4, shows the uncoloured transverse band; 5, longitudinal division; 6, possible male and female forms; 7, encystment.

Reproduction takes place by both longitudinal and transverse divisions; it has been described by Fantham and Porter in *C. anodontæ* Keysselitz, 1906, and *C. balbianii*. The basal granule first divides, and then the membrane, followed by the cytoplasm, as far as one end, which does not divide at once, but later, thus completing the act of asexual reproduction.

Dobell gives a very different description of *C. anodontæ*, which he states has a chambered structure, and divides only by transverse division.

Bosanquet has observed the formation of coccoid bodies in Cristispira analogous to those presently to be described in Spiroschaudinnia.

Classification.—The following genera are recognized:—

Spirochæta Ehrenberg 1838, *sensu stricto*.
Cristispira Gross, 1910.
Saprospira Gross, 1911.
Pseudospira Dobell, 1912.
Spiroschaudinnia Sambon, 1907.

But it is only the last genus which contains the forms of importance in tropical medicine.

Noguchi has created the genus *Leptospira* Noguchi, 1917, for the spiroschaudinnia found in Weil's disease and the spiroschaudinnia he has observed in yellow fever. Characteristic features would be the fine elicoid structure with persistent spirals, and the resistance to the action of saponin.

Cristispira balbianii Certés, 1882.

This spirochæte is found in the crystalline style of oysters. The oysters are apparently affected, at all events, they are poorly developed. It has a well-defined, undulating membrane, strengthened by myonemes, and also a diffuse nucleus of rodlets of chromatin on an achromatic spiral, as has already been described.

Cristispira anodontæ Keysselitz, 1906.

Synonym. *Spirochæta anodontæ* Keysselitz, 1906, *emendavit* Schellach, 1909.

S. anodontæ was found in the crystalline style of *Anodonta mutabilis* by Keysselitz in 1906, and in that of *A. cygnea* by Fantham in 1908.

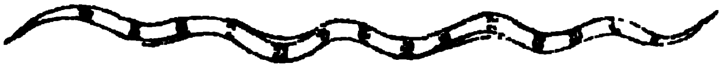

FIG. 125. DIAGRAM OF S. *duttoni*, SHOWING CHROMATIN GRANULES, POINTED ENDS, AND SLIGHT MEMBRANE EDGE. (After Fantham.)

It is 90 μ in length by 0·7 μ in breadth, with pointed ends and a spirally wound undulating membrane. The nucleus is diffuse, consisting of chromatin rodlets on a more faintly staining spiral.

S. plicatilis Ehrenberg, 1833, found in pond-water.

Spiroschaudinnia Sambon, 1907.

Spirochætidæ parasitic in the blood and tissues of vertebrates and in some blood-sucking invertebrates.

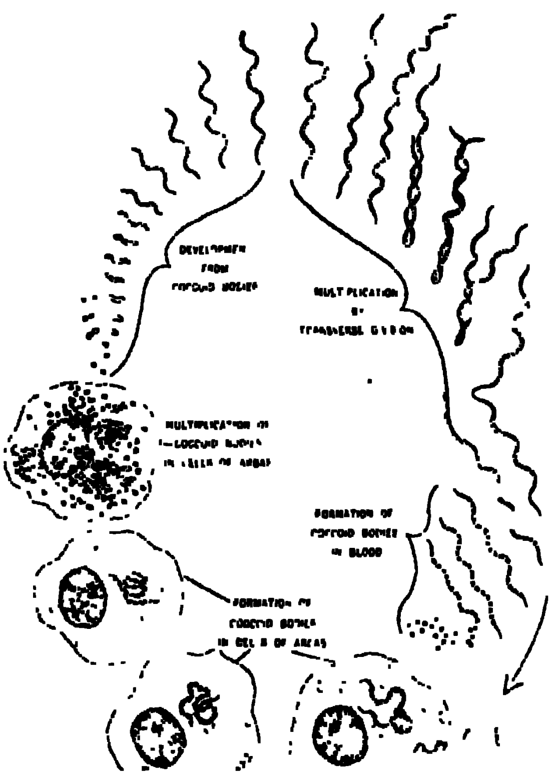
Remarks.—This genus, as we believed would happen, is now recognized by many authorities, and therefore we adopt it, though we had hesitated to do so in the previous edition.

Type Species.—*Spiroschaudinnia recurrentis* Lebert, 1874.

Morphology.—This has been most carefully studied by Fantham in *S. recurrentis*, *S. duttoni*, and *S. marchouxi*, and he finds that they have long, narrow bodies, bent into many spiral coils, enclosed in a firm periplast, with a very tenuous membrane, which is often invisible. The nucleus consists of granules of chromatin distributed along the body.

Life-History.—Multiplication can take place by longitudinal and by transverse division, and also by multiple transverse fission, in which case the protoplasm concentrates around the chromatin masses, giving rise to a number of round or oval granules, probably the same as the infective granules of Fry and Balfour, which are known to escape from one end or the other of the periplastic sheath when in the internal organs. These infective granules enter the red cells, and divide into a number of merozoites, which escape from the red cell and enter the liquor sanguinis; but their further development is unknown, though it is possible that they become spirochætes.

Fantham's observations have confirmed this granule stage of the life-history, but it must not be forgotten that every granule seen in a spirochæte is *not* an infective granule, which our own observations support.



DEVELOPMENT FROM COCCOID BODIES
MULTIPLICATION BY TRANSVERSE DIVISION
MULTIPLICATION OF COCCOID BODIES IN CELLS OF ARGAS
FORMATION OF COCCOID BODIES IN BLOOD
FORMATION OF COCCOID BODIES IN CELLS OF ARGAS

FIG. 126.—LIFE-CYCLE OF *Spiroschaudinnia marchouxi* NUTTALL

(After Hindle, from the *Journal of Parasitology*.)

Minchin regarded these granules as true endogenous chromidial buds, and considered therefore that the term infective granule should be replaced by the term 'endogenous' bud formation.

The life-history of a spiroschaudinnia in the invertebrate has been traced by Leishman for *S. duttoni* in the tick *Ornithodoros moubata*, and his account has been confirmed by Balfour, Hindle, Blanc, Fantham, and others.

The *Spiroschaudinniæ*, on entering the tick, penetrate the gut wall, and on reaching the body cavity divide by multiple transverse fission into minute ovoid or rod-like bodies, which reach the ovary and become incorporated with some of the ova. In this situation they are not often infective. When laid, the egg only contains a few ovoid bodies, but in three to five days' incubation, when the Malpighian tubes have begun to develop, ovoid and more elongate bodies may be seen therein. In six to seven days' incubation these bodies have elongated and become bacillary, and may rupture the cell and appear in the lumen of the tube. It is believed that these bacillary forms give rise to spirochætes either by elongation and growth, or by fusion of rods. The recently hatched tick contains ovoid bodies, bacillary forms, and a very few fully developed spirochætes. Infection takes place towards the end of feeding by the excretion from the Malpighian tubules, which contains the spirochætes, passing into the wound caused by the bite.

Some of the *Spiroschaudinniæ*, on entering the tick, pass into the cells by the alimentary canal, and undergo multiple transverse division, while others may live for some weeks in the gut.

Cultivation.—Noguchi has successfully cultivated *S. duttoni* in sterile ascitic or hydrocele fluid, to which a piece of fresh rabbit's kidney has been added. For inoculation of this medium he uses a few drops of the citrated heart blood from a mouse forty-eight to seventy-two hours after infection.

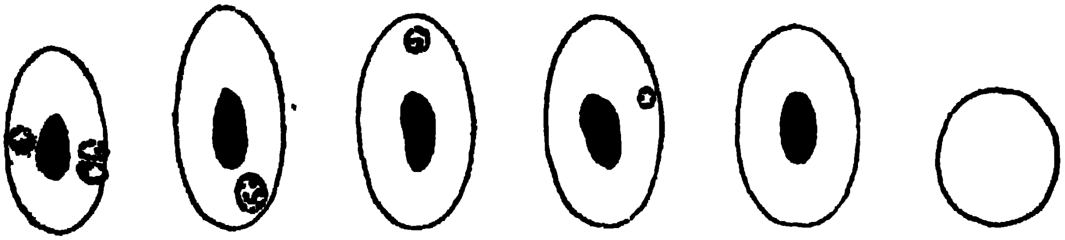


FIG. 127.—SCHIZOGONY OF *Spiroschaudinnia marchouxi* NUTTALL. (After Sambon.)

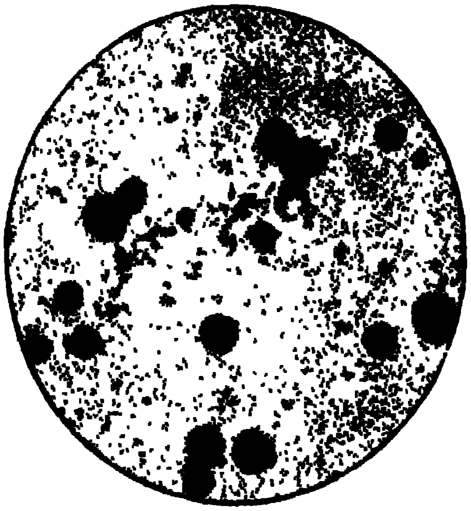

FIG. 128.—DEVELOPMENT OF *S. Duttoni*. (× 1,000.)

The small dots are chromatin bodies and the large granules are digested blood, while the pale outlines are spirochætes in the contents of the intestinal sac of a tick two days after an infective feed. (From a micro-photograph by Sir William Leishman.)

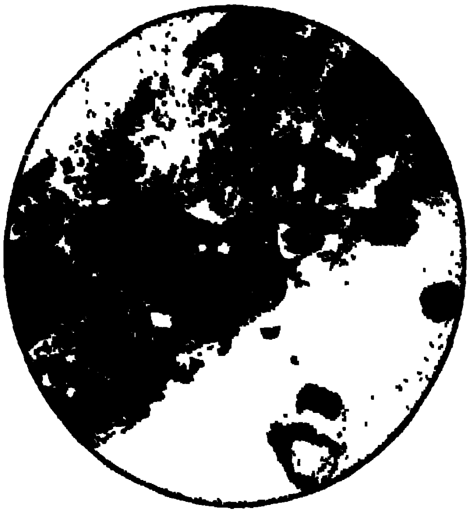

FIG. 129.—CHROMATIN GRANULES IN THE MALPIGHIAN TUBULE OF A TICK SIX DAYS AFTER INFECTIVE FEED. (× 1,000.)

(From a microphotograph by Sir William Leishman.)

At a temperature of 37° C. the maximum growth is found about the eighth to ninth day, after which disintegration sets in, resulting in total disappearance about the fifteenth day. Subcultures are best made from the fourth to the ninth day, but after that date the virulence diminishes. The subcultures do not lose their virulence even after the ninth passage.

He has also cultivated in this way *S. recurrentis* Lebert, 1874, when the maximum growth occurs on the seventh day; *S. rossi* Nuttall, 1905, with a maximum on the ninth day; and *S. novyi*, which is the most difficult, with a maximum on the seventh day. *S. marchouxi* has also been cultivated. Bronfenbrenner in 1914 simplified this method of cultivation.

Carriers. The *Spiroschaudinnia* are spread by the agency of ticks and lice.

Method of Infection. The *Spiroschaudinniæ* infect the ova of the tick, and so pass into the second generation, from which they escape in the fæces and enter the wounds made by the tick when it bites, and so infect the vertebrate host. Whether the same method of development takes place in the louse is not known, but the method of infection is thought to be due to the irritation of the louse bite causing the vertebrate host to scratch, and thus to crush the louse and at the same time to cause abrasions of the host's own skin. The *Spiroschaudinniæ* escaping from the crushed louse, enter the vertebrate host through the abrasions caused by the scratches. Both these are contaminative methods of infection. It is believed that *Spiroschaudinnia* in the vertebrate can pass from the mother via the placenta to the fœtus, thus giving rise to an hereditary method of infection, in contradistinction to the contaminative methods mentioned above.

(From a microphotograph by Sir William Leishman.)

I. HUMAN SPIROCHÆTES.

A. Blood Spirochætes.

Spiroschaudinnia recurrentis Lebert, 1874.

Synonyms.—*Spirochæte recurrentis* Lebert, 1874; *S. obermeyeri* Cohn, 1875.

This spirochæte was discovered by Obermeyer in cases of relapsing fever in Berlin.

Morphology.—It exists in the blood in short and long forms. The short forms, which are from 7 to 9 μ in length, are probably early stages. The long forms, 16 to 19 μ, result from multiplication or agglutination. The latter condition in a hyperimmune blood may lead to forms 18 to 100 μ in length, brought about by agglutination of two or more cells end to end. The width is 0·25 μ. The number of spirals in the short form, which is considered to be one cell, is two to three.

The short form is said by Novy and Knapp to have a long flagellum at one end while the other has a faint appendage. The presence of flagella in this as well as in other spirochætes is denied by Nuttall.

FIG. SCHAUDINNIA FROM CASE OF ASIATIC RELAPSING FEVER.
(From a microphotograph by J. J. Bell.)

Life-History.—This spirochæte is pathogenic to man, monkeys, rats and mice; but these latter have to be infected from a monkey. Rabbits or guinea-pigs are not susceptible. It is found in the peripheral blood during the attacks and relapses, but not in the intermission, unless occasionally after very protracted search. It can also live in the bed-bug—*Clinocoris lectularius*—for some days, and Nuttall has succeeded on one occasion in transmitting *S. recurrentis* from mouse to mouse by the bites of the same bug. Positive results have also been obtained by Sikul in Odessa. Most authorities consider lice to be the carriers.

Immunity.—The blood serum of animals immunized to *S. recurrentis* is without effect upon *S. duttoni* and *S. novyi*.

Pathogenicity.—It is the cause of European relapsing fever.

Spiroschaudinnia duttoni Novy and Knapp, 1906.

Synonyms.—*Spirillum duttoni* Novy and Knapp, 1906; *Spirochæta duttoni* Todd, 1906.

This spirochæte is the cause of the West African and the Colombian tick fever.

Morphology.—Its length is variously described; thus Novy and Knapp say that the young forms are 16 μ in length, while Breinl and Kinghorn make them 24 μ in length and 0·45 μ in width when fully grown. The number of spirals varies from two to three to eight to ten, with a width of 2·2 μ. The parasite is ribbon-shaped on transverse section, and though it is often in spirals, may be simply waved. The two ends are pointed (*vide* Fig. 125).

The central core is seen to consist of lighter and darker portions, which correspond to the chromatic and the achromatic portions of the nucleus. The chromatic portion can break up into granules, when the parasites begin to disappear from the circulation.

The periplast is well marked, but there is great doubt as to the presence of an undulating membrane. Breinl, who has studied the subject carefully, could not definitely define one, but Dutton and Todd have seen it in blood taken directly from the circulation in man, or animals, or from the gut of *Ornithodoros moubata*. A small uncoloured transverse band is often to be seen in specimens stained by Giemsa lying across the parasite, about one-third its length from one end.

Life-History.—Reproduction can take place by longitudinal and transverse division. In the former the parasite thickens and then divides from one end, while in the latter the parasite increases in length and divides in the middle. Some authors deny the occurrence of transverse division, but this is untenable after Fantham and Porter's experiments.

There is, however, another and but little known method of reproduction, which appears to be analogous to spore-formation.

Just before the crisis, when the blood is swarming with parasites, they can be seen, according to Breinl, in the spleen and bone-marrow, and more rarely in the liver, coiling themselves up, and either showing a swollen appearance, or becoming thinner and rolling themselves into more and more complicated skein-like forms, which may be engulfed by phagocytes in the spleen, but in other organs become more regular and surrounded by a thin cyst-wall, the interior of which is filled with faintly blue-staining plasma.

In this cyst the parasite becomes more and more indistinct, and at a later stage small red granules are to be seen, which are thought to be the cause of the infection in the blood when filtered through a Pasteur-Chamberland filter. Therefore, according to the investigations by Breinl, the life-history of the parasite has two well-defined stages in the vertebrate. In the first it is found free in the liquor sanguinis in its typical form; in the second it enters a cell, and, becoming coiled, its chromatin breaks up into a number of granules, each of which is believed to become a new spirochæte.

The stage in the liquor sanguinis is associated with the febrile attacks, and that in the cells with the apyrexial intervals.

Carriers.—It is spread by the agency of *Ornithodoros moubata* in Africa, and by *Argas americanus* (chinche) in Colombia.

In the Tick.—*S. duttoni* in Africa is conveyed to man and animals by fæcal infection of the bites of a tick, *Ornithodoros moubata.* Leishman has demonstrated that when *S. duttoni* enters the intestinal sac of the tick it loses its mobility and characteristic appearance, and chromatic masses escape into the lumen of the gut in the form of small rods or rounded bodies resembling micrococci. These multiply and pass into the cells of the Malpighian tubules, and also into the immature eggs in the ovary. They can be followed through all the stages of the egg into the adult tick, as small chromatin bodies lying in the cells of the Malpighian tubules. These bodies are voided with the fæces, and when the tick feeds are capable of entering the wound produced by the bite, and in this manner infecting the host.

The tick remains infective for a very long time—according to Möller as long as eighteen months—and the infection can be passed not merely through the eggs into a new generation of ticks, as has been demonstrated by Dutton, Todd, Leishman, and others, but also according to Möller into the third generation, even if the second generation have only fed on clean animals.

Pathogenicity.—It is the cause of West African and Colombian relapsing fever.

Spiroschaudinnia rossi Nuttall, 1908.

This spirochæte is distinguished from *S. duttoni* by its biological reactions, though some authorities consider it identical with *S. duttoni.* It is the cause of East African relapsing fever, and is conveyed by *Ornithodoros moubata.*

Spiroschaudinnia novyi Schellach, 1907.

History.—In 1907 Professor Manteufel, while investigating an accidental laboratory infection of relapsing fever, found that the serum of the patient agglutinated a spirochæte found by Novy in a case of relapsing fever in America in a dilution of 1 in 100, but showed no such power over the spirochæte of the European disease. Moreover, it gave Pfeiffer's reaction, being active in doses of 0·05 c.c. in experimentally infected mice. Schellach has investigated this spirochæte, and given it the specific name used above.

Morphology.—It is 17 to 20 μ in length, with six to eight undulations and a thickness of 0·31 μ. He gives the dimensions for the *S. recurrentis* as 19 to 29 μ, with eight to ten undulations and a thickness of 0·39 μ, and *S. duttoni* as 24 μ at the most, with eight to ten undulations and a thickness of 0·45 μ; which appear to be very different from Novy's table given under *S. carteri.*

The spirochæte appears to have great flexibility and activity of movement. One end has a filiform prolongation about 5 μ in length, while the other is merely pointed. No undulating membrane could be differentiated; but he states that he was able to demonstrate lateral cilia, which he considers to be artificial; but this, in our opinion, is highly suggestive of the presence of an undulating membrane. Coloured granules could be made out when stained by Giemsa. Reproduction was usually by transverse division.

Life-History. The spirochætes are found in the blood during the attacks of fever, and equally distributed in the organs in the apyrexial interval.

Inoculation.—It can be inoculated into monkeys, but small rodents are especially susceptible. Subinoculations can be made from monkey to monkey and from mouse to mouse.

Immunity.—Serum of animals immunized for *S. novyi* is without effect upon *S. recurrentis*, *S. duttoni*, or *S. carteri*.

Cultivation. It has been cultivated by Noguchi as mentioned above (see p. [illegible]).

Pathogenicity. It is the cause of North American relapsing fever.

Spiroschaudinnia carteri Manson, 1907.

S. carteri has a minimal length of 12 *μ*, with open flexures. It is thinner than *S. novyi*, and it is not agglutinated by serum of animals immunized against *S. novyi*. It can be inoculated into monkeys and with difficulty into mice, and can be subinoculated from monkey to monkey or mouse to mouse.

Novy and Knapp give the following differences between *S. carteri*, *S. duttoni*, and *S. novyi*:—

Character.	*Spiroschaudinnia novyi*	*Spiroschaudinnia duttoni.*	*Spiroschaudinnia carteri*
Length of simple cell .. .	8 *μ*	10 *μ*	8 *μ*
Length of double cell .	16-20 *μ*	30 *μ*	16-20 *μ*
Width	0·25 *μ*	0·2 *μ*	0·2 *μ*
Number of turns in a single cell	2-3 *μ*	2·5 *μ*	2-3 *μ*
Distance between the turns	1·5 *μ*	1·5 *μ*	2-3 *μ*
Movement	Vigorous	Little	--
Number in peripheral blood	Many	Few	Many

According to Strong's experiments, rats immunized against *S. recurrentis* and *S. novyi* are immune to *S. carteri*. He therefore believes these three strains to be closely allied if not identical.

They can also be distinguished by agglutination, immunization tests, by Pfeiffer's reaction, and by certain animals being susceptible to some species and not to others. Mackie has suggested that *S. carteri* may be transmitted by a pediculus. It is the cause of Asiatic relapsing fever.

Spiroschaudinnia berbera Sergent and Foley, 1910.

Spiroschaudinnia with minimal length of 12 μ and irregular open spirals or flexures. It can be inoculated into monkeys (*Macacus cynocephalus*) and with difficulty into rats and mice. Subinoculations can be made with difficulty from rat to rat and from mouse to mouse. The immune serum is without effect upon *S. recurrentis*. It produces a mild infection in animals, but a severe one in man, for whom it is the cause of North African and possibly Egyptian relapsing fever. Probably it is spread by the agency of lice.

Spiroschaudinnia morsusmuris Futaki, Takaki, Taniguchi, and Osumi, 1917.

Synonym. *Spirochæta morsusmuris.*

This spirochæte was found in the blood, skin, and lymph glands of six patients suffering from rat bite disease.

The spirochæte is mobile and shows a single flagellum at each pole, but no undulating membrane, and has generally three or four curves, but may have two to nineteen. The smaller forms occur in the blood and the larger in the tissues.

Mice and white rats become affected, but guinea-pigs and monkeys fail to do so.

Spiroschaudinnia icterohæmorrhagiæ Inada, Ido, Hoki, Kaneko, and Ito, 1915.

Synonyms.- *Spirochæte icterohæmorrhagiæ* Inada, etc., 1915; *S. icterogenes* Uhlenhuth and Fromme; *S. nodosa* Huebener and Reiter.

Nomenclature. Noguchi has created a new genus (see p. 139) for this parasite, calling it *Leptospira icterohæmorrhagiæ*, and this will probably be generally accepted.

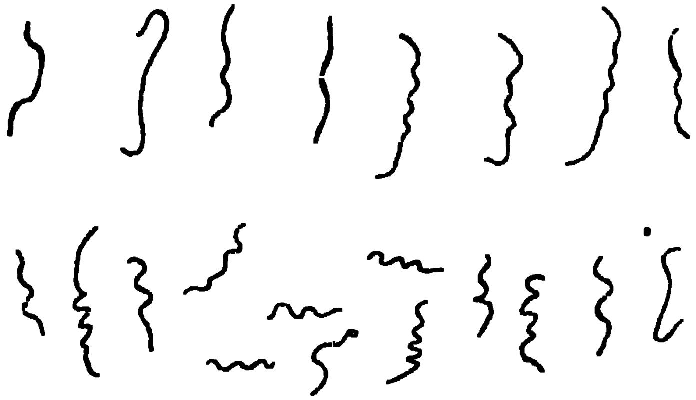

FIG. 133. *Spiroschaudinnia icterohæmorrhagiæ* Inada, etc.

This spirochæte is found during the first four weeks in the blood and urine of patients suffering from infective jaundice (Weil's disease) of the spirochætal type, and can be inoculated into animals, producing jaundice. These observations have been confirmed by French, Italian, and German workers. The spirochætes found in Japan and Belgium have been shown by Noguchi to be identical morphologically and serologically. The parasite seems to occur in the kidneys and urine of wild rats in Japan, in the rats in the trenches in Belgium, in those in France, where the disease in unknown, and in America, where it is rare.

The organism can enter through the alimentary canal, via abrasions on and even through the healthy skin, and, as it can live in water, this is thought to be the principal means of infection—*i.e.*, by walking barefoot or in sandals on wet earth or in stagnant water.

The spirochætes are 6-9 microns long on an average, but may reach to 20 microns and about 02·5 micron in breadth, with two to three large or four to five small waves. It often contains refractile granules, to the number of twenty-five to forty (these may in reality represent small waves, as shown by Dobell).

Guinea-pigs may be infected orally, subcutaneously, or intraperitoneally, with the blood of patients up to the seventh day of the illness, but usually not later, though there are exceptions to this. The incubation period in these animals is seven to eight days, and the symptoms resemble those produced in man. Rabbits cannot be infected. Ito and Matsuzaki obtained it in pure culture from the heart blood of subinoculated guinea-pigs, by sowing this on blood agar or blood gelatine and incubating from 20°-25° C., though it can grow from 15°-37° C. It produces neither odour, gas, nor liquefaction of the medium. The organism so cultivated remains pathogenic for guinea-pigs. A good medium is a mixture of rabbit blood-serum and 0·85 per cent. saline in the proportion of 1 to 5.

Spiroschaudinnia hebdomadis Ido, Ito, and Wani, 1918.

Morphologically similar to *S. icterohæmorrhagiæ*, differs serologically. Found by Ido, Ito, and Wani in cases of a seven-day fever called Nanukayami, which somewhat resembles atypical Weil's disease.

The field mouse (*Microtus montebelli*) seems to be the normal host of the spirochæte.

Spiroschaudinnia in Yellow Fever.

Stimson in 1909 described a spirochæte in the organs of persons who had died of yellow fever (*S. interrogans* Stimson 1909), but little importance was given to this observation. In 1918 Noguchi cultivated from the blood of several yellow fever patients a spirochæte similar to *S. icterohæmorrhagiæ* (*Leptospira icterohæmorrhagiæ*), and by inoculating cultures of the organism he produced in monkeys the same hæmorrhagic lesions as seen after the successful inoculation of blood of yellow fever patients.

B. CUTANEOUS SPIROCHÆTES.

Spiroschaudinnia vincenti Blanchard, 1906.

Synonym.—*Spiroschaudinnia schaudinni* Prowazek, 1907.

This is a very active motile spirochæte 10 to 20 μ in length, with a well-marked undulating membrane and one rather short flagellum. Male and female forms can be seen, according to Prowazek. Division is longitudinal.

It is, according to Prowazek, the cause of ulcus tropicum, and is possibly transmitted by a leech. Induces formation of pseudo-membranes.

It is often associated with the so-called fusiform bacilli causing angina Vincenti and, according to certain authors, hospital phagedæna and noma.

Spiroschaudinnia aboriginalis Cleland, 1909.

This spirochæte was found by Wise in British Guiana in 1906, and by Cleland in West Australia in 1909 in cases of granuloma inguinale. Its length is 6 to 18 μ, and it possesses but few coils, which vary in depth. The extremities, according to Cleland, are blunt. Similar spirochætes have been found by Wise and others in a peculiar granulomatous affection, which attacks the genital organs of dogs and bitches. It is believed at the present time that this *Spiroschaudinnia* is not the cause of granuloma inguinale, but merely a saprophyte.

Spiroschaudinnia phagedenis Noguchi, 1912.

Noguchi discovered this spirochæte in an indurated and ulcerated swelling of the labium which had lasted ten days. It has been cultivated by him on ascitic agar medium, and is a strict anaerobe. Length varies from 4 to 30 μ. and the curves from 1 to 8 μ, while young forms may be quite straight. Inoculated into monkeys and rabbits it causes transient inflammation.

S. acuminata Castellani, 1905, and **S. obtusa** Castellani, 1905.

Found in the open sores of yaws.

S. pseudopallida Mulzer, 1905.

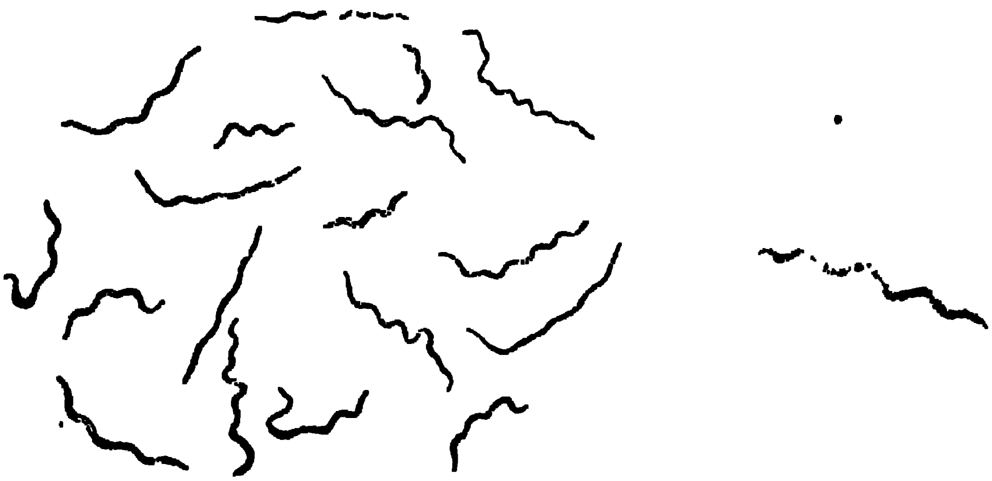
Found in ulcerating carcinomata.

Unnamed forms of cutaneous spirochætes have been seen by von Prowazek in cases of psoriasis.

C. RESPIRATORY SPIROCHÆTES.

Spiroschaudinnia bronchialis Castellani, 1907.

The presence of this spirochæte and the disease which it causes was first described by Castellani in 1906. They have been confirmed by Branch in the West Indies, by Chalmers and O'Farrell in the Sudan,



FIGS. 134 AND 135.—*Spiroschaudinnia bronchialis* CASTELLANI.

by Macfie in West Africa, by Castellani and Jackson in the Balkans, by Toro Villa in Colombia and South America, by Ragazzi in Bengazi, by Galli-Valerio in Switzerland, by Lurie in Serbia, by Violle in France, and by Broughton-Alcock in North Italy (see p. 1882).

It was originally found by Castellani in cases of bronchitis in Ceylon, and its morphology has been carefully studied by Fantham in the Anglo-Egyptian Sudan.

S. bronchialis is an organism with marked polymorphism, varying in length from 5-25 microns and in breadth from 0·2-0·3 micron. The variations indicate different stages of growth and division. As a rule the ends, though varying considerably, are acuminate. Its movements are active, but cease shortly after removal from the body, and are succeeded by a granule stage, as described by Fantham, and from these granules new spirochætes are believed to be formed. The granules are probably the infective agent, and spread the infection from man to man by the air.

It is believed to be different from *S. dentium* and *S. buccalis*, the mouth spirochætes, of which the former measures 4-10 and the latter 9-22 microns in length.

Chalmers and O'Farrell's experiments tend to show that monkeys can be infected.

Spiroschaudinnia minuta Castellani, 1916.

Found in cases of rhinopharyngitis (p. 1881). With Romanosky it stains a pinkish red, and has very few spirals. Length 3-10-12 microns.

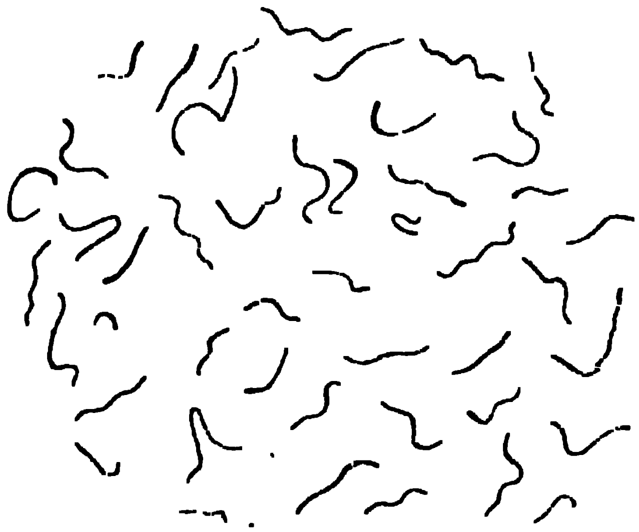


FIG. 136.—*Spirochaudinnia minuta* CASTELLANI.

D. ALIMENTARY CANAL SPIROCHÆTES.

Spiroschaudinnia subtilis Castellani, 1907.

Found in scrapings from oral mucosa and in intestinal contents.

Spiroschaudinnia eurygyrata Werner, 1909, *emendavit* Fantham, 1916.

Synonyms.—*Spirillum hachaizæ* Kowalski (perhaps); *S. eurygyrata* Werner, 1909.

The spirochæte was first noted under the name spirillum in cholera motions in 1884-86 and 1893-94. In 1903 Le Dantec saw them in cases of so-called spirochætal dysentery. In 1909 Werner gave them the two names mentioned above, which Fantham in his 1916 researches considers to be the same.

The spirochætes were found by Fantham in the fæces of soldiers suffering from diarrhœa or dysentery in Gallipoli and Flanders, and also in healthy people. It has pointed ends, and varies from 3-15 microns in length by about 0·25 micron in breadth. The number of waves is from two to nine, while chromatin granules can be seen along the body. It is actively motile, and has been seen to enter the shed epithelial cells found in the fæces, where it produces coccoid bodies.

NOTE.—It is essential not to confuse true spirochætes found in the fæces with vegetal organisms with pseudo-spirochætal shapes, as has occurred—*e.g.*, *Spirobacillus* (*Bacillus*) *zeylanicus* Castellani, 1910, has often been mistaken for a true spirochæte (see p. 1838).

E. URINARY SPIROCHÆTES.

Spiroschaudinnia urethræ Macfie, 1917.

These spirochætes have been seen by Macfie in urine in natives on the Gold Coast, where it caused an acute urethritis.

The parasite was found free in large quantities in the pus and also in the pus cells. It measured from 5-20 microns in length, and showed a membrane or crest. The cytoplasm, which was homogeneous, contained chromatin granules or rodlets at intervals. Some pus cells contained coccoid granules.

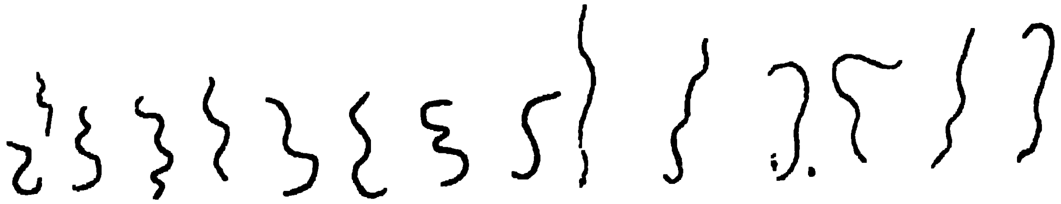

FIG. 137.—*Spiroschaudinnia mitis* CASTELLANI.

Spirochætes have been found in the normal urethra by various authors—*e.g.*, Mendelson.

S. mitis was found by Castellani in the centrifuged urine of certain cases of camp jaundice of mild type. It is thicker than *S. icterohæmorrhagiæ*, and has larger and better defined waves. Of doubtful pathogenicity.

THE DIFFERENTIATION OF HUMAN SPIROCHÆTES.

The differentiation of spirochætes is exceedingly difficult, as morphological characters seldom help, and measurements with wave formations are useless for this purpose.

As many of the so-called species are probably only variants produced by environment, it seems correct to classify them according to site in the human body, according to their action on man and animals, and according to immunity experiments.

The following is an attempt on these lines:—

A. Found in the blood:—
- I. In cases of relapsing fever:—
  - (*a*) Clinical symptoms in man mild, but in animals severe —*S. novyi*.
  - (*b*) Clinical symptoms in man severe:—
    - 1. In animals severe—*S. duttoni*.
    - 2. In animals mild:—
      - (1) Berbera immune serum protective—*S. berbera*.
      - (2) Berbera immune serum ineffective and recurrentis immune serum protective; closely allied forms:—
        - (*a*) Found in Europe—*S. recurrentis*.
        - (*b*) Found in India—*S. carteri*.
- II. In cases of infectious jaundice—*S. icterohæmorrhagica*.
- III. In cases of rat-bite disease—*S. morsusmuris*.

B. Found in the skin:—
- I. In ulcus tropicum:—
  Not cultivated, with undulating membrane and short flagellum—*S. vincenti*.
- II. In granuloma inguinale:—
  Not cultivated without undulating membrane or flagellum —*S. aboriginalis*.
- III. In cutaneous inflammation:—
  - (*a*) Cultivated, strictly anaerobic; causes transient inflammation in animals—*S. phagedenis*.
  - (*b*) Not cultivated; found in open yaws ulcers:—
    - 1. Acuminate—*S. acuminata*.
    - 2. Obtuse—*S. obtusa*.
  - (*c*) Not cultivated; found in ulcerating carcinomata—*S. pseudopallida*.

C. Found in the respiratory passages:—
- I. In bronchial spirochætosis—*S. bronchialis*.
- II. In rhinopharyngitis—*S. minuta*.

D. Found in the alimentary canal and skin lesions:—
- **I. In the mouth:—**
  - **(*a*) Produces pseudo-membranes. In cases of angina and ulcus tropicum—*S. vincenti*.**
  - **(*b*) Non-pathogenic:—**

1. Short forms—*S. dentium.*
2. Long forms—*S. buccalis.*

II. In vomit:—
Rather doubtful forms in vomit of Belyando spew in Queensland—*Unnamed.*

III. In fæces:—
In health and disease—*S. eurygyrata.*

E. Found in the urethra:—

I. In free and in coccoid form in pus cells from urethritis. With crest or membrane—*S. urethræ.*

II. In urine from cases of mild camp jaundice. With well-marked waves—*S. mitis.*

ANIMAL SPIROCHÆTES.

Spiroschaudinnia macaci Castellani and Chalmers, 1910.

Synonym.—*Spirochæta macaci* Castellani and Chalmers, 1910.

This spirochæte was found by us in monkeys in Ceylon in 1906. In length it measures about 12 *μ*, and closely resembles *S. carteri* Manson, 1907. It can be easily inoculated from monkey to monkey. Spirochætes which may be of a different species have also been found by Leishman, Balfour, and by Plimmer in *Cercopithecus sebæ* from Sierra Leone.

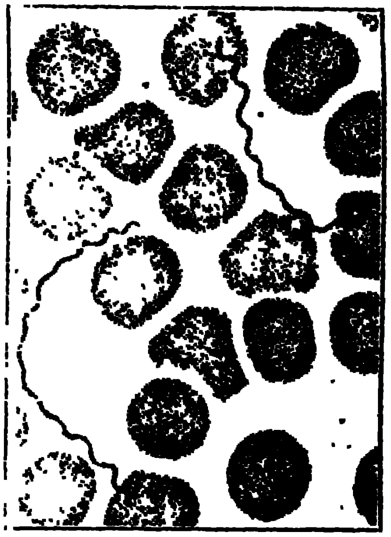

FIG. 138.—SPIROCHÆTES IN THE BLOOD OF *Cercopithecus sebæus* FROM SIERRA LEONE. (× 1,000.)

(From a microphotograph by H. G. Plimmer.)

Spiroschaudinnia anserina Saccharoff, 1891.

Found in enormous numbers in the blood of geese in the Caucasus and Tunis. It causes fever, diarrhœa, tenderness of the feet, and death in about a week, the mortality being 80 per cent. It can be inoculated into other geese.

Spiroschaudinnia marchouxi Nuttall, 1904.

Synonym.—*Spirochæta gallinarum* R. Blanchard, 1905.

This spirochæte, which has been discovered by Marchoux and Salimbeni, and studied by Balfour, is about 10 to 20 *μ* in length, causes disease in fowls in many countries—*e.g.*, Brazil, the Sudan, Egypt, Tunisia, and Serbia. The symptoms are fever, diarrhœa, anæmia, somnolence, convulsions, and death in four to five days, or in chronic cases cachexia and death in fourteen days. As first observed by Sambon, it appears to enter the red corpuscle, and to break up within it in a way which reminds one of the description already given for *S. duttoni.* Balfour has made an important investigation on granule spreading and the infective granules. It is spread by *Argas persicus* and other Argasidæ, as Fulleborn has shown with *Ornithodoros moubata.* Balfour has made the important observation that in the infected ticks chromatic granules are present as described by Leishman in *S. duttoni.*

* Recent researches by Balfour tend to show that the Sudan strain is a separate species: *S. granulosa* Balfour, 1910. Aragão has attempted to obtain a serum and a vaccine with a certain degree of success.

Spiroschaudinnia neveuxi Brumpt, 1909.

Brumpt describes this spirochæte as morphologically identical with *S. marchouxi*, but cross immunization shows that the two species are different. It is the cause of fowl spirochætosis in Senegal, and is spread by *Argas persicus*.

Spiroschaudinnia theileri Laveran, 1904.

This spirochæte, discovered by Theiler in 1902, is found in cattle in Africa about Pretoria, in the Cameroons, and in East Africa. The symptoms are not clear, as babesia has also been seen in the same animals. It is spread by *Margaropus decoloratus*, the blue tick.

Spiroschaudinnia ovina R. Blanchard, 1906.

This spirochæte may be the same as *S. theileri*. It was found by Martoglio and Carpano in sheep in Erythræa, on the Red Sea, and by Theiler in the Transvaal.

Spiroschaudinnia equi Novy and Knapp, 1906.

Found by Theiler in the Transvaal, and by Martin in French Guinea, and may be the same as *S. theileri*.

Other Spirochætes.—*S. vespertilionis* Novy and Knapp, found by Nicolle and Comte in 1905, in *Vespertilio kuhli*.

S. gracilis Levaditi and Stanesco, 1909, very like *Treponema pallidum*.

S. culicis Jaffé, 1907, found in the gut and Malpighian tubules of *Culex pipiens* and the larva of *Anopheles maculipennis*.

S. muris Wenyon and *S. laverani* Breinl and Kinghorn, in mice.

S. bufonis Dobell, 1908, found in the rectum of a frog.

S. glossinæ Novy and Knapp, 1906, in the stomach of tsetse-flies.

S. microgyrata Gaylord and Calkins, 1907, in cancer of the breast in mice.

S. balanitidis Hoffmann and Prowazek, 1906, found by Hoffmann and Prowazek in balanitis.

S. lutræ Prowazek, 1907, found by Prowazek in the otter.

Sambon has found spirochætes in scrapings from gastric ulcers in a fox.

Various spirochætes have also been observed in the stomach of normal cats, dogs, and rats (Bizzozzero, Salomon), in the intestinal ulcers of dogs and monkeys affected with trypanosomiasis (Balfour), in the intestine of normal mice (Wenyon) and birds (Kent).

Treponemidæ Schaudinn, 1905.

Definition.—Spirochætacea with a minute thread-like body twisted into numerous fine coils, with pointed tapering extremities. The body is cylindrical on section, and not flattened, and the spirals appear preformed. There is no undulating membrane. Transverse and longitudinal division have been observed, the latter type being the only one found in cultures.

Classification.—Only one genus.

Treponema Schaudinn, 1905.

Synonym.—*Spirochæta* Ehrenberg *pro parte; Spironema* Vuillemin, 1905, von Klebs, 1892.

Treponemidæ with the characters of the family.

Type Species.—*Treponema pallidum* Schaudinn, 1905.

Treponema pallidum Schaudinn, 1905.

Synonyms.—*Spirochæta pallida* Schaudinn, 1905; *Spironema pallidum* Vuillemin, 1905; *Microspironema pallidum* Stiles and Pfander, 1905; *Trypanosoma luis* Krzysztalowicz and Siedlecki, 1905.

History.—This treponema was discovered by Schaudinn in syphilis in 1905. The history of the finding of parasites in syphilis is interesting, for as long ago as 1546 Frascastorius considered syphilis to be a parasitic disease. In 1879 Klebs, and, later, Losdorfer and Döhle in 1901, described parasites, and saw cell inclusions in the disease, and in 1905 Siegel described an organism, *Cytoryctes luis*, in which there are flagellate bodies very closely resembling spirochætes. In 1905 Schaudinn, after investigating and reporting unfavourably on Siegel's work, found the *Treponema pallidum*, which is accepted as the cause of the disease. Korté in 1906 described free round bodies and cysts with threads in primary sores. E. H. Ross has described an intracellular formation allied to his *Lymphocytozoon cobayæ*, which develops into spirochætes, and these researches have in part been confirmed by Jennings. McDonagh also has described a complicated life-cycle.

FIG. 13[illegible].—*Treponema pallidum* SCHAUD.
(From a microphotograph by J. J. Bell.)

Morphology.—It varies from 4 to 10 μ in length, average 7 μ, with a width up to 0·5 μ. It is twisted into spirals, which vary from six to twelve and more in number, the average being eight to ten, and are to a certain extent preformed—*i.e.*, not due to the parasite's movements. It moves by rotation on a long axis by gliding movements, forwards and backwards, and also by flexion of the whole body. The periplast is continued as long delicate processes at each end, which are considered by some to be flagella.

Krzysztalowicz and Siedlecki say that not far from the middle the body may be nearly straight, and a clear spot can be observed which they think is a nucleus; but it might correspond to the similar area in *S. duttoni*. They also describe male and female gametes and conjugation, which they think leads to the formation of a cyst or spore, which may be carried via the blood stream to different parts of the body, and there develop into Treponemata.

The parasite is found in the primary sores and in the secondary lesions, but is very difficult to detect in tertiary eruptions, though it is abundantly present in the liver, spleen, decidua, the placental villi, the umbilical cord of syphilitic fœtuses, and infants.

It is distinguished from other spirochætes (*S. refringens*) which may be met with on ulcerated surfaces by difficulty in staining; number, character, and permanence of the spirals; the terminal prolongations; absence of an undulating membrane; minute size and delicacy.

Inoculation.—Syphilis can be inoculated into chimpanzees (as shown by Metchnikoff and Roux) and other monkeys, and *T. pallidum* can be found in the lesions so caused, the incubation being fifteen to forty-nine days, average thirty days, for the primary sore; and nineteen to sixty-one days, average thirty-three days, for the secondary eruption after the primary have appeared. In the lower monkeys the lesion remains localized to the seat of the inoculation.

Cultivation.—Schereschewsky has cultivated, with a certain degree of success, *T. pallidum* on a medium of horse serum, brought to a gelatinous consistence by heating to 60° C., and partly autolyzed by keeping in an incubator at 37° C. for three days. Later Muhlens and Hartmann also cultivated it, Hartmann inoculating a pure culture with success in the testicles of a rabbit, and more recently it was grown by Noguchi quite successfully, as described above for Spiroschaudinnia, and he has also been successful in reproducing the disease in monkeys by inoculation of the pure culture. The monkeys present a positive Wassermann reaction two weeks after inoculation. Noguchi has made the important observation that there are several varieties of *T. pallidum*; he distinguishes a normal type of medium thickness, a thick type, and a thin type. Inoculated in the testicles of rabbits, the normal type gives rise to a diffuse induration, which develops the third week after inoculation; the thick type gives rise to several small hard nodules, which develop slowly; the thin type induces a diffuse swelling, which develops very quickly, ten to fourteen days after inoculation. It is interesting to note that Mott, several years ago, suggested—on clinical and pathological grounds—that there might be more than one variety of *T. pallidum*.

Biological Reactions.—By heating the cultures to 60° C. Noguchi has produced a product which he calls luctine, by means of which a cutaneous reaction can be obtained in syphilitic patients.

Life-History.—Unknown.

E. H. Ross found cellular inclusions resembling Kurloff's bodies in mononuclears in non-ulcerated Hunterian chancres, and examined them in detail by placing the blood from such a chancre upon H. C. Ross's coefficient jelly.

Similar bodies have been described by McDonagh, who has given an account of a complicated life-cycle for *T. pallidum* (see second edition of this book, p. 409).

Pathogenicity.—*T. pallidum* is the cause of syphilis.

Treponema pertenue Castellani, 1905.

Synonyms.—*Spirochæta pertenuis* Castellani, June, 1905; *Spirochæta pallidula* Castellani, November, 1905.

History.—It was discovered by Castellani in 1905 in the scrapings from yaws papules.

Morphology.—*Treponema pertenue* is an extremely delicate spiral-shaped organism, varying in length from a few microns to 18 and 20 μ and even more. It is very slender. Some individuals are, however, thicker than others. It does not stain easily, but good results may be obtained with Giemsa's method, and also with Leishman's stain, provided the alcoholic solution is allowed to act for five minutes, and the subsequent admixture with distilled water for from one half-hour to several hours. Using either of these methods, the Treponemata stain purplish. Occasionally a few more deeply stained granules may be seen in the body of the organism. The extremities of the parasite are often pointed, but forms may be met with presenting blunt extremities, or one extremity pointed and the other blunt. In some individuals one of the extremities may present a large pear-shaped expansion or a loop-like formation. The number of coils varies from six to twenty or more, but they are, as a rule, numerous, uniform, and of small dimensions. Occasionally a portion of the *Treponema* shows numerous close uniform coils, while the rest of its body shows no coils at all. Sometimes two Treponemata may be attached end to end, or apparently twisted together. Castellani has not been able to detect any undulating membrane, though its presence has been asserted by other observers (Blanchard). Occasionally, in preparations stained by Löffler's method of flagella staining, it has seemed to several observers that some of the organisms present an extremely delicate flagellum at one end. Prowazek has described a resting form, oval or round, produced by a coiling up of the spiral. Ranken, by means of the dark-ground illumination, has been able to observe the extrusion from the parasite of small, highly-refractile granules, which are apparently shot out by free lateral motion. These granules immediately after extrusion remain stationary, then begin to rotate and move about, though apparently not supplied with flagella.

Intracellular Stage.—Castellani in 1905 described some peculiar bodies, free and intracellular, in leucocytes, which possessed an oval or roundish shape, and contained chromatin dots. At the time he was inclined to consider them to be stages in the development of the parasite, but later he held that they were cell inclusions of non-parasitic origin. In view, however, of the work of E. H. Ross and McDonagh on the organism of syphilis, it is possible that they are in reality a stage in the development of *T. pertenue*.

Comparison with T. pallidum.—From the above description it is evident that the frambœsia organism is morphologically very similar to that of syphilis. Blanchard, Martin, Prowazek, and others seem to have been able to make out some slight morphological differences between the two. Martin states that the frambœsia *Treponema* is even more slender and more difficult to stain than the *T. pallidum* of Schaudinn. On the other hand, some authorities consider it to be thicker. Rivas states that it has closer coils. Prowazek, Levaditi, and Nattan-Larrier state that *T. pertenue* shows less regularly shaped coils, and one extremity terminates in a loop much more frequently than in *T. pallidum*. Moreover, according to Levaditi and Nattan-Larrier, in fresh preparations *T. pertenue* displays whip-like lateral movements rather than translatory ones. Russell and Archibald consider that *T. pertenue* is slightly thicker than *T. pallidum*; the distance from crest to crest of the waves and the dip from the crest to the hollow is greater; the parasite has greater tendency to curl up into a loop at one end. Ranken states that the parasite does not show any corkscrew-like motion, nor any progressive motion. We believe that the differentiation of the two organisms, and in general of spirochætes and Trypanosomata, is to be based more on the results of the biological tests than on slight morphological differences. The animal tests clearly show that *T. pertenue* and *T. pallidum* are two different species, inasmuch as monkeys immunized with *T. pertenue* do not become immune for *T. pallidum*.

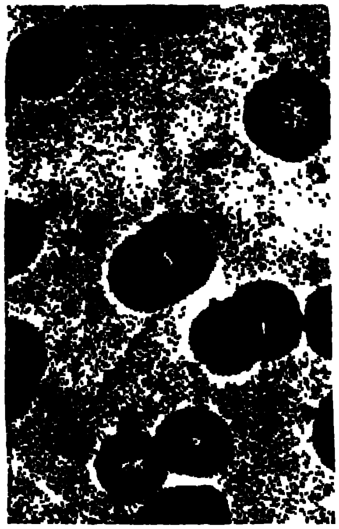

FIG. 140.—*Treponema pertenue* CASTELLANI.

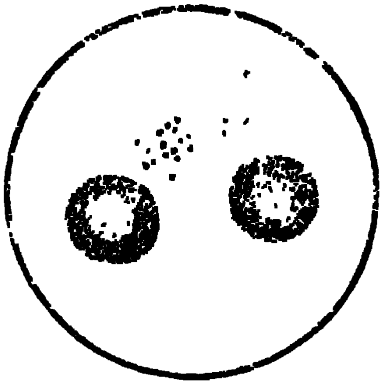

FIG. 141.—BASOPHILE CELL, WITH CHROMATIN DOTS, IN A CASE OF FRAMBŒSIA.

Incidence of the T. pertenue in Frambœsia Lesions.—The presence of the *Treponema* is constant in the primary lesion and in the unbroken papules of the general eruption. It may be found in the spleen, lymphatic glands, and bone-marrow. In the blood it has not yet been demonstrated microscopically, though there is no doubt that the blood of the general circulation is infectious, inasmuch as monkeys inoculated with it develop typical yaws lesions, in which the *Treponema* is abundantly present. The *Treponema* is absent in the cerebro-spinal fluid, and generally in the tertiary lesions.

Bacteriological Flora found in Open Sores of Framboesia.—While *T. pertenue* is the only germ found in the non-ulcerated lesions, the ulcerated lesions of framboesia are soon invaded by all kinds of germs. Apart from innumerable bacteria, various kinds of spirochætes are present. One form is rather thick, and takes up the stain easily. It is morphologically similar to the *Spiroschaudinnia refringens* of Schaudinn. Another form is thin, delicate, with coils varying in size and number, and with blunt extremities—*S. obtusa* Castellani. A third form is likewise thin and delicate, but tapers at both ends—*S. acuminata* Castellani; *T. pertenue* is also present in many cases.

Inoculation Experiments of Framboesia in Man.—Paulet, in 1848, inoculated fourteen negroes with the secretion taken from framboetic granulomata. All of them developed framboesia, the inoculation period varying from twelve to twenty days, when at the seat of inoculation in ten cases the first nodule appeared, soon followed by a typical general eruption. In two cases apparently the eruption did not start from the seat of inoculation.

Charlouis, in 1881, inoculated thirty-two Chinese prisoners, who had never suffered from the disease, with crusts and scrapings from a case of yaws. The disease developed in twenty-eight of them, beginning invariably at the seat of inoculation. Moreover, he inoculated a native suffering from typical yaws with syphilis. The inoculation was quite successful, a primary syphilitic sore developing, followed by all the usual types of secondary eruption. That yaws patients are not immune against syphilis is proved also by Powell and Nicolas and others, who have described several cases of syphilis supervening on yaws. Syphilitic patients may contract framboesia naturally and experimentally.

Inoculation Experiments in Monkeys.—Neisser, Prowazek, Halberstadter in Java, and shortly afterwards Castellani in Ceylon, have shown that monkeys are susceptible to framboesia. According to their experiments, the inoculation period varies from a minimum of sixteen days to a maximum of ninety-two. The appearance of the lesions developing at the seat of inoculation is practically the same in all cases—viz., an infiltrated spot slowly increasing in size, and soon becoming moist, the secretion drying into a thick crust. Removal of the crust exposes a raw, granulating, red surface.

In the monkeys of a low class (genus *Macacus*, genus *Semnopithecus*) the eruption is, as a rule, localized to the seat of inoculation. The infection, however, is general, as is proved by the presence of *T. pertenue* in the spleen and lymphatic glands besides the local lesions. Halberstadter has obtained a general eruption in ourang-outangs. According to Castellani's experiments, splenic blood, obtained by puncturing the spleen of a patient affected with frambœsia, can reproduce the disease in monkeys. The inoculation of the blood of the general circulation also may occasionally produce the disease. The inoculation of cerebro-spinal fluid into normal monkeys has always proved negative.

Neisser, Halberstadter, J. Prowazek in Java, and later Castellani in Ceylon, have proved that monkeys successfully inoculated with frambœsia do not thereby become immune to syphilis, and, *vice versa*, monkeys successfully inoculated with syphilis do not thereby become immune to frambœsia. According to Levaditi, monkeys immunized for frambœsia do not acquire any immunity for syphilis, but monkeys immunized for syphilis may acquire a partial immunity for frambœsia. According to Ashburn and Craig, monkeys of the species *Cynomolgus philippinensis* are susceptible to frambœsia, but not to syphilis.

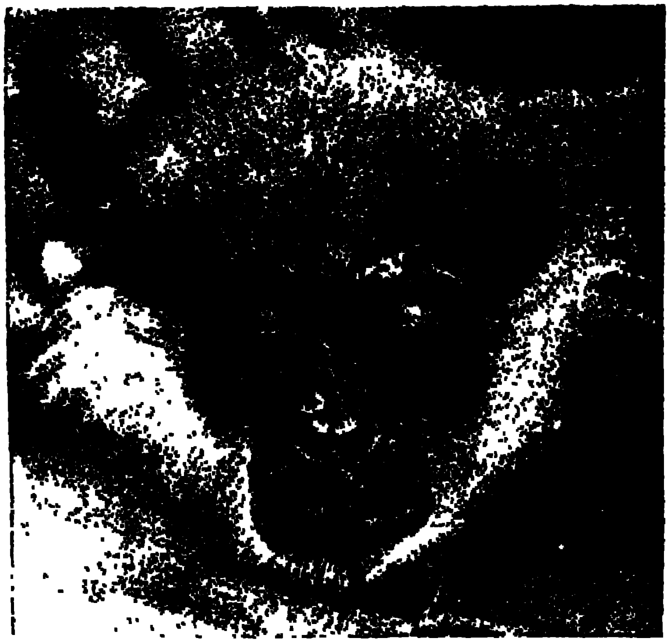

FIG. 142.—MONKEY INOCULATED WITH FRAMBŒSIA.

The following facts are in favour of the *T. pertenue* being the specific cause of frambœsia:—

1. In the non-ulcerated papules, in the spleen, in the lymphatic glands of frambœsia patients, as well as in inoculated monkeys, the *T. pertenue* is the only organism present. No other germ can be demonstrated, either microscopically or by cultural methods.

2. The extract of frambœsia material containing the *T. pertenue*—but, so far as our present methods of investigation permit us to say, no other germs—is effective when inoculated into monkeys.

3. The extract of frambœsia material from which the *T. pertenue*

has been removed by filtration becomes inert, and monkeys inoculated with it do not contract the disease.

Inoculation Experiments in Rabbits.—Nichols has inoculated rabbits successfully, and finds that the incubation period is shorter than that for *T. pallidum* in the same animal. He finds that 4·5 milligrammes of salvarsan per kilogramme of the animal's weight injected intravenously will effect a cure, which is less than for *T. pallidum.* Complement fixation is positive by the fourteenth day, but after administration of salvarsan it becomes negative. He has not been able to produce immunity, and he finds that if reinoculation is unsuccessful it is because the animal is still infected; whereas, if it is cured, reinoculation can be successfully performed. It is possible to demonstrate the difference between syphilis and framboesia by the reinoculation of rabbits after treatment by salvarsan. Castelli has inoculated rabbits intravenously, and states that the general clinical symptoms, papules, etc., are so different from those obtained after a similar injection of *T. pallidum* that this method may be of use for differentiating them.

Cultivation.—*T. pertenue* has been successfully cultivated by Noguchi, as described for Spiroschaudinnia (p. 441).

Pathogenicity.—It is the cause of framboesia tropica (*vide* Chapter LXI., p. 1535).

Treponema mucosum Noguchi, 1912.

This *Treponema* was isolated from the pus of a case of pyorrhœa by Noguchi. It closely resembles *T. pallidum* and *T. microdentium,* but differs in certain biological properties. It can be cultivated in citrate dilution of ascitic agar. Cultures have a strong fœtid odour, and mucin is produced in the medium, but this property is lost by repeated subcultures. It is a strict anaerobe. Inoculated into monkeys or rabbits it causes transitory local inflammation.

Treponema calligyrum Noguchi, 1913.

Found by Noguchi in condylomata—cultivated by the same observer. It shows deep, regular curves, not so closely set as in *T. pallidum.* It is also thicker.

Other species are: *T. microdentium, T. refringens, T. termitis* Leidy, 1881, in *Calotermes militaris*; *T. minei* Prowazek, 1910; *T. vivax* Dobell, 1911, in *Oscillatoriæ*; *T. stylopygæ* Dobell, 1911, in *Stylopyga orientalis*; *T. parvum* Dobell, 1911; *T. minutum* Dobell, 1911; *T. dentium* Koch, 1877. *T. buccale* Cohn, 1872; *T. intermedium* Dobell, 1911, in the human mouth.

A rather doubtful *Treponema* has been described by Dobell in the intestine of *Bufo vulgaris* L.

T. urethrale Castellani, 1915, found in the mucopurulent discharge from the urethra. It is very delicate and has numerous spirals all equal. Length, 6-12 microns. The patient had no sign of gonorrhœa or syphilis.

CHAPTER XX

DIPLOZOA AND OCTOMITIDÆ

Preliminary—Diplozoa—Octomitidæ—Octomitus—Giardia—References.

PRELIMINARY.

WE now return to the classification of the Protomonadina given on p. 332, where the order is divided into two suborders, Monozoa and Diplozoa. The Monozoa we have just considered, and in the present chapter the Diplozoa are described.

SUBORDER 2. DIPLOZOA Hartmann and Chagas, 1911.

Definition.—Protomonadina with more or less tendency to bilateral symmetry in *undividing forms*, as shown by the arrangement of the flagella, by the duplication of the axostyle, with sometimes the nucleus and more rarely of the cytostome. An undulating membrane is absent.

Classification.—This suborder may be divided into two families, of which one is of importance in tropical medicine.

A. Cytostome single or absent; flagella eight in number—Family 1, *Octomitidæ* Minchin, 1912.
B. Cytostome double; flagella variable in number—Family 2, *Distomatidæ* Senn, 1900.

Only the first of these families concerns us.

FAMILY 1. OCTOMITIDÆ Minchin, 1912.

Definition.—Diplozoa with eight flagella and with or without a cytostome.

Type Genus.—*Octomitus* Prowazek, 1904.

Classification.—The family is divisible into several genera as follows:—

- A. Anteriorly three pairs and posteriorly one pair of flagella; nucleus single, bilaterally lobed or doubled; sucker absent.
  - I. Parasitic—*Octomitus*.
  - II. Free living—*Hexamita*.
- B. Antero-laterally one pair, mesially two pairs, and posteriorly one pair of flagella; nucleus usually double; sucker present—*Giardia*.

Octomitus and Giardia concern us; Hexamita does not.

GENUS I. OCTOMITUS PROWAZEK, 1904.

Definition.—Octomitidæ, parasitic with anteriorly three pairs and posteriorly one pair of flagella; nucleus single, bilaterally lobed or doubled; sucker absent.

Type Species.—*O. intestinalis* Prowazek, 1904, found in rats.

Classification.—The known species of Octomitus may be recognized as follows:—

A. Nucleus situate close to the anterior end:—
  I. Nucleus often bilobed—*Dujardini*.
  II. Nucleus double:—
    (*a*) Measurements 8-12 × 5-7 microns—*Intestinalis*.
    (*b*) Measurements 4-6 × 2 microns—*Muris*.
B. Nucleus not situate close to the anterior end:—
  Nucleus single and rounded; size 6 × 3 microns—*Hominis*.

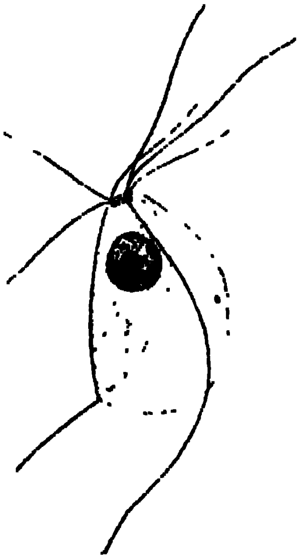

FIG. 143.—*Octomitus hominis* CHALMERS AND PEKKOLA, 1916. (× 2,000.)

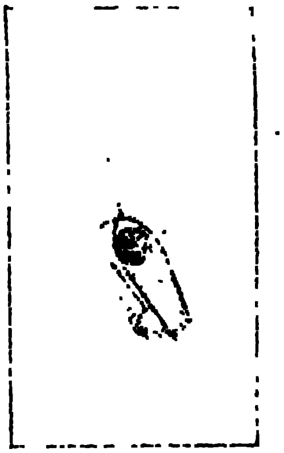

FIG. 144.—*Octomitus hominis* CHALMERS AND PEKKOLA, 1916. (× 2,000.)

Octomitus hominis Chalmers and Pekkola, 1916.

Definition.—Octomitus with single rounded nucleus, not situate close to anterior end.

Morphology.—Small fusiform or pear-shaped flagellates, in size 5·6-6·0 × 2·8-3·0 microns.

When examined in the stained condition it showed a circular clearly defined nucleus (Figs. 143 and 144), measuring about 1·4 microns in transverse diameter, and lying near the junction of the anterior third with the posterior two-thirds of the body. This nucleus is bounded by a well-marked membrane, which limits the homogeneous dark staining contents, in which there is often a centrally or excentrically placed karyosome.

In front of the nucleus and closely approximated to the anterior end of the body is a well-defined blepharoplast, which, though typically single, may have a secondary smaller blepharoplast associated with it. No sign of a rhizoplast could be seen.

From this blepharoplast there arise six anteriorly directed flagella, though occasionally one accidentally appears as though directed backwards. When there are two blepharoplasts, then three flagella arise from each.

These flagella vary considerably in length, being generally much longer than the body, but it is exceedingly difficult to be certain where they end, and in the specimens drawn only such portions as could be clearly seen are portrayed, though in other specimens the length was clearly much greater, in some instances quite three times the length of the parasite.

Directed backwards, and also arising from the blepharoplast or blepharoplasts, there are two chromatic lines, which, diverging and running on either side of the nucleus, may or may not converge, but in either case end near the posterior margin of the body in very minute chromatic particles, which are generally very difficult to see. From each of these chromatic particles there arises a posteriorly directed flagellum.

The chromatic rods are obviously axostyles, and the little particles in which they end may be termed axoplasts.

It is not often that the axostyles are seen together, as the parasite usually lies so that only one is visible, while the other is almost invisible; but at times they are seen as described above, or at other times when the parasite has shrunk into a rounded mass they may be observed crossing one another.

No cytostome has been observed, while the periplast is thin and without markings.

The cytoplasm is vacuolated with food vacuoles.

Life-History. Nothing is known of the life-history.

Pathogenicity. Believed to cause diarrhœa.

Genus Giardia Künstler, 1882.

Synonyms. *Lamblia* R. Blanchard, 1888; *Dimorphus* Grassi, 1879, *nec* Haller, 1878; *Megastoma* Grassi, 1881, *nec* de Blainville.

Definition. Octomitidæ with one antero-mesial pair, two pairs of mesial and one pair of posterior flagella; nucleus usually double; sucker present.

Type Species. *Giardia intestinalis* (Lambl, 1859).

Giardia intestinalis (Lambl, 1859).

Synonyms.— *Lamblia intestinalis* Lambl, 1859; *Cercomonas intestinalis* Lambl, 1854; *Hexamitus duodenalis* Davaine, 1875; *Dimorphus muris* Grassi, 1879; *Megastoma entericum* Grassi, 1881; *Megastoma intestinale* Blanchard, 1886; *Lamblia intestinalis* Blanchard, 1888.

This parasite lives in the intestine of different species of the genera Mus and Epimys (*M. musculus, E. rattus, E. norvegicus, M. silvestris*); also in species of Arvicola (*A. arvensis* and *A. amphibius*); also in the rabbit, the cat, the dog, the sheep, and man.

It was first observed by Lambl in the mucous intestinal evacuations of children in Russia; then by Grassi in Italy, who made a complete study of the parasite; by Moritz in Germany; by Jaksch in Austria; by Kruse in Egypt; and we have observed it several times in Ceylon; while it has been carefully studied by Werner in 1901, and more especially by Wenyon in 1907 and 1910, and his account is classical. It is common in the Anglo-Egyptian Sudan.

It occurs in the small bowel of man, and it and its cysts can be found in the fæces. Infection is brought about by swallowing the encysted forms. This has been proved experimentally by Grassi, and as it occurs in mice, it is quite easy to see how infection of foodstuffs is possible.

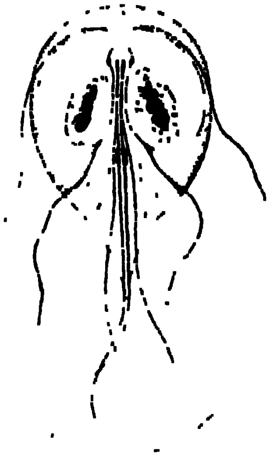

FIG. 145. — *Giardia intestinalis* (LAMBL, 1859).
(After Wenyon.)

G. intestinalis is an actively motile organism about 12 to 21 μ in length, and about 5 to 12 μ in breadth. It is pear-shaped, being surrounded by a thin periplast (ectoplasm), which keeps its form. The under surface (when attached) is excavated with a well-defined border, which is interrupted at the site of the cytostome. This hollow is probably a kind of peristome, and is useful in fixing the parasite to the intestinal epithelium.

There are two oval nuclei, with definite nuclear membranes and with large irregular karyosomes in their centres. There is no connection between these nuclei, but between them lie two darkly staining rods with expanded ends, and which posteriorly are continuous with the prolongations of the posterior flagella into the body. From the thickened posterior ends of the two rods spring the mesial pair of flagella, while at their anterior ends is a small granule, from which arises the anterior pair of flagella, which, running forwards and inwards, cross one another and pass across the peristome, or sucking disc or sucker, to its raised margin, around which they run, forming a kind of membrane, till nearly at the level of the nucleus they become free on each side.

From the same anterior pair of granules there arise the second and finer pair of mesial flagella, running down on the mesial aspect of the nuclei, behind which they turn outwards along the margin of the sucker and finally become free.

Sometimes there is a row of granules extending from the anterior granules to the nucleus on the same side.

Behind the two nuclei there is a triangular area, which forms a groove running towards the tail. Dorsal to this groove lie two darkly staining masses.

In addition in the living animal refractile granules can be seen lying in the anterior part of the animal on each side of the mesial line. From each of these granules a fine line runs posteriorly, and all these lines converging, as it were, into the handle of a fan, end in the tail, with the movements of which they may be concerned.

Life-History.—Reproduction may take place by binary fission. The process is very complicated, the whole system of sucking disc and flagella being reproduced dorsally, and then the flagellate splits longitudinally, the fissure passing from before backwards between the sucking discs.

Kofoid and Christiansen have described multiple fission in the lamblia of mice, but this has not been seen in those in man.

Encystment begins by a thin wall being excreted, inside which the flagellate can be seen moving. Later the cyst becomes ovoid and the wall tougher, and the contained lamblia may or may not have undergone division. Conjugation is not known to occur.

The cysts are oval and measure 13-14 × 6-7 microns; the wall is smooth and transparent. Later the nuclei divide, giving rise to four nuclei in all, which are crowded together.

Method of Infection.—The cysts escape in fæcal matter and are taken into house-flies, Musca and Fannia etc., and passing into the intestine, eventually escape in the flies' droppings, and so can infect human food.

Pathogenicity.—It is usually believed to be the cause of the diarrhœa with which it is associated.

CHAPTER XXI

TELOSPORIDIA

Telosporidia—Gregarinida—Coccidiidea—Hæmosporidia—Hæmogregarinidæ—Toxoplasmidæ—Piroplasmidæ—Plasmodidæ—Hæmoproteidæ—References.

PHYLUM III. TELOSPORIDIA Schaudinn, 1900.

Synonym.—*Eimerioinea* Poche, 1913.

Definition.—*Parasitic plasmodromata* without motile organs, in which the reproductive phase of the life-cycle, which produces spores, is distinct from and follows after the trophic phase.

Remarks.—All the Telosporidia are parasitic, and usually begin their life-cycle as small amœboid bodies, with a single nucleus, called trophozoites, which absorb nutriment and grow, and when fully developed show a cuticle, an ectoplasm, and an endoplasm. The endoplasm is granular, and contains a vesicular nucleus with chromatin karyosomes. The nucleus of the fully-grown trophozoite now begins to divide, and the parasite is known as a schizont, which reproduces by spore-formation. These spores, called merozoites, complete the cycle of asexual reproduction called schizogony. At some stage in the life-history of the parasite, generally when conditions of life are not favourable, some merozoites are produced, which, instead of developing into trophozoites, become sexual gametocytes, male and female. These forms, which are often resistant, are the means of transmitting the given species from one host to another. They produce gametes, which conjugate and form bodies called sporoblasts, and, lastly, spores called sporozoites.

Classification.—The Telosporidia are divided into three orders: Gregarinida, Coccidiidea, and Hæmosporidia, while the two latter are often put together into the Coccidiomorpha.

These may be recognized as follows:—

A. Only young trophozoites intracellular—*Gregarinida*.
B. Full trophozoite stage intracellular—*Coccidiomorpha*.
    I. With resistant spores in the sporocysts—*Coccidiidea*.
    II. Without resistant spores in sporocysts—*Hæmosporidia*.

ORDER I. GREGARINIDA Lankester, 1866.

Synonyms.—*Gregarinidea* Lankester, 1885; *Gregarinæ* Haeckel, 1866.

Definition.—Telosporidia, in which only the young trophozoites are intracellular, the fully-grown forms being extracellular.

Reproduction by Schizogony or Sporogony.— The gregarines are essentially parasites of the invertebrata, not being found in true vertebrates, though known in Amphioxus and Ascidians. They are generally found in the Arthropoda and worms, and appear to be non-pathogenic.

Their life history may be briefly described as follows: The young trophozoite enters a cell, generally of the alimentary canal, in which it grows, apparently causing considerable damage, for the cell first swells and afterwards degenerates.

In the meanwhile the parasite has found its way either wholly or partially out of the cell, to the remains of which, however, it is attached until all nourishment is extracted, when it becomes cœlozoic—*i.e.*, it leaves the remains of the cell, and dwells either in the alimentary canal, the cœlome, or the blood stream. The young parasite is unicellular, having its cytoplasm divided into ectoplasm and endoplasm. The ectoplasm is hyaline, and when fully developed has three layers—(1) external epicyte, (2) middle sarcocyte, (3) internal myocyte.

The last named contains contractile fibrils called myonemes. The endoplasm is granular, and contains a well-developed vesicular nucleus. A unicellular gregarine, such as this, belongs to the suborder Acephala, and is illustrated by *Monocystis agilis* Stein, which is found in the vesiculæ seminales of *Lumbricus terrestris*.

On the other hand, in such a gregarine as *Pyxinia frenzeli* Laveran and Mesnil, a part of the sporozoite grows out from the cell, and into this external portion the nucleus travels. The portion left in the cell is known as the 'epimerite,' while the external portion, growing considerably, is divided by a septum into a 'protomerite' near the cell, and a 'deutomerite' away from the cell.

The parasite in this condition is called a cephalont, and belongs to the suborder Cephalina.

In due course the trophozoite, whether entirely or partially in the cell, is set free, either by bursting its way out, or by a separation between the epi- and protomerite. The cell now degenerates, and the parasite may be called a sporont. Sporogony takes place by two sporonts or gametocytes lying side by side becoming enclosed in a cyst with two walls—an external epicyst and internal endocyst.

The karyosomes of the nuclei of the gametocytes now break up into chromidia, which collect to form the generative nucleus. This divides by mitosis to form a large number of nuclei, which, travelling to the surface and surrounding themselves with cytoplasm, become detached as gametes, the rest of the cell forming a *masse de reliquat* or residual mass. Thus, inside the cyst-walls there are gametes from two separate parasites and two residual masses.

Gametes presumably from different individuals fuse and form a true zygote with a synkaryon. Each zygote represents a sporoblast, and each sporoblast becomes a single spore by the secretion of a chitinous cuticle and the contraction of its protoplasm (called by Minchin the 'sporoplasm'). This sporoplasm divides by amitosis into eight sporozoites and a residual mass. During this process the two residual masses of the original cyst disappear. The cyst now contains only the spores which used to be called pseudonavicellæ. These spores are intended to convey infection to a new host, in the intestine of which they set free the sporozoites, which promptly attack either the cells of the intestine or some other organ, thus completing the cycle of sporogony.

Schizogony. This is uncommon in the gregarines, being only found in the Schizogregarinidæ. It is typically seen in *Schizocystis*, in which the trophozoite grows into a schizont, whose nucleus divides into a large number of daughter nuclei, round each of which a portion of cytoplasm gathers, forming a merozoite. This, escaping from the schizont, infects another cell, thus completing the cycle of schizogony. Some of the merozoites may develop by sporogony.

Classification.— The gregarines are classified as follows:

SUBORDER I. SCHIZOGREGARINARIA Doflein, 1909.

Synonyms.—*Schizogregarinæ* Minchin, 1903, *Schizocystina* Poche, 1913.
Reproduction by schizogony and sporogony.
Genera.—*Schizocystis* Léger, 1900, in the intestine of *Ceratopogon*; *Ophryocystis* Schneider, 1884, in the Malpighian tubules of beetles.

SUBORDER II. EUGREGARINARIA Doflein, 1901.

Reproduction as usual by sporogony. Schizogony very rare, if present at all, and only in the earliest cytozoic stages. The Eugregarinida are divided into two tribes.

TRIBE 1. ACEPHALINA Delage Hérouard, 1896.

Synonym.—*Monocystidea* Haeckel, 1866. No epimerite and no septa.
Genera (eighteen described by Minchin).—*Monocystis* Stein, 1848, parasite in the vesiculæ seminales and body cavities of the Oligochætæ and Cyclopidæ: *Zygocystis* Stein, 1848, in *Lumbricus agricola*; *Zygosoma* Labbé, 1899, *Lankesteria* Mingazzini, 1891, in *Ascidians*

TRIBE 2. CEPHALINA Delage Hérouard, 1896.

Synonym.—*Polycystidea* Haeckel, 1866. With epimerite, and with or without a septum in the body.

SUBTRIBE 1 GYMNOSPOREA Léger. Cyst with naked sporozoites (gymnospores).
FAMILY 1: AGGREGATIDÆ Labbé, 1899.
Genus. *Aggregata* Frenzel, 1885 Sporozoites grouped about residual masses.
FAMILY 2 POROSPORIDÆ Labbé, 1899 Each sporoblast giving rise to numerous sporozoites grouped round a residual mass.
Genus.—*Porospora* Schneider, 1875. *P. gigantea* in the lobster.
SUBTRIBE 2: ANGIOSPOREA Spores well developed
FAMILY 1 GREGARINIDÆ Greene, 1859 Trophozoites with simple epimerites.

Genera. *Gregarina* Dufour, 1828. Epimerite conical or knobbed. Species found in cockroaches, earwigs, meal-worms, and in the intestines of other insects. *Gamocystis* in the cockroach, also *Eirmocystis*, *Hyalospora*, *Lasperia*, *Sphærocystis*, *Cnemidospora*, *Stenophora*.
Other families are Didymophyidæ, Dactylophoridæ, Actinocephalidæ, Acanthosporidæ, Monosporidæ, Stylorhynchidæ, and Dolichocystidæ.

ORDER II. COCCIDIIDEA.

Synonyms. *Coccidiomorpha* Doflein, 1901; *Eimeridea* Poche, 1913.
Definition. Telosporidia, parasitic, as a rule, in epithelial cells of vertebrates and invertebrates. Reproduction always by both schizogony and sporogony.
Remarks.—The Coccidiidea were recognized as long ago as 1839 by Hake, who did not know that they were animals, that discovery being made by Remak (1845); while Lieberkühn in 1854 showed that they were allied to Gregarines. Leuckart (1879) gave them the name Coccidium, while Schaudinn in 1900 first described a full and complete life-history of *Coccidium schubergi*, which will be taken as the type.

Coccidium schubergi Schaudinn, 1900.

Coccidium schubergi begins its life-history in the intestinal cell of the centipede (*Lithobius forficatus* L.) by a sporozoite pressing its anterior end against an intestinal cell, and thus forcing a way into its interior.

Inside this cell it becomes the young trophozoite, an oval body which grows rapidly at the expense of the protoplasm of the cell, and in twenty-four hours attains its full size.

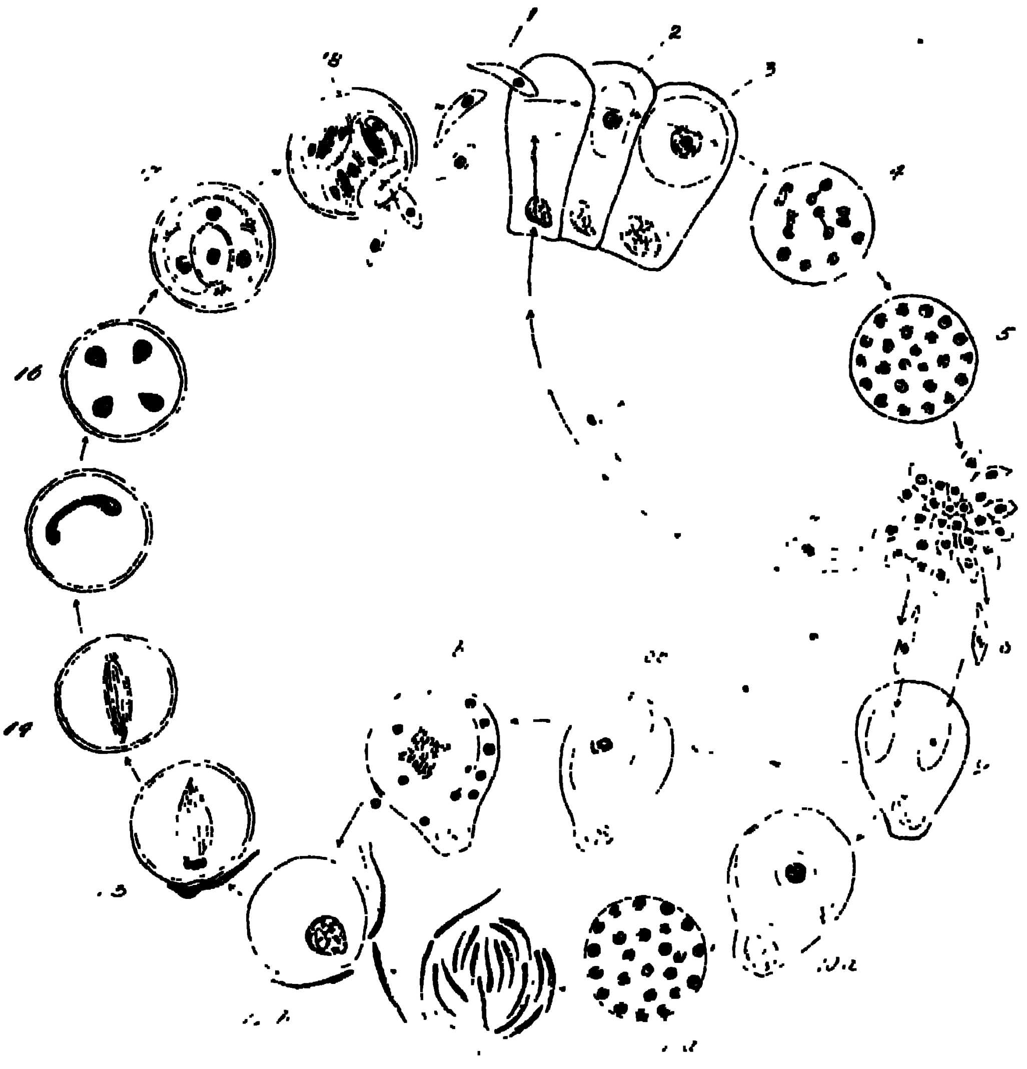

FIG. 190 - DIAGRAM OF THE LIFE-HISTORY OF *Coccidium schubergi* SCHAUDINN. (After Schaudinn)

1, Sporozoite entering an intestinal canal; 2-3, trophozoites; 4-5, schizonts; 6-8, merozoites; 9, young gametocyte; 10a-11a, microgametocyte; 10b-11b, macrogametocyte; 12a, microgametes; 12b, macrogamete; 13-16, oöcyst; 17, sporocysts; 18, sporozoites.

It is now called a schizont, because its nucleus divides into a number of daughter nuclei, which are formed into merozoites in the usual way. These merozoites, set free by the breaking up of the schizont, attack new intestinal cells, thus increasing the infection of the host.

This process cannot, of course, go on for any length of time, for a limit to the nutritive power of the host is reached in five days, when the parasite must attempt to infect a new host, and this is done by sporogony.

Some merozoites now become differentiated into micro- and macro-gametocytes. The former consist of finely granular cytoplasm, with little reserve material, while the latter are bean-shaped and have much food-material. The microgametocyte forms the microgametes by its nucleus becoming irregular, and forming fine achromatic paths through the cytoplasm to the periphery of the parasite, along which chromidia travel from the nucleus. At first, scattered evenly along the periphery, these chromidia gather into patches, and finally fuse into masses, enclosing in each a vacuole. The masses of chromatin lengthen, and by bending project from the cytoplasm, which now forms two flagella, whose active movements set free the microgamete.

In the meanwhile the macrogametocyte becomes a macrogamete by expulsion of the karyosome of the nucleus.

Micro- and macro-gametes now fuse and form a zygote with a synkaryon. The oöcyst, as it may be called, now passes out of the body of the host, and divides into four sporoblasts. Each sporoblast now develops two vacuoles and a cyst-wall, the sporocyst, so that the sporoblast is often called the spore. The nucleus of the spore divides into two, while the two vacuoles fuse and the cytoplasm divides, forming two sporozoites which are capable of infecting a new host, being set free by the acid of the digestive juices.

Sporogony takes about two to three days for completion.

It may be as well at the present time, when so much disputation is taking place *re* Schaudinn's work on trypanosomes, to mention that he worked out this life-history, which has never been refuted, though the parasite was found in company with *C. lacazei* Labbé and *Adelea ovata* A. Schneider.

Classification of the Coccidiidea.—The usual classification is that by Léger in 1900, and is based upon the number of sporozoites in each cyst.

FAMILY 1. ASPOROCYSTIDÆ.—Sporozoites naked, no sporocysts inside the oöcyst.

FAMILY 2. DISPOROCYSTIDÆ.—Oöcyst has two spores.

FAMILY 3. TETRASPOROCYSTIDÆ.—Oöcyst has four spores.

FAMILY 4. POLYSPOROCYSTIDÆ.—Oöcyst has many spores.

FAMILY ASPOROCYSTIDÆ Léger, 1900.

The genus included in this family is *Eimeriella* Stiles, 1902, of which there is only one species. *Eimeriella nova* Schneider, 1819 in the Malpighian tubules of Glomeris.

FAMILY DISPOROCYSTIDÆ Léger, 1900.

The genera of this family are: *Cyclospora* A. Schneider, 1881 (spores dizoic); *Diplospora* Labbé, 1893 (spores tetrazoic); *Isospora* A. Schneider, 1881 (spores polyzoic).

Isospora A. Schneider, 1881.

Definition.—Disporocystidæ with polyzoic spores.

Isospora bigemina Stiles, 1891

Synonym.—*Cytospermium villorum intestinalium canis et felis* Rivolta, 1874.

This parasite lives in the intestinal villi of dogs and cats, and is distinguished because it is small and because it is in pairs, the oocyst dividing into two equal portions, which become encysted and form two spores (*vide* Coccidiosis in man *infra*).

FAMILY TETRASPOROCYSTIDÆ Léger, 1900.

Type Genus.—*Eimeria* A. Schneider, 1874.

Synonym.—*Coccidium* Leuckart, 1879 (the dizoic spores are spherical or oval). **Other Genus:** *Crystallospora* Labbé, 1896 (the dizoic spores have the form of a double pyramid).

Eimeria A. Schneider, 1875.

Telosporidia with the formation of an oocyst after fecundation; sporoblasts in the form of a pyramid; spores globular or oval, provided with a micropyle.

Eimeria stiedæ Lindemann, 1865.

Synonyms.—*Psorospermium cuniculi* Rivolta, 1878; *Coccidium oviforme* Leuckart, 1879, *C. perforans* Leuckart. *Pfeifferia princeps* Labbé, 1896.

This is the common species found in the liver of rabbits. The spores swallowed by the rabbit are opened by the action of the acid of the gastric juice, and the sporozoites set free ascend the bile-duct, and pass into the cells lining the small bile ducts. Here they propagate vigorously by schizogony, causing proliferation of the epithelium and connective tissue of the ducts, so that thick-walled nodules, more or less isolated and containing caseous material (consisting of detritus, pus, epithelial cells, and coccidia), are formed. The inflammation may be severe enough to kill the rabbit.

Sporogony proceeds with the formation of macrogametocytes with macrogametes, and the microgametocytes with microgametes, which conjugate and form zygote, sporoblast, spores, and sporozoites (*vide* Coccidiosis in man, *infra*).

FAMILY POLYSPOROCYSTIDÆ Léger.

Comprises a large number of genera: *Adelea* A. Schneider, 1875 (dizoic); *Klossia* (tetrazoic) A. Schneider, 1875, *Minchinia* Labbé, 1896; *Klossiella* Smith and Johnstone, 1902, *Barrouxia* (monozoic); *Benedenia* (trizoic).

Coccidiosis in Man.

The utmost confusion has existed as to this infection of man, but now, thanks to the labours of Dobell, whose writings we have followed, the subject is more defined.

In 1841 Johannes Muller introduced the name 'psorosperms' for the spores of the myxosporidia, and as the coccidia were believed to resemble these bodies, they were called 'oviform psorosperms' until Leuckart in 1879 gave them the name *coccidium*. The various diseases and cases rightly or wrongly called coccidiosis at any time in man may be considered as follows:—

Diseases now known not to be Coccidiosis. These are (1) a form of blastomycosis (granuloma coccidioides); (2) rhinosporidiosis; (3) Darier's disease, (4) molluscum contagiosum.

Cases wrongly diagnosed as Coccidiosis.—These are the cases described by Virchow (1860), Rivolta (1873 and 1878), Grassi (1879), Podwyssoki (1889), Giles (1890), Jurgens (1895), Quincke (1899), Thomas (1899), Grunow (1901),—and probably by Künstler and Pitres (1884).

Cases correctly recognized as Coccidiosis.—Dobell considers that over seventy cases, mostly from the Near East, have recently been recognized as coccidiosis. The earlier cases are:—

Hepatic.—Gubler in Paris (1858), Dressler in Prague (recorded by Leuckart in 1863), Sattler in Vienna (recorded by Leuckart in 1879), Perls in Giessen (recorded by Leuckart in 1879); Perls and von Sömmering (?) (recorded by Leuckart in 1879), and Silcock in London (1890).

Intestinal.--Kjellberg (recorded by Virchow in 1860) and two cases by Eimer (1870).

Fæcal.--These are numerous. The earliest are Woodcock (1915), Low (1915), Wenyon (1915), Woodcock and Penfold (1916), Dobell (1916), Roche (1917), Cragg (1917), Wenyon and O'Connor (1917), Savage and Young (1917), Castellani and Richards (1917), Martin, Kellaway, and Williams (1918), Boney, Crossman, and Boulenger (1918), while Dobell (1918) has found a new form.

Coccidia found in Man.--The coccidia found in the above cases may be classified as:--(1) *Isospora hominis* Rivolta, 1878, *emendavit* Dobell, 1918; (2) *Eimeria wenyoni* Dobell, 1918; (3) *Eimeria oxyspora* Dobell, 1918; (4) the hepatic coccidium of man. These species may be described as follows:—

Isospora hominis Rivolta, 1878, *emendavit* Dobell, 1913.

Synonyms.--*Psorospermien* Virchow, 1860, Leuckart, 1863, Eimer, 1870; *Cytospermium hominis* Rivolta, 1878, *Coccidium perforans* Leuckart, 1870; *Coccidium bigeminum* var. *hominis* Railliet and Lucet, 1891, *Coccidium perforans* var. *kjellbergi* Labbé, 1896, *Coccidium hominis* Rivolta, 1878, *emendavit* Labbé, 1896, *Eimeria stiedæ* Lindemann, *pro parte* Luhe 1906, *Isospora bigemina* Stiles, 1891, *pro parte* Luhe, 1906.

Definition.--Isospora with oöcysts elongate, ovoid in form, narrow end drawn out into a neck, 25-33 × 12·5-16 microns, with clear, colourless, and porcellaneous wall, with two or more layers and an inconspicuous micropyle at narrow end. Development of spores takes place outside of host, and requires several days for completion. Oöcyst forms two round sporoblasts, from which arise two sporocysts, which form four vermiform sporozoites and leave a large granular sporocystic residue. Habitat, man.

History.--*I. hominis* was discovered by Kjellberg about 1860, in the villi of the small intestine, it was seen in 1870 by Eimer, and was named in 1878 by Rivolta. Its oöcysts were probably first found in human fæces by Railliet and Lucet in 1890, but the first clearly recognizable account is that given by Wenyon in 1915, since when some fifty cases of infection have been recorded, making in all, with the cases seen by Castellani and Richards in the Balkans, about seventy infections.

Distribution.--It has been found in people coming from Gallipoli, Salonika, Egypt, Mesopotamia, and in the Balkans.

Pathogenicity.--This is believed to be nil, as most cases showed merely a small and transitory infection. Animals have so far not been infected with this parasite.

Eimeria wenyoni Dobell, 1918.

Synonyms.--*Eimeria* (Coccidium) Wenyon, 1915; *Coccidium* (Eimeria) Wenyon, 1916; *Eimeria* sp. Dobell, 1917.

Definition.--Eimeria with a spherical oöcyst, 20 microns in diameter, with outer surface rough and rugose, inner smooth and lined by a delicate membrane. Four oval spores measuring 10 × 7 microns. External surface of sporocyst rough. No oöcystic residual body. Each spore contains two typical sporozoites and one or two sporocystic residua. Habitat, man.

History.—This parasite was found by Woodcock and Wenyon, in 1915, in the fæces of a British soldier from Gallipoli. It was again found by Roche in 1917 in three cases at Salonika, so that the total infections up to date (1918) are four.

Distribution.—Shores of the Eastern Mediterranean.

Pathogenicity.—Unknown and no attempts so far made to infect animals.

Eimeria oxyspora Dobell, 1918.

Definition.—Eimeria with spherical oöcyst 36 microns in diameter, with faintly yellow transparent wall, composed of at least two distinct layers, containing four dizoic spores and a small oöcystic residue. Spores long, sharply pointed at both ends, 30-32 × 7·5 microns. Sporocyst has a tough endospore and deciduous epispore, the remains of which give the spore a frilled appearance. There are two sporozoites in each spore, with pointed anterior and rounded posterior ends which contain the nucleus.

History.—The parasite was found by Dobell in a young man who had been in South Africa, Ceylon, and India.

Distribution.—Unknown.

Pathogenicity.—Infection small, but pathogenicity not certainly known, because the patient was infected with *E. histolytica* and *Ancylostoma*. Believed not to be pathogenic.

The Hepatic Coccidium of Man.

Synonyms. *Cellules ovoides* (?) *œufs d'helminthes* Gubler, 1858; *Corps oviformes* Davaine, 1860; *Psorospermien* Leuckart, 1863; *Psorospermi* Rivolta, 1873; *Coccidium oviforme* Leuckart, 1879; *Coccidien leberpsorospermien* Butschli, 1882; *Coccidium cuniculi* (Rivolta) Blanchard, 1896; *Eimeria stiedæ* (Lindemann) Lühe, 1906; *Eimeria* (?) sp. Dobell, 1918.

Definition.—Not at present capable of definition.

History.—It was first recorded by Gubler in 1858, in a quarryman, aged forty-five, in Paris. This man is said to have died from peritonitis. He suffered from digestive troubles, anæmia, and had an enlarged liver. Post-mortem the liver contained many tumours of a cancerous appearance, in which were numerous ovoid cells or eggs of helminthes, at least four times the size of the largest cells of the surrounding tissue. Some had a distinct double contour, and were completely filled with granular contents. One end was rather blunter than the other, which showed a slight constriction, and had a small depressed surface, as though an operculum or micropyle were present.

The second case was found by Dressler of Prague, and consisted of three small nodules in the margin of a human liver. These nodules contained a whitish pulp, which surrounded oval bodies 18-20 microns in length, and his drawings show four oöcysts. The third case was discovered by Sattler of Vienna in a pathological preparation. It showed a dilated bile-duct with greatly proliferated epithelium and coccidia.

The fourth case is by Perls; it was from a preparation made by von Sömmering, and is said by Leuckart to have contained coccidia.

The fifth and last case is that described by Silcock in 1890 at St. Mary's Hospital, London. A woman aged fifty had enlargement of the liver and spleen, with fever and slight diarrhœa. At the post-mortem the liver was much enlarged and showed a number of caseous foci. The ileum contained six papule-like elevations surrounded by an inflammatory zone, and the large intestine had deeply congested patches of mucosa.

In the caseous nodules were agglomerations of small oval, egg-like bodies, with granular contents and a well-marked capsule, and were considered to be identical with Leuckart's coccidia. They were kept in water, and psorosperms freely developed. He considered them to be *Coccidium oviforme*, and to be present in the spleen, but does not state anything definite as to the intestine.

In all, therefore, up to 1918, five cases have been recorded.

Dobell does not consider this parasite to be *Eimeria stiedæ*, judging from Dressler's drawings.

Gubler's case was considered to be a hydatid cyst. Dobell's conclusions are that there is a coccidial parasite which very rarely occurs in the human liver, and resembles *E. stiedæ*, but is considerably smaller and is probably a distinct species, though perhaps belonging to the same genus.

Distribution.—Europe.

Pathogenicity.—It causes cyst-like swellings of the liver, with enlargement of that organ.

ORDER III. HÆMOSPORIDIA Doflein, 1901.

Synonym.—*Hæmocytozoa* Mesnil, 1915.

Definition.—Telosporidia, Coccidiomorpha without resistant spores in the sporocysts and with the trophozoite stage intracellular. With alternations of generation, schizogony in a vertebrate and sporogony in a blood-sucking arthropod or leech.

Remarks.—Mesnil considers that the family Hæmogregarinidæ is related to Léger's Adeleidea division of the Coccidiidea, and the Plasmodidæ to the *Eimeridea* division, and that they should find their places in that group. He considers that the genus Leucocytozoön should come into the Hæmosporidia, and that the Piroplasmidæ require more study in the invertebrate before being classified. There is no doubt that Hæmosporidia is merely a temporary order in which to place forms pending a fuller classification, which will probably be on the lines indicated by Mesnil.

Classification.—The following families may be temporarily placed in this order for convenience, and can be differentiated as follows:—

A. *Without hæmozoin* :—
  I. Live in red and white blood cells in the peripheral blood—*Hæmogregarinidæ*.
  II. Live in white cells in the organs—*Toxoplasmidæ*.
  III. Live in red cells in the peripheral blood—*Piroplasmidæ*.

B. *With hæmozoin* :—
  I. Oökinete encysts and forms an oöcyst—*Plasmodidæ*.
  II. Oökinete is not known to encyst—*Hæmoproteidæ*.

FAMILY HÆMOGREGARINIDÆ Neveu-Lemaire, 1901.

Synonyms.—*Hæmosporidia* Labbé, 1894; *Hæmosporea* Minchin, 1903.

Definition.—*Telosporidia*, in which either the gametocytes or the schizonts, or both, are present in red or white cells in the peripheral blood of vertebrates, and in which schizogony takes place either in the cells of the peripheral blood, or in those of some organ, while sporogony takes place in the body of some blood-sucking invertebrate, such as a leech, a tick, a mite, or an insect. Neither schizonts nor sporonts contain hæmozoin.

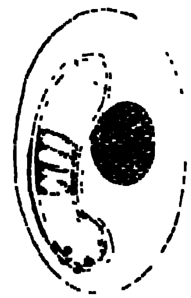

FIG. 147.—*Hæmogregarina canis* SAMBON. (After Sambon.)

History.—Although the first hæmogregarine was discovered in a frog as far back as 1850 by Chaussat, who thought it was a nematode, it is only quite recently, owing to the labours of Sambon, Miller, Miss Robertson, Christophers, and others, that any accurate knowledge has been obtained.

The evolution of the knowledge concerning these parasites may be briefly stated.

Discovered, as mentioned above, by Chaussat, they were next seen by Ray Lankester in 1871, and thought to be a stage in the life history of the frog trypanosome, *T.* (*Undulina*) *rotatorium*, and then by Gaule in 1880, who mistook them for cell inclusions. In 1885 Danilewsky first applied the name 'Hæmogregarina' to the parasites he found in the blood of tortoises and lizards. In 1894 Labbé classified them, according to the relationship between the length of the parasite and that of the blood cell, into (1) *Drepanidium*, parasite not more than three quarters of the length of the host cell; (2) *Karyolysus*, parasite not exceeding host cell in length, and destroying the nucleus; (3) *Danilewskya*, parasite exceeding the host cell in length, and bent upon itself.

The term *Drepanidium* having been previously employed for one of the Heterokaryota, it was necessary to alter it to *Lankesterella*, and the term *Danilewskya* was also altered by Danilewsky in 1897 to 'Hæmogregarina' (*sensu stricto*); but since Sambon and others have described so many new species this classification no longer stands, nor can a natural arrangement be proposed until the life-histories of the various species are fully known; therefore the suggestion of Laveran is being universally adopted, which consists of arranging them according to the classes, orders, and genera of the hosts, and distinguishing only one genus, *Hæmogregarina* Danilewsky, 1885, the various species of which are arranged into four groups: (1) Hæmogregarinida of mammals; (2) Hæmogregarinida of reptiles; (3) Hæmogregarinida of amphibia; (4) Hæmogregarinida of fish. With regard to the Hæmogregarinida of mammals, they were first discovered by Bentley in the blood of a pariah dog (*Canis familiaris*) in Assam, and confirmed by James in 1905. In 1905 Balfour discovered *Hæmogregarina jaculi* Balfour, 1905, in *Jaculus gordoni* in Khartoum, and described the cycle of schizogony, but though numerous experiments were conducted with *Xenopsylla cleopatræ*, species of *Dermanyssus* (mites), and *Clinocoris rotundatus*, only the liberated gametocytes have been traced. A danger is to mistake *Crithidia pulicis* of the flea for a developmental stage of the *H. jaculi*.

In 1905 Christophers discovered *H. gerbilli* in the Indian field rat (*Gerbillus indicus*), and traced its schizogony and later cyst formation in a louse (*Hæmatopinus stephensi*); but he did not observe conjugation, nor did he reinfect rats from the louse, and finally in 1907 he appears to think it probable that the cysts he described may have nothing to do with the hæmogregarine.

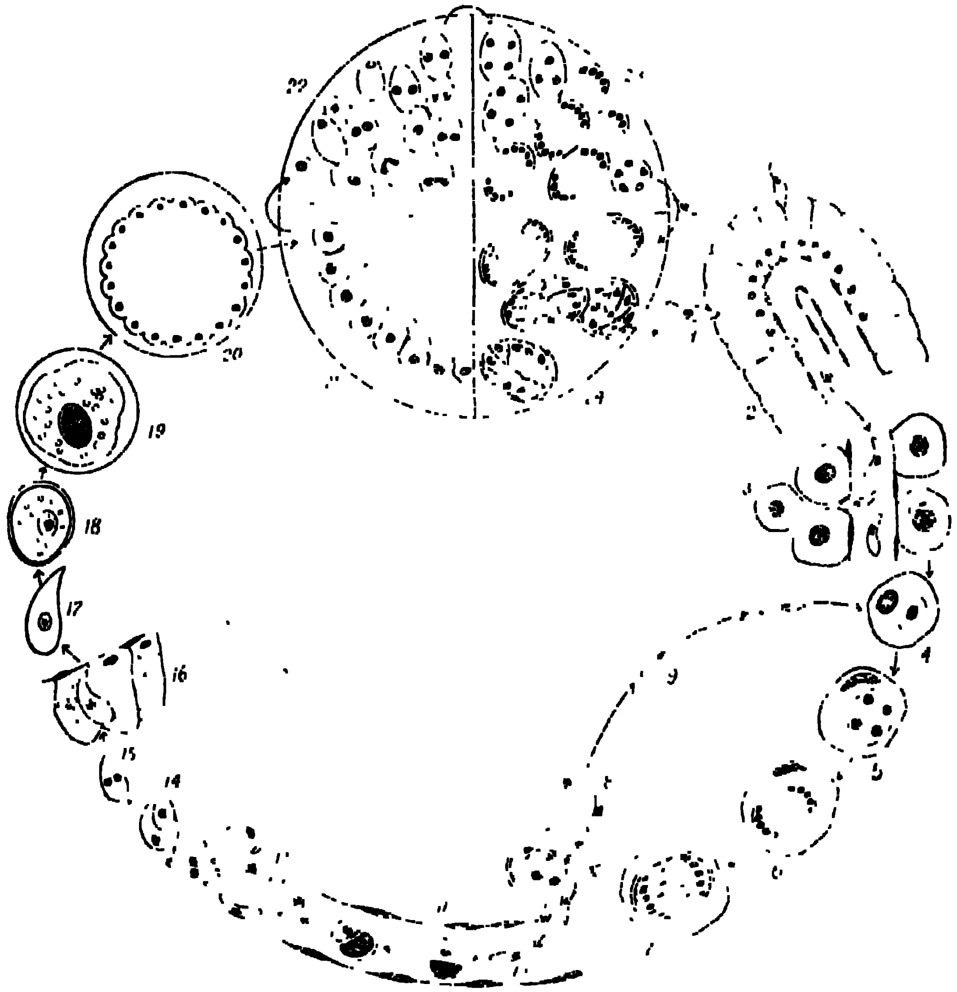

FIG. 198.—LIFE-CYCLE OF *Hæmogregarina muris* BALFOUR.
(After Miller.)

1, 2, Free sporozoites in the intestine of the rat penetrating the villus and entering the blood; 3, entering the liver cells; 4-8, schizogony in the liver; 9, merozoite about to reinfect a liver cell; 10-11, merozoite infecting a white blood cell; 12, free vermicules in the stomach of the louse; 13, conjugation; 14, the zygote; 15, ookinete in the stomach; 16, ookinete in the wall of the stomach; 17, oökinete; 18-19, oöcyst; 20, sporoblasts appearing; 21, early sporoblasts; 22, sporoblasts; 23, late sporoblasts; 24, formation of sporozoites

In 1906 Adie discovered a hæmogregarine in *Epimys rattus*, Balfour one in *E. norvegicus*, Christophers another in *Felis domestica*, Patton another in *Funambulus pennantii*.

In 1907 Christophers traced the sporogony of *H. canis* in *Rhipicephalus sanguineus*. In 1908 Miller contributes a most valuable paper on *H. muris* Balfour, 1905, under the term *Hepatozoon perniciosum* Miller, 1908, in which he not merely traced out the cycle of schizogony, but also fully that of sporogony. This was the first description of the full life-history of a hæmogregarine ever given. This paper is also of the greatest importance in arranging the classification of the Hæmogregarinida, for, as already stated, Ray Lankester in 1871 believed that *H. minima* might be a stage of *Trypanosoma rotatorium*, and in this was supported by Billet in 1904, who considered that he could infect clean frogs with hæmogregarines by the bites of leeches containing trypanosomes.

Brumpt's experiments in 1904 on the sporogony of *H. bagensis* in the leech (*Placobdella catenigera*) also supports this theory by finding a binucleate condition in the oökinetes. Miss Robertson believes that hæmogregarines have a trypanosoma stage. These observers would therefore classify the Hæmogregarinida with the Binucleata; but against this Brumpt in 1907 has shown that Billet was probably mistaken, for if leeches infected with *T. inopinatum* are placed on a 'clean' frog a trypanosomiasis results, and the fact that though Sambon has often seen hæmogregarines in snakes and lizards, trypanosomes are absent or rare.

The life-history of *H. muris* as worked out by Miller shows no trypanosome stage, and clearly indicates that the Hæmogregarinida belong to the Telosporidia, and are related to the Gregarinida and Coccidiidea, as was pointed out by Laveran in 1898.

With regard to the Hæmogregarinida of reptiles, a very complete work is that of Sambon in 1908 on the parasites in snakes, where a full history will be found. Those which occur in tortoises and crocodiles have been studied by Danilewsky, Castellani and Willey, Miss Robertson, Dobell, and others, while Siegel has worked out fully the schizogony and sporogony of *H. stepanowi* in the leech.

The Hæmogregarinida of lizards have been studied by Danilewsky, Laveran, Minchin, C. França, and others, and those of amphibia by Chaussat, Lankester, Billet, Durham, Brumpt, Labbé, Lesage, and others.

Life-History.—The most accurately known life-history is that given for *H. muris* Balfour by Miller.

Schizogony.—The asexual reproduction takes place in the cells of the liver, in which the young trophozoite appears as a small spherical organism with a large vesicular nucleus containing a well-defined karyosome. The trophozoite grows at the expense of the liver cell, the nucleus of which is pushed to one side, and in due course becomes a schizont, which divides into twelve to twenty merozoites, and a 'rest' body.

Some of these merozoites on liberation enter fresh liver cells, and continue the cycle of schizogony, while others enter mononuclear leucocytes, in which they become encysted, and develop into gametocytes.

Sporogony.—Sexual reproduction takes place in a mite belonging to the Gamasidæ called *Lelaps echidninus* Berlese, which lives on the blood of the rat.

The gametocytes, liberated from the leucocytes by the digestive action of the juices of the mite's gut, arrange themselves in couples, which are at first exactly similar, but which later differentiate into a large encircling form, which is more granular, and which is probably the macrogamete, and a smaller, more rounded, and less granular microgamete. Zygosis now takes place, forming an oökinete, which grows, and leaving the gut by piercing the wall, forces its way into the body cavity, which consists of a series of small spaces between the organs, and further into the sheaths of the muscles, and into the investing membrane of the salivary glands.

In the tissues the oökinete encysts and becomes the oöcyst, which grows rapidly in size, and undergoes nuclear division.

The daughter nuclei migrate to the periphery, which becomes covered with 50 to 100 bud-like projections, in each of which a nucleus is to be found. These buds break off from the central mass, and form the sporoblasts, the nuclei of which divide, forming daughter nuclei, which gather at the poles, while the whole sporoblast encysts. Short rod-like processes of cytoplasm, each containing a nucleus, now break off from the sporoblasts, each of which becomes a sporozoite, of which there are on an average sixteen to each sporoblast.

Infection of the rat takes place by ingestion of the mite, when the sporozoites are liberated by the juices of the duodenum, and become actively motile striated vermicules, which penetrate the intestinal villi, enter the blood stream, and are carried to the liver, into the cells of which they penetrate, and start the cycle of schizogony.

As the mites leave the rats during the day-time, and only feed on them during the night, it is easy to understand the manner in which the disease spreads from the sick to the healthy.

Variations in the Life-Cycle.—The life-history of *H. muris* is peculiarly interesting, because it is fully known, but it is not quite typical for all hæmogregarines, for in it the gametocytes alone are found in the peripheral blood, and they are enclosed in leucocytes.

Other species, however, show marked differences from *H. muris*, for the majority are found in red, not white, corpuscles, while in some the whole process of schizogony is completed in the blood stream; therefore a few more general remarks are necessary to supplement the life history given above.

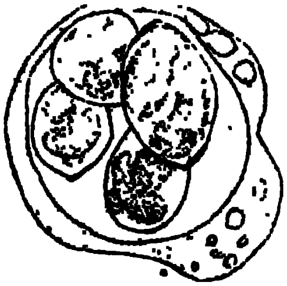

FIG. 149.—*Hæmogregarina nicoriæ* ROBERTSON, SHOWING SCHIZOGONY.

(After Miss Robertson.)

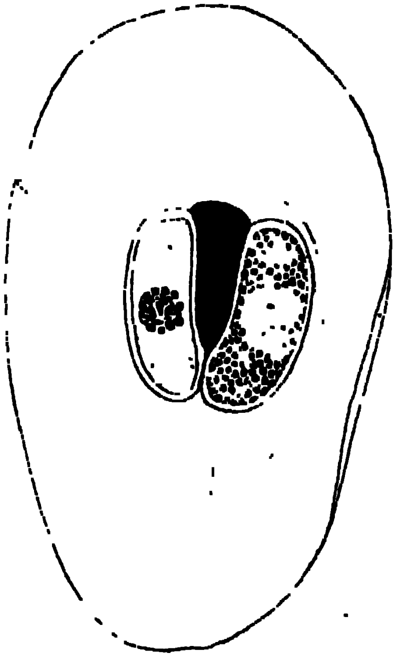

FIG. 150.—*Hæmogregarina rarefaciens* SAMBON, SHOWING MALE AND FEMALE SCHIZONTS.

(After Sambon.)

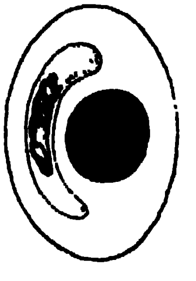

FIG. 151.—*Hæmogregarina rarefaciens* SAMBON: YOUNG GAMETOCYTE.

(After Sambon.)

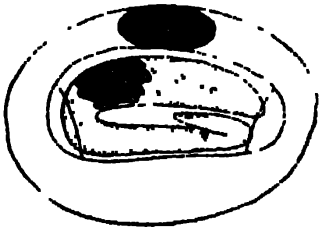

FIG. 152.—*Hæmogregarina seligmanni* SAMBON, SHOWING CAPSULE AND CLEAVAGE LINES.

(After Sambon.)

The peripheral blood of the vertebrate can contain trophozoites, schizonts, and gametocytes lying either in red or white corpuscles, the two latter being contained in a double capsule, which is probably formed by the parasite, and which is always in close attachment to the nucleus of the host cell.

Schizogony begins with the young trophozoite lying free in the enclosing cell, as an oval, fusiform, or club-shaped mass of cytoplasm with a large, homogeneous nucleus. As this trophozoite grows it becomes encapsuled, and forms the schizont, which, when fully grown, is a large oval or rounded body, with a central nucleus, and with the cytoplasm filled with spherules. This schizont usually lies in an enlarged and dehæmoglobinized cell, in which it is seen to be surrounded by a thick capsule, which shows three definite cleavage lines, of which two cross it transversely a short distance from either pole, while the third is longitudinal.

There are two varieties of schizonts, one which gives rise to relatively few large merozoites called ' macromerozoites,' while the other breaks up into relatively many small micromerozoites.

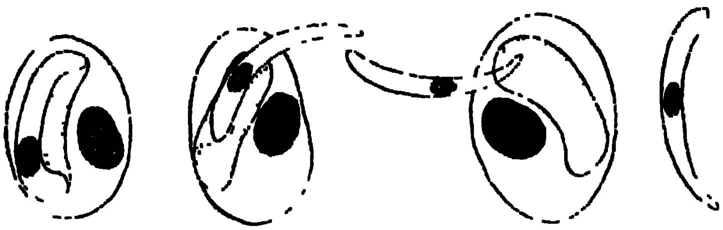

FIG. 153.—*Hæmogregarina mirabilis* CASTELLANI AND WILLEY, SHOWING THE ESCAPE OF THE GAMETOCYTE FROM ITS CAPSULE.

(After Castellani and Willey.)

This differentiation is considered to be a prelude to the formation of macro- and micro-gametocytes. Usually the schizont divides into eight, twelve, or sixteen merozoites, which may escape from the enclosing cell in the peripheral blood, but more generally do so in an organ, such as the liver, lung, or bone-marrow. Other hæmogregarines, like *H. jaculi* and *H. muris*, undergo segmentation in the cells of an organ such as the liver.

The gametocytes are easily recognizable from the schizonts, as they lie bent up in the capsule, and because the enclosing cell is not affected by the parasite. It is not possible at present to differentiate between the macro- and the micro-gametocyte.

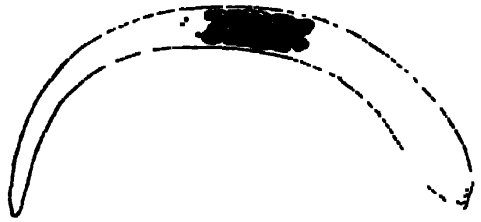

FIG. 154.—*Hæmogregarina seligmanni* SAMBON: FREE SPORONT.

(After Sambon.)

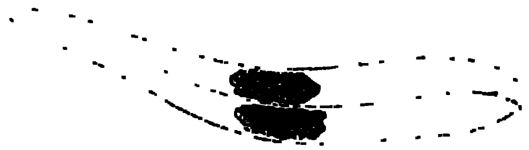

FIG. 155.—*Hæmogregarina seligmanni* SAMBON.

According to Sambon, this figure probably represents conjugation.

(After Sambon.)

In shed blood they quickly escape from the capsule, which may be seen to be double, for Sambon depicts a gametocyte which has escaped from the outer wall of the capsule, but has the inner wall still adherent.

When free, they are seen to be of an elongated, club-shaped form. At the thicker end, which is anterior, there projects a small retractile rostrum or beak, from which a clear line, probably a cytostome or pharynx, runs backwards through the cytoplasm, and ends near the nucleus.

The ectoplasm shows at times a differentiation into three layers—epicyte, sarcocyte, and myocyte—while the endoplasm is granular, and about its middle is found the round or oval nucleus.

According to Sambon, conjugation can be seen taking place in blood spread on an ordinary slide. The further history of the cycle of sporogony is only known in *H. muris* and *H. canis*; the former has already been described, and the latter will be mentioned later.

Recently Henry has shown that Balfour's infective granule is a phase in the life-history of *H. simondi*. Hæmogregarines can be cultivated in Nicolle's blood-agar medium.

No hæmogregarines are at present known in birds nor, until recently, in man, but some peculiar parasites have been seen by Castellani and Willey and others in the peripheral blood of man (p. 538); whether these will prove to be hæmogregarines, or whether they belong to some other order of the protozoa, remains to be seen. Krempf has recently described a hæmogregarina in the spleen of a Chinese.

Classification.— As already mentioned, the species of the genus *Hæmogregarina* Danilewsky, 1885, will be arranged according to their hosts. Some authors recognize *Hepatozoon* Miller, 1908, with *H. muris* Balfour, 1905, as a type, and distinguish it by living in leucocytes, and sometimes undergoing schizogony in the cells of the internal organs.

HÆMOGREGARINES OF THE MAMMALIA.

Hæmogregarina hominis Krempf, 1917.

Definition.— *Hæmogregarina* found only in the spleen of man suffering from splenomegaly, in China.

Remarks.— The infection appears to have been acquired in China.

Morphology.— The parasite lives in red cells which increase in size. Inside the red cells the organism lies in a capsule, 10 × 5 microns, and is vermicular in shape, being bent or twisted. There is a granular nucleus, mostly central in position. Parasites which have escaped from the red cells and lie free in the plasma are identical with those found in the cells.

Life-History.—Unknown.

Pathogenicity.—Believed to cause splenomegaly.

Hæmogregarina muris Balfour, 1905.

Synonyms.—*Leucocytozoon muris* Balfour, 1905; *Hepatozoon perniciosum* Miller, 1908.

H. muris is found in the mononuclear leucocytes of *Epimys norvegicus* in Khartoum, and in white rats in Washington, D.C. Its schizogony and sporogony in *Lelaps echidninus* have already been described (p. 479). It caused anæmia, severe illness, and death in the rats.

Hæmogregarina canis James, 1905.

Synonym.— *Leucocytozoon canis* James, 1905.

Hæmogregarina canis was discovered by Bentley in the blood of a pariah dog, *Canis familiaris*, in Assam, and this discovery was fully confirmed by James in 1905. Christophers was the first investigator to trace out its full life-history in 1906-07.

It appears to be common in pariah dogs in Assam and Madras, but more particularly in the puppies and less common in the adults. It is also found in Ceylon, and, according to Dutton, Todd, and Tobey, it probably occurs in dogs in the Gambia.

Morphology.—The parasite is seen in the white corpuscle of the peripheral blood as an oval, unpigmented mass which is difficult to stain, and which lies in two envelopes—an outer formed from the cytoplasm of the corpuscle, and an inner formed by itself. The cell in which it lies is not typical of any corpuscle, though at first sight it resembles a polymorphonuclear leucocyte. When stained, it is seen to possess a nucleus in the shape of a mass of chromatin stretching across the body at one end.

Schizogony.—Schizogony appears to take place only in the bone-marrow, and has not been seen in the liver or spleen. It begins by the parasite gathering into schizonts in liver cells. The schizont divides into a large number of merozoites, leaving no residual mass of undivided cytoplasm. The merozoites probably infect the red blood cells, and after a time can escape into the liquor sanguinis as free trophozoites, and invade the liver cells.

What happens to the free vermicule is not known.

Hæmogregarina funambuli Patton, 1906.

Synonym.—*Leucocytozoon funambuli* Patton, 1906.

This parasite was found by Patton in the large mononuclear leucocytes of *Funambulus pennatii* (the Kathiawar palm-squirrel).

It is found in cysts in the leucocytes, and as free forms in the plasma. No evidence of schizogony could be found. In the gut of the louse (*Hæmatopinus* sp.) parasitic on these squirrels vermicules could be found, and also in the cœlome, but no further development took place.

Hæmogregarina ratti Adie, 1906.

This is a hæmogregarine found in the leucocytes of *Epimys rattus*.

Hæmogregarina felis Christophers, 1906.

Like *H. can* only found in cats. It was discovered by Patton. Schizogony and spor

HÆMOGREGARINES OF REPTILIA.

Hæmogregarines of the Crocodilia.

H. hankini Simond, 1901, in *Gavialis gangeticus* Gmel; *H. crocodilinorum* Börner, 1901, in *Osteolæmus tetraspis* Cope, and in C *cataphractes* Cuv.

Hæmogregarines of the Chelonia.

A very large number of hæmogregarines are known in Chelonia, but the best-studied life-history is that of *H. stepanovi*

Hæmogregarina stepanovi Danilewsky, 1889.

H. stepanovi is a parasite in the red blood-corpuscles of tortoises—*e.g.*, *Emys orbicularis* L. and *Cistudo*

It appears in two forms—one kidney-shaped, and the other long and thin, and bent upon itself

The young trophozoite is club shaped, and grows into the broad kidney form, which in the bone marrow, liver, or spleen breaks up into merozoites, which, escaping from the red cell, complete the cycle by entering new cells.

The trophozoite grows into a large oval form, which elongates until it gives rise to the long thin form which is bent upon itself. If blood containing this form is sucked by a leech (*Placobdella catenigera* Moqu.-Tand), it escapes from the corpuscle in the intestine, and, entering between the epithelial cells, develops into a macrogamete or a microgamete, and forms an oökinete, which wanders into the bloodvessels around the intestine, and so gets to the pharyngeal glands, in which it becomes an oöcyst forming numerous sporoblasts and sporozoites, which complete the cycle of sporogony by entering the tortoise, when it is again bitten by the leech. There is also evidence of the infection of the ova of the leech in the finding of sporozoites in the pharyngeal glands of immature embryo leeches.

Hæmogregarina nicoriæ Castellani and Willey, 1904.

This parasite is common in the tortoises (*Nicoria trijuga* Schweigg) which are found in the ditches and marshy lands round Colombo, and also in Colombo Lake. The young trophozoite grows into the schizont, which divides into merozoites.

Other parasites are:- *H. laverani* Simond, 1901, in *Emyda granosa* Schoepff, *H. mesnili* Simond, 1901, in *Kachuga tectum* Gray; *H. billeti* Simond, 1901, in *Trionyx cartilagineus* Boddert; *H. stepanoviana* Laveran and Mesnil, 1902, in *Damonia reevesii*; *H. rara* Laveran and Mesnil, 1902, in *Damonia reevesii*; *H. mauretania* Sergent, 1904, in *Testudo ibera* Pall.; *H. bagenesis* Ducloux, 1904, in *Clemmys leprosa* Schweigg. Its sporogony is said to occur in *Placobdella catenigera* Moqu.-Tand. *H. vittatæ* Robertson is *Emyda vittata* (Figs. 149, 157, and 158).

Hæmogregarines of the Ophidia.

The hæmogregarines of Ophidia are numerous, but their life-history has not been properly studied. They have mostly been described by Sambon.

Hæmogregarina mirabilis Castellani and Willey, 1904 (Fig. 153).

H. mirabilis is a parasite in the red cells of *Tropidonotus piscator* Schn.

The trophozoite is vermicular and large (12 μ), and stains uniformly blue, leaving no clear pole. The nucleus is dense, and placed near the anterior end, and is enclosed in a well-developed cytocyst, which is stippled with Schüffner's dots.

Other forms are: *H. pythonis* Billet, 1895, in *Python reticularis* Schn.; *H. pococki* Sambon and Seligmann, 1907, in *P. molurus* L.; *H. shattocki* Sambon and Seligmann, 1907, in *P. spilotes* Lacep.; *H. najæ* Laveran, 1902, in *Naja tripudians* Merr.; *H. mocassini* Laveran, 1902, in *Ancistrodon piscivorus* Pal.; *H. crotali* Laveran, 1901, in *Crotalus confluentus*; *H. seligmanni* Sambon, 1907, in *Lachesis mutus*; *H. zamenis* Laveran, 1902, in *Zamenis hippocrepis* L.; *H. mansoni* Sambon and Seligmann, 1907, in *Zamenis flagelliformis* L.; *H. refringens* Sambon and Seligmann, 1907, in *Pseudaspis cana* L.; *H. rarefaciens* Sambon and Seligmann, 1907, in *Coluber corais* Holb.; *H. cantliei* Sambon, 1907, in *Eryx conicus*; *H. terzii* Sambon, 1907, in the boa-constrictor; and many others.

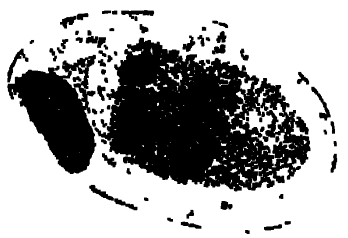

FIG. 157.—*Hæmogregarina vittatæ* ROBERTSON: A BROAD FORM, SHOWING PECULIAR RED BODIES.

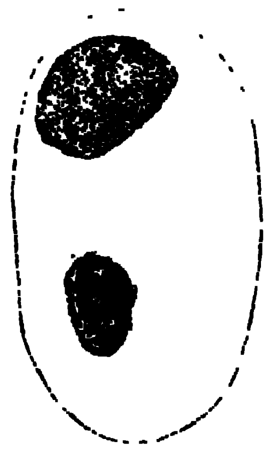

FIG. 158.—*Hæmogregarina vittatæ* ROBERTSON: GAMETOCYTE.

(After Miss Robertson.)

Hæmogregarines of the Sauria.

The best known of these is *H. lacertarum* Danilewsky, 1885, in the red cells of *Lacerta muralis* Laur., *L. viridis* Laur., *L. agilis* L., and *L. ocellata* Daud.

The young trophozoite grows into a schizont, which is enclosed in a cytocyst, and which breaks up into merozoites in the liver, spleen, or kidney.

Among the merozoites there may be macromerozoites or micromerozoites, which are thought to be precursors of the macro- and micro-gametocytes which develop in *Ixodes ricinus* L. This tick may infect the lizard in the adult stage, though this must be rare, as it usually attacks mammals, and then only by its nymphæ and larvæ.

A number are described: *H. thomsoni* Minchin, 1907, in the Himalayan lizard (*Agama tuberculata*); *H. schaudinni* C. França, in *Lacerta ocellata* Daud.

HÆMOGREGARINES OF THE AMPHIBIA.

The best studied of these is *Hæmogregarina minima* Chaussat.

Synonyms. —*Drepanidium ranarum* Lankester, *Laverania ranarum* Grassi, *H. ranarum* Kruse, *Lankesterella ranarum* Labbé.

This parasite is found in the red cells, leucocytes, and tissue cells of *Rana esculenta* L.

Schizogony takes place in the spleen, liver, kidney, and bone-marrow, where the cytocysts containing round schizonts, which break up into five to eight macromerozoites (5 to 8 μ) or numerous micromerozoites (3 to 4 μ).

The sporont is club-shaped, and sporogony takes place, according to Billet, in the leech (*Helobdella*), but his account is very doubtful, and will require confirmation.

Hintze gives a quite different development in the intestine of the frog, but it is possible that he mistook a coccidial parasite for the sporogenic stages.

Durham notes a *Drepanidium* (hæmogregarine) in the blood of a toad in Pará, and a *Dactylosoma* (Labbé) in the internal organs—the former is the schizont, and the latter the sporont—and found evidences of conjugation and cyst-formation in ticks fed on these toads.

H. splendens Labbé, 1908, is found in *Rana esculenta* in Portugal. *H. leptodactyli* Lesage, 1908, is found in *Leptodactylus ocellatus* in Argentina; *Lankesterella tritonis* Fantham, 1905, in *Triton cristatus*.

HÆMOGREGARINES OF THE PISCES.

Fish of all kinds and in all parts of the world appear to contain these parasites.

Hæmogregarina simondi Laveran and Mesnil, 1901.

H. simondi is a parasite in *Solea vulgaris* (the sole). Schizogony takes place in the red corpuscles, the schizont dividing longitudinally into two, four, or eight merozoites. Sporogony takes place in *Platybdella soleæ* Kroger, a leech found on the sole in which ookinetes have been found.

Hæmogregarina anarrhichadis Henry, 1912.

H. anarrhichadis is found in the catfish *Anarrhichas lupus*.

Other fish hæmogregarines are *H. bigemina* Laveran and Mesnil, 1901, in *Blennius pholis*, *H. quadrigemina* in *Callionymus lyra*, *H. platessæ* Lebailly, 1904, in *Pleuronectes platessa*, *H. rovignensis* Minchin and Woodcock, 1910, in *Trigla lineata*.

FAMILY *Toxoplasmidæ* França, 1917.

Definition. Hæmosporidia without hæmozoin generally living in white cells in the organs of vertebrates.

Type Genus. *Toxoplasma* Nicolle and Manceaux, 1908.

Remarks. Only two genera. It is possible that some authors might place *Elleipsisoma* França, 1911, and some allied genera therein. At present we have classified these with the Piroplasmidæ. Ovoplasma may also come here.

Classification. The genera of the Toxoplasmidæ may be recognised as follows:

A. With a definite nucleus—*Toxoplasma*.
B. Without a nucleus—*Ovoplasma*.

Genus Toxoplasma Nicolle and Manceaux, 1908.

Definition.—Toxoplasmidæ of oval or reniform shape, reproducing by longitudinal division or by multiple division inside cells. Live usually in mononuclear and polymorphonuclear cells in the spleen and internal organs. Rarely seen in the blood.

Type Species.—*Toxoplasma gondii* Nicolle and Manceaux, 1908.

Other Species.—*T. cuniculi* Splendore, 1909, found in *Oryctolagus cuniculus* in Brazil, and *T. canis* Mello, 1910, found in the dog in Italy, Germany, and Brazil. These two forms and *T. pyrogenes* Castellani, 1913, found in man are all pathogenic.

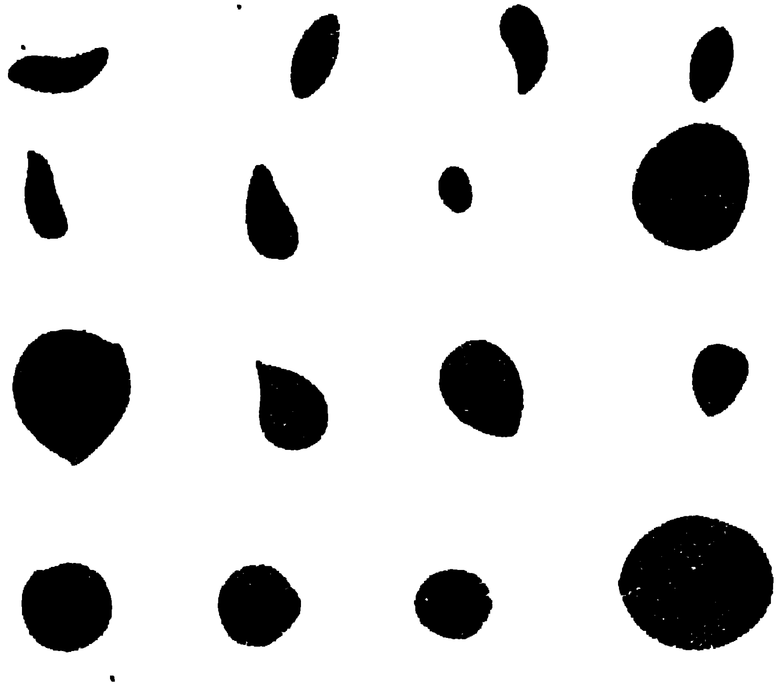

FIG. 159.—*Toxoplasma pyrogenes* CASTELLANI, 1913.

T. talpæ Prowazek, 1910, in Japan, *T. musculi* Sangiorgi, 1913, in *Mus musculus* in Italy; *T. sciuri* Coles, 1914, in England; *T. ratti* Sangiorgi, 1915, in *Mus rattus* in Italy; *T.* sp. (?) Plimmer, 1915, in *Cryptoprocta ferox*; *T. caviæ* Carini and Migliano, 1916; *T.* sp. (?) Thézé, 1916, in *Myceles seniculus* are mammalian parasites.

FIGS. 160-162. *Toxoplasma pyrogenes* CASTELLANI, 191

A number of forms are known in birds—*e.g.*, *T. avium* Adie, 1909; *T. sporophilæ* (Aragão, 1911); *T. neophrontis* Todd and Nolbach, 1912; and *T. françæ* de Melo, 1915; with two unnamed species by Plimmer, 1916, and five by Carini and Maciel in 1916. In snakes one species unnamed was found by Plimmer in 1916.

Toxoplasma gondii Nicolle and Manceaux, 1908.

Endoleucocytic crescentic parasites 6 to 7 μ by 3 to 4 μ, found in the spleen and other organs of *Ctenodactylus gondii*.

Toxoplasma cuniculi Splendore, 1909.

Found by Splendore in the spleen and other organs of the rabbit, in which it produces lesions resembling kala-azar. Shape, oval or reniform; length 5 to 8 μ, breadth, 2·5 to 4 μ.

Toxoplasma pyrogenes Castellani, 1913.

Definition.—Toxoplasma pathogenic to man.

History.—Found by Castellani in 1913 in a case of splenomegaly in the tropics. In 1916 a similar parasite was found by Fedorovitch in the peripheral blood of a case of splenomegaly in a child on the Black Sea coast, and also in the blood of a dog from the same neighbourhood.

Morphology. Roundish oval or crescentic bodies 2·5-6·0 microns in diameter, with blue staining cytoplasm, and with one large roundish mass of chromatin at one pole or in the centre. In one instance the faintest appearance of a flagellum seemed to be present. Occasionally the bodies were larger, roundish or pear-shaped, and possessed two chromatin masses, one at each pole or close together. The bodies were generally free, and only in one specimen were a few found in a leucocyte.

While in the spleen numerous bodies of this description were found in this case, in the peripheral blood they were absent. In the peripheral blood some peculiar structures were observed of roundish or pyriform appearance. They were mostly vacuolated, and took a pale blue colour with Romanowsky, and showed several large masses of chromatin. Castellani at first thought that these might be related to Koch's bodies or *plasmakugel*, which are roundish, oval, or irregularly shaped cells 8-12 microns in diameter, found by Koch in African cattle suffering from East Coast fever. Koch's bodies were later classified under Piroplasma by Gonder who believed them to represent a stage in the life cycle of *Theileria parva*.

Against this hypothesis Castellani observed that they were only present in the blood and not in the spleen, and the chromatin masses were much larger than those in typical Koch's bodies. Castellani was inclined to believe that these bodies found in the blood were related to Toxoplasma found in the spleen in some similar manner to that by which Koch's bodies are related to Theileria. It must be remembered that Castellani's slides were examined by a number of protozoologists and medical men, all of whom agreed as to the parasitic and protozoal nature of the bodies; but while the majority regarded them to be *Toxoplasma*, others held the view that they might represent a new genus between Toxoplasma and Leishmania, and a few thought that they might be a mixture of Toxoplasma with Theileria and Anaplasma.

Life-History.—Unknown.

Cultivation.—So far not cultivated.

Pathogenicity.—Probably the cause of a splenomegaly in man.

Genus Ovoplasma De Raadt, 1913.

Definition.—Toxoplasmidæ without definite nucleus.

Remarks.—Some doubt has been thrown upon this genus and its species.

Type Species.—*Ovoplasma anucleatum* De Raadt, 1913.

Ovoplasma anucleatum De Raadt, 1913.

Definition.—Ovoplasma ring-like, with large vacuole, found in man.

History.—This parasite was found in Borneo in the spleen of a Madurese with splenomegaly, who was born in Java.

Morphology.—The organisms were generally found in mononuclear leucocytes, though rarely they were in the red cells. They were ring-like, with large vacuoles and without any nucleus, but the cytoplasm collects on one side of the vacuole. Sometimes it was pyriform.

Life-Cycle. It reproduces by budding and by binary fission.

Pathogenicity.—May be harmless, but in certain cases pathogenic.

FAMILY *Piroplasmidæ* França, 1909.

Definition.—Hæmosporidia without hæmozoin living in red blood-corpuscles.

Classification.—*Paraplasma* Seidelin, 1911, is the resultant of certain blood conditions, and is not a parasite. *Globidium* Neumann, 1909, and *Immanoplasma* Neumann, 1909, require further investigation.

The following genera can be differentiated:—

1. *Piroplasma* Patton, 1895.
2. *Smithia* França, 1909.
3. *Nuttallia* França, 1909.
4. *Theileria* Bettencourt, França, and Borges, 1907.
5. *Achromaticus* Dionisi, 1900.
6. *Rangelia* Carini and Maciel, 1914.
7. *Rossiella* Nuttall, 1910.
8. *Elleipsisoma* França, 1910.
9. *Nicollia* Nuttall.
10. *Anaplasma* Theiler, 1910.
11. *Bartonella* Strong, Tyzzer, Brues, Sellards, and Gastiaburu, 1915.

A. *Cytoplasm voluminous*:—
   I. Rounded forms in red cells with circular nucleus. Schizogony by binary division inside red cells. Division may continue and form a number of large merozoites—*Rossiella*.
   II. Oval forms in red cells, which they dehæmoglobinize. Nucleus large at one side of parasite. Schizogony in the lung—*Elleipsisoma*.

B. *Cytoplasm easily visible :—*

I. Schizogony known:—

(*a*) Large pear-shaped solitary forms. Numerous merozoites—*Achromaticus*.

(*b*) Small oval or pear-shaped forms, often in pairs, 30-100 merozoites—*Rangelia*.

II. Schizogony unknown:—

(*a*) Division in pairs—*Piroplasma*.

(*b*) Division in fours:—

1. Nucleus without dimorphism—

(A) Pear-shaped swollen parasites occupying the whole breadth of the corpuscle—*Smithia*.

(B) Small oval forms, no bacillary forms—*Nuttallia*.

(C) Bacillary forms—*Theileria*.

2. Nucleus with dimorphism—*Nicollia*.

C. *Cytoplasm usually invisible :—*

I. Coccus-like bodies found in animals—*Anaplasma*.

II. Rounded and rod-like bodies:—

Extremely small, and found in man in Oroya fever—*Bartonella*.

Genus Piroplasma Patton, 1895.

Synonyms.—*Hæmatococcus* Babès, 1888 (*non* Agardh); *Pyrosoma* Smith and Kilborne, 1893 (*non* Péron); *Ixodioplasma* Schmidt, 1904; *Apiosoma* Von Wandollek, 1875 (*non* Blanchard, 1855); *Babesia* Starcovici, 1893; *Amœbosporidium* Bonome, 1895.

Definition.—Piroplasmidæ living inside red cells, without voluminous, but with easily visible, cytoplasm, not possessing any pigment, and multiplying by division.

Type Species.—*Piroplasma bovis* (Babès, 1888).

Classification.—There are a number of species.

A. *In bovines :—*

1. *P. bovis* (Babès, 1888), spread by *Boophilus annulatus*, *B. australis*, and *B. decoloratus*—America, Australia, Asia, and Africa.

2. *P. divergens* MacFadyean and Stockman, spread by *Ixodes ricinus*—Europe.

B. *In sheep :—*

3. *P. ovis* Starcovici, 1893, spread by *Rhipicephalus bursa*—Europe.

C. *In dogs :—*

4. *P. canis* Piana and Galli-Valerio, 1895, spread by *Rhipicephalus sanguineus* everywhere.

D. *In horses :—*

5. *P. caballi* Nuttall, 1910—Europe.

E. *In rodents*:—

6. *P. muris* Fantham, 1905 -England.
7. *P. avicularis* Wenyon, 1908- -Sudan.

F. *In monkeys*:

8. *P. pitheci* P. H. Ross, 1905—-Uganda.

Piroplasma canis Piana and Galli Valerio, 1895.

Synonym.- *Babesia canis* Piana and Galli Valerio, 1895

In 1895 Piana and Galli Valerio found a characteristic hæmatozoon in the red blood corpuscles of a dog which was infested by ticks (*Ixodes reduvius* L.), and which was suffering from fever, weakness, and slight jaundice, after having hunted in marshy localities. This hæmatozoon occupied 3 to 4 per cent. of the corpuscles, and also occurred free in the plasma. In the corpuscles the parasites appeared as pyriform bodies, as many as two, three, four, or five in one corpuscle, and showed amœboid movement. The dog in question recovered, but in other dogs the post-mortem showed fluid blood, congested liver and spleen, with icteric staining of the tissues and necrotic foci in the omentum near the pancreas. Other symptoms noted by them in dogs were hæmoglobinuria, anorexia, prostration, and emaciation.

In 1899 Hutcheon described the disease caused by this parasite as ' malignant jaundice ' or ' bilious fever ' in dogs. It is also known as ' malignant malaria,' ' hondziekté,' and ' malarial fever,' and is said to have often been mistaken for distemper. The disease is by no means uncommon in dogs in the tropics, and should be called ' canine piroplasmosis.'

Geography.- It is known in Europe, especially in Lombardy and other parts of Italy; also in France. In Africa it is found in South Africa, East Africa, Senegal, and other parts of West Africa, and also in North Africa, including Egypt. Nuttall suggests, however, that the African Piroplasma may be different from the European. In Asia it is found in India and Ceylon.

Place and Season. -It appears to be more common in coast towns and districts, and less common in higher inland places. It seems to have a seasonal variation, but this is not properly understood.

The Parasite. The life-cycle in the dog has been most carefully studied by Nuttall and Graham Smith.

In the fresh blood it is noted that the infected corpuscles are pale and enlarged, and contain irregular, dark coloured, pear shaped bodies, possessing a central refractive portion. Amœboid or globular non motile bodies may be noted, and also many free forms.

In specimens stained by Leishman's method the parasites seem to consist of a blue-coloured cytoplasm, with a delicate vacuolated or trabecular structure centrally, but more condensed around the periphery. This cytoplasm may contain a single homogeneous nucleus, which has a vivid red colour, and is often connected by a thin strand with a loose mass of chromatin, which is situated near the blunt end. The parasite contains a vacuole.

Schizogony.- A free pyriform parasite (pyriform stage) enters a normal red blood-corpuscle and becomes rounded (ring stage) in shape, while the loose mass of chromatin is drawn near to the original nucleus, where it condenses. Finally it fuses with that nucleus, forming a single chromatin mass.

The parasite now throws out pseudopodia and appears as an amœba (amœboid stage), and the chromatin subdivides into two unequal masses, connected with a thin strand.

This amœboid stage lasts for a long time, at the end of which the parasite enters upon a quiescent stage, in which the vacuole appears in a subcentral position, and the chromatin, which lies along its margin, has its two masses widely separated, though still connected by the thin strand already referred to. The smaller mass has divided into two, making in all three masses of chromatin connected together by chromatin strands.

Two small symmetrical processes of cytoplasm protrude from the parasite in the neighbourhood of the two small chromatin masses, which they carry with them.

The processes enlarge at the expense of the rest of the cytoplasm, and the vacuole divides, and the so-called trefoil stage is reached, in which the main mass of the chromatin, much reduced in size, lies at the base of the two processes.

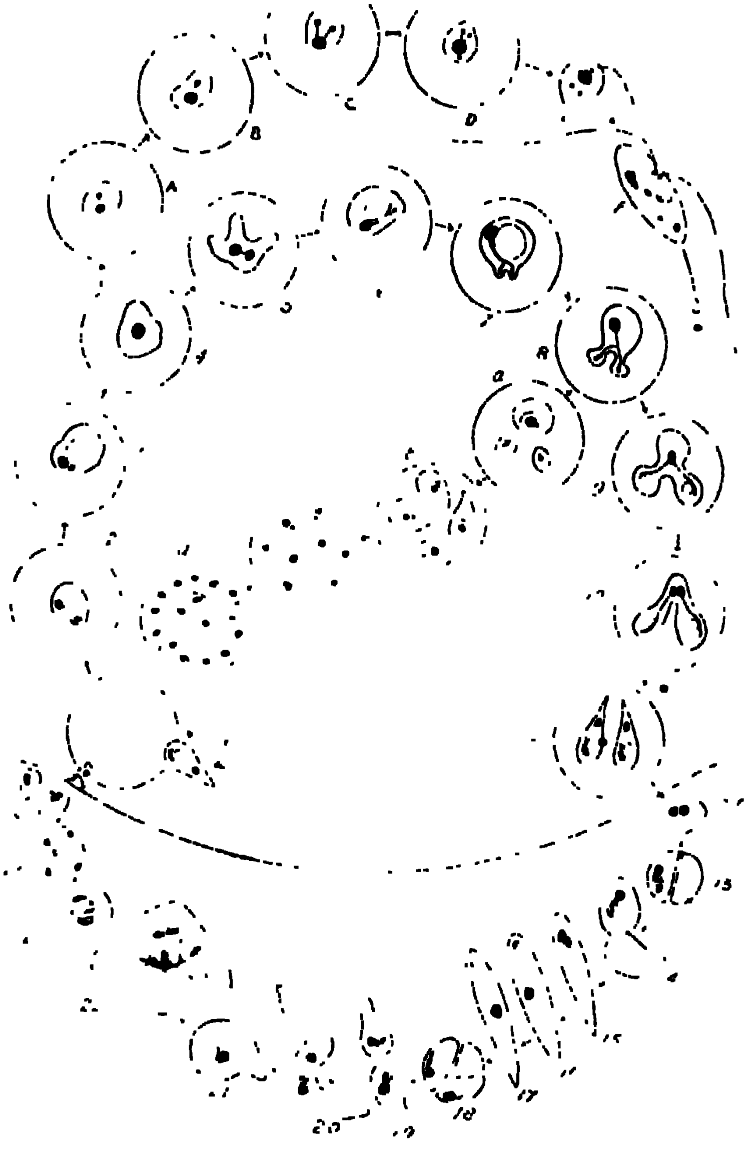

FIG. 163.—DIAGRAM OF THE LIFE-CYCLES OF *Piroplasma canis*.

(After Nuttall and Graham-Smith, Christophers and Breinl and Kinghorn.)

1-12*x*, Reproduction by simple division, *a-a*, reproduction by multiple division, A-F development of a flagellate form; 12*y*-25, sporogony in the tick.

The single strand connecting the two smaller chromatin particles has shortened and disappeared, so that the strand of each small mass now rises directly from the principal chromatin mass. This now divides into two nuclei, connected by a strand, while the cytoplasmic processes become large. Finally, the cytoplasm divides, and two pyriform parasites are found lying side by side in one corpuscle, an arrangement considered typical of a piroplasma. In each parasite is a vacuole, and a principal chromatic nucleus situated near the pointed extremity, from which a tail of loose chromatin runs alongside the vacuole towards the blunt extremity.

The corpuscle now ruptures and liberates the two parasites and some granules, representing residual matter, from the parasite or the corpuscle, or both.

Two slight variations of the process have been described by Nuttall and Graham-Smith; in one the two nuclei and their strands form an hourglass-shaped mass, and in the other the strand and second nucleus form a reticular mass; but both develop into the stage depicted in the diagram. Four pyriform parasites may be found in a corpuscle instead of two, and this may come about by an invasion of the corpuscle by two pyriform shapes, which proceed to division, or by the division of the uninuclear shape into two, both of which proceed to develop regularly. Reproduction by gemmation with the formation of one or two buds has been described by Breinl and Hindle, and of many buds by Kinoshita.

Flagellate Forms.—Nuttall and Graham Smith in 1905 described large forms in the blood of the first dog which they infected in Cambridge by ticks from South Africa. These forms were found on the fourth, fifth, and tenth days, and occurred in the peripheral blood and in that from a kidney. They were sausage-shaped, with rounded or tapering extremities. In some the chromatin was almost entirely concentrated in the middle, while in others it appeared to be of loose texture. Kinoshita has seen similar parasites in blood from the heart, the pancreas, and the lungs after death. The significance of these parasites is not yet understood.

Free parasites with flagella-like processes have been seen by Pound, Bowhill, Le Doux, Nuttall and Graham-Smith, Kinoshita, Fülleborn, and Breinl and Hindle, the last-mentioned observers describing the development of large biflagellate forms from the normal intracellular parasite.

The significance of these forms is not understood, Breinl and Hindle considering that they are such very transient stages in the life-history that they may easily be overlooked.

The development as given by Breinl and Hindle is associated with a binucleated form.

Cultivation.—Kleine, Nuttall, and Graham-Smith have attempted to cultivate *Babesia canis* in defibrinated blood. Kleine has observed elongated forms with radiating processes, similar to those found by Koch in ticks.

Nuttall and Graham-Smith have observed the same forms, but consider them to be intracellular, the hæmoglobin having nearly disappeared from the red cells.

Inoculation.—It was first shown by Dr. Corrington Purvis in 1900 that the disease could be spread from dog to dog by blood inoculation.

Infection from Tick-Bites.—Piana and Galli Valerio, when they discovered the parasite in 1895 in Italy, suspected that it was transmitted by the tick *Ixodes reduvius* L., but the first actual demonstration that this really took place was by Loundsbury in 1901, by the bites of the tick *Hæmophysalis leachi* Audouin, in South Africa.

Dermacentor reticulatus Fabr. is suspected as the spreader of the disease in France.

This subject has been carefully investigated by Loundsbury, who finds that the parent tick, having gorged with blood, falls to the ground and lays her eggs, which develop into six-legged larvæ.

These larvæ do not infect the dog, which they attack as soon as possible, and on whom they remain two days sucking blood. After dropping off, they in due time shed their larval skin, and become eight-legged nymphs, which again bite the dog, but do not infect it.

The nymph, after dropping off, undergoes metamorphosis, and sheds its nymphal skin and becomes the sexually mature tick, which is the only form that spreads the infection, a fact confirmed by Nuttall.

Christophers has traced out the development in *Rhipicephalus sanguineus* Latreille, thus finally confirming the idea of the transmission through the tick.

Development in the Tick.—When an adult tick or a nymph bites a dog and takes in blood containing the oval parasites already described, these parasites develop in the gut into round or oval bodies, 4 to 5 μ in diameter, the chromatin remaining undisturbed.

The cytoplasm now partially divides into a portion with and a portion without chromatin, the latter turning round to form a tail to the former, thus constituting a club-shaped body, which gradually becomes an oökinete.

In the adult these wander into the ova, while in the nymph they simply pass into the embryonic tissue.

In either case they become rounded, and form the zygote, which breaks up into sporoblasts, and these, again, into sporozoites, which infect the salivary glands of the nymph and the adult of the second generation. This development explains Lounsbury's experiments.

Pathogenicity.—The pathological effects are divided by Nocard and Leclainche into two types—the acute, always fatal, and the subacute, ending in recovery.

Acute Form.—In the severe attack the dog quickly becomes ill with high fever ([illegible] C.), accompanied with great weakness. After the attack of fever comes a stage of subnormal temperatures. The mucous membrane becomes pallid, bluish, or icteric. Respiration is laboured, and the movements of the animal are shaky. Vomiting is frequent. The spleen is enlarged, the urine albuminous, and in 3·5 per cent. of cases there is hæmoglobinuria. The blood is pale and watery, and the serum stained with hæmoglobin or bile pigments; the red corpuscles are reduced (in one dog, according to Wright, from 5,800,000 to 1,000,000) and altered, some becoming larger, others smaller, than normal, and often nucleated. The hæmoglobin is diminished, the smallest amount observed being 17 per cent. Usually the leucocytes are increased up to even 60,000, but in some cases they are reduced. Polymorphonuclear and mononuclear leucocytes share the general increase. Phagocytosis is not energetic, being rarely met with. The animal dies in from three to six days.

Subacute Form.—This is characterized by progressive anæmia and feebleness, with sometimes a little hæmoglobinuria or a little icterus. Fever may at first be high, but generally falls to normal. The anæmia is very pronounced, and is accompanied with paralysis, etc.

The attack lasts six weeks, and the convalescence takes three months.

Post-Mortem Appearances.—The mucous membranes are pale, and there is icteric staining of the tissues. Congestion and enlargement of the spleen, more rarely of the liver, œdema of the lungs, congestion of the kidneys, and inflammation of the stomach and intestines may be noted, but sometimes no macroscopical lesions are to be seen.

Histological.—The capillaries of the alveoli are dilated, and their walls show some proliferation of the cells, and there may be leucocytes and red corpuscles in the lumen of the air-cell.

In the heart the capillaries are dilated, and there may be slight hæmorrhages. There is no change in the skeletal muscles. The liver has the central vein and the interlobular capillaries much dilated, as are the intralobular vessels. The fibrous tissue is normal, but the liver cells are distorted, and in many cases destroyed. The spleen contains a large quantity of blood in its pulp. The kidneys only show dilatation of the bloodvessels, especially those of the glomeruli. The suprarenal capsules have all the capillaries (cortex and medulla) dilated, as has the pancreas. In the brain and spinal cord there is only slight dilatation of the capillaries, and slight excess of cerebro-spinal fluid. In the small intestine the vessels of the villi are congested and crowded with infected corpuscles, as are those of the mesentery and omentum. The lymphatic glands are normal, except dilatation of their smaller vessels. The general histological condition is engorgement of the organs by dilatation of the capillaries.

Treatment.—Quinine, benzoate of soda, calomel, etc., have all been advised. Nuttall and Hadwen have introduced Trypanbleu treatment with success.

Piroplasma gibsoni Patton, 1910.

This Piroplasma has been found in dogs and in the jackal (*Canis aureus*) in India by Patton.

Morphology.—In films from the peripheral blood it is seen as small rings 0·1 µ in diameter, with one or two chromatin masses, of which the second is much smaller than the first, to which it is often joined by a pink thread Oval parasites, with a long amœboid process, are also seen.

Division.—Division is by binary fission, giving rise to a number of forms enclosed in one leucocyte.

Pathogenicity.—It causes one variety of canine piroplasmosis.

Piroplasma bigeminum Smith and Kilborne, 1893.

Synonyms.—*Pyrosoma bigeminum* Smith and Kilborne, 1893; *Apiosoma bigeminum* Wandollek; *Babesia bovis* Chauvelot; *Ixodioplasma specificum bovum* Schmidt.

P. bigeminum is the cause of Texas fever in oxen, and appears as pyriform, round, or amœboid cells, and also as flagellate forms. It can be cultivated on artificial media.

Koch has traced the development in the tick, in whose gut the parasites leave the red cell and become long and club-shaped, at the broad end of which is found a round chromatin mass. From the club pseudopodia project.

This club then becomes spherical, and immense numbers of amœba-like forms appear, which are said to grow into clubs.

Pathogenesis.—The disease may exist in two forms, a grave and a benign.

The usual symptoms of high fever, hæmoglobinuria, icterus, anæmia, paralysis, constipation, and death in a week or less, are exhibited in the grave form, in which the mortality is 60 to 80 per cent.

In the benign form there is anæmia without hæmoglobinuria as a rule, and the duration is about fourteen days

The disease can be spread by inoculation or naturally by the bites of infected ticks *Margaropus australis* Fuller in South America, Cuba, Porto Rico, Australia, and the Philippines, and by *M. decoloratus* Koch in South Africa.

Post-Mortem. The usual post mortem signs are visible.

Treatment.—There is no specific treatment. Krägerud advises intravenous injections of 1 in 100 of protargol or formol, and afterwards a beverage of 10 grammes of lysol and carbolic acid in 500 grammes of distilled water.

Lignières recommends chloride of sodium and purgatives. Quinine has also been advised. Nuttall and Hadwen's treatment should be tried.

Piroplasma bovis Babès, 1888.

Synonyms.—*Piroplasma annulatum* Dschunkowsky and Luhe, 1888, *Piroplasma bigeminum* Babès, *Hæmatococcus bovis* Babes.

P. bovis is the cause of red water or hæmoglobinuric fever in European cattle and in red deer (*Cervus elaphus* L.), and is spread by the ticks *Ixodes reduvius* L. and *Margaropus annulatus* Say.

The disease produced may be acute or chronic. In the acute form about 90 per cent. of the red cells are infected by bacillary or ring-like parasites, which cause high fever, quick pulse and respirations, seldom hæmoglobinuria, with convulsions and death in one or two weeks; or a chronic form, with minute coccus-like parasites in 10 to 40 per cent. of the red cells, producing weakness, jaundice, and anæmia. The post-mortem shows hæmorrhages into many organs.

Piroplasma ovis Babes, 1880.

Synonyms.—*Hæmatococcus ovis* Babès, *Piroplasma ovis* Laveran, *Amœbosporidium polyphagum* Bonome.

P. ovis is found in sheep in Europe, Africa, and the West Indies, as large intracorpuscular and extracorpuscular forms, and causes anæmia, hæmoglobinuria, hæmaturia, and bile in the urine, and also blood in the motions. The mortality is 50 per cent.

The post mortem shows œdema of the tissues, enlargement of the spleen, inflammation of the liver, kidney, and bowels, in the last of which there may be ulcers.

The *Piroplasma* is spread by the daughter adult tick developed from the *Rhipicephalus bursa*, which sucked the infected blood. It is inoculable into other sheep.

Piroplasma pitheci P. H. Ross, 1905.

This organism caused piroplasmosis in a species of *Cercopithecus* from Kikuga, in Uganda.

The parasite is a non-pigmented, pear-shaped, oval, or round endocorpuscular body, being 1·5 μ in diameter when round, and 3 by 2 μ to 2·5 by 1·5 μ in the pyriform shapes. It may be single, double, or in multiples of two, four, eight, or sixteen.

Nuttall and Graham Smith have investigated the parasite carefully, and conclude that it is a true *Piroplasma*, and multiplies in the same manner as *P. canis*, and they figure one body in a corpuscle very like the peculiar free forms noted in *P. canis*.

Ross tried inoculation into dogs twice, but though one of the dogs showed a temporary rise of temperature, the experiment failed. No ticks were found on the monkeys, or in the box in which they lived. The disease causes fever, and killed four out of twelve monkeys.

Piroplasma muris Fantham, 1906.

P. muris causes a chronic disease in mice, in which it exists as pyriform intracorpuscular parasites, singly and in pairs (as many as four and six have been seen). The secondary mass of chromatin has not been observed, and no typical dividing forms have yet been seen.

Piroplasma cervi França and Borges, 1907.

This *Piroplasma* is found as bacillary and cross forms in the blood of *Cervus dama* L. Its development is not known.

Piroplasma minense Yakimoff, 1909.

Found in Russia in hedgehogs, and spread by *Dermacentor reticulatus* (?).

Piroplasma aristotelis Denier, 1907.

This parasite is found in *Cervus aristotelis* in Annam.

Genus Theileria Bettencourt, França, and Borges, 1907.

Synonym. *Lymphohæmatocytozoon* Meyer, 1913.

Definition.—Bacilliform or rod shaped forms arranged at times in the form of a cross.

Type Species. *Theileria parva* Theiler, 1903.

Theileria parva Theiler, 1903.

Synonyms.—*Piroplasma theileri*, *Babesia parva* Theiler, 1903; *Lymphohæmatocytozoon parvum* Meyer, 1913.

This is the cause of East Coast fever in cattle in Rhodesia, and is also found in India and Japan.

Parasite.—The parasite appears in the blood as minute bacillary forms or as small rings, which later become larger, and give the typical pyriform appearance, being frequently arranged in the form of a cross. Very large forms, consisting of protoplasmic masses containing numerous chromatin particles, may be found in the endothelial cells of the spleen and lymphatic glands.

Schizogony.—According to Gonder, the large multinucleated plasmodial masses divide into minute merozoites, and lead to the breaking up of the enclosing lymphocyte. The merozoites penetrate into another lymphocyte in the spleen or lymphatic glands, in which they grow and become the multinucleated masses, and so complete the process of schizogony.

Sporogony.—After a time merozoites are produced with a different nuclear structure; these multiply and produce the gametocytes, which, penetrating into the red blood cells, appear in the peripheral circulation. The microgametocytes are the bacillary forms, and the rounded or pear-shaped forms are the macrogametocytes. In Eurhipicephalus these come out of the corpuscles, and the male forms creep about like little amœbæ, while the nucleus undergoes reduction, forming the microgamete. In a similar manner the macrogamete is formed. Copulation takes place, and a zygote in the form of an active oökinete is formed, which enters the salivary glands and breaks up into sporozoites.

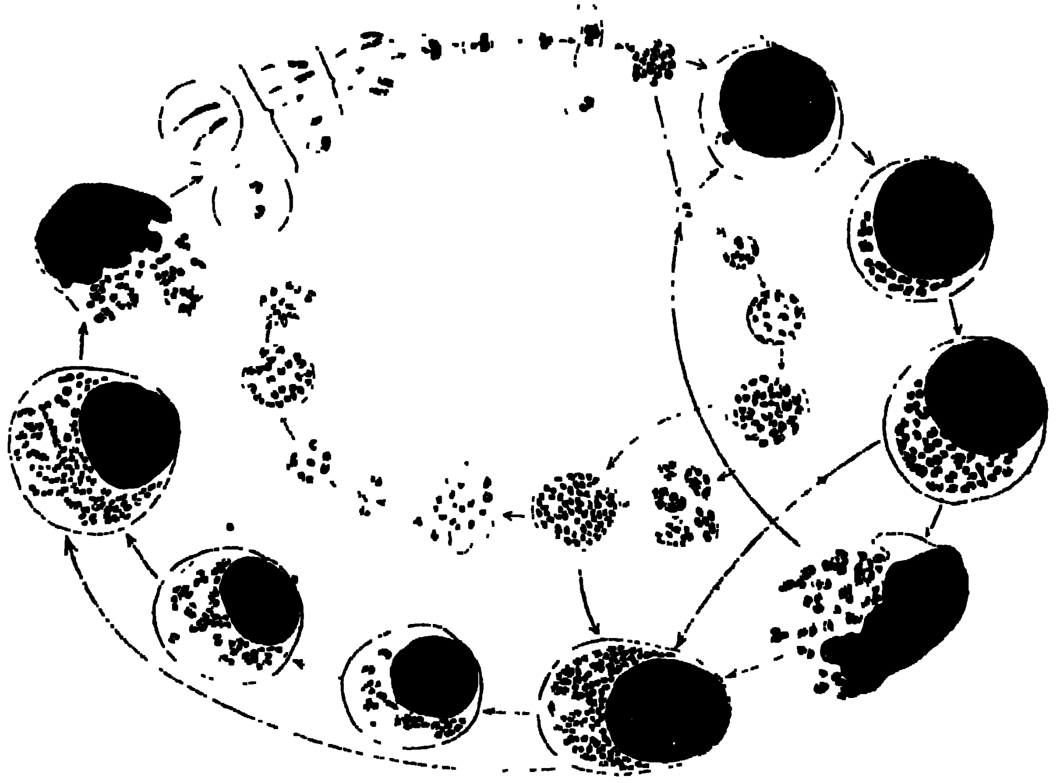

FIG. 164. LIFE CYCLE OF *Theileria parva* (THEILER, 1903).
(After Gonder, from the Report of the First Expedition of the Harvard School of Tropical Medicine to South America in 1913.)

It is spread by *Eurhipicephalus appendiculatus* Neumann, by the nymphs and the adults.

Cultivation.—Miyajima states that he has cultivated the parasite in broth, producing trypanosome-like bodies, but this has not been confirmed.

Inoculation.—It cannot be inoculated successfully.

Incubation.—Fourteen days.

Symptoms.—The symptoms produced are very similar to those caused by *P. bigeminum*, but there is very little anæmia and no hæmoglobinuria.

Mortality.—The mortality is about 90 per cent.

Post-Mortem.—The autopsy shows œdema of the lungs, inflammation of the lymphatic glands, and infarcts in the lungs, liver, and kidneys.

Theileria mutans Theiler, 1907.

Synonym.—*Piroplasma mutans* Theiler, 1907.

This *Piroplasma* is found along with *P. bigeminum*, in cattle in the Transvaal, and produces forms like *Theileria parva*, but distinguished by being inoculable. It is not known how it is spread.

Theileria celli Castellani and Chalmers, 1910.

This parasite is found in *Macacus pileatus* in Ceylon, in bacillary and pear-shaped forms, lying side by side in the same erythrocyte. The development has not been traced.

Theileria buffali Neveu-Lemaire, 1912.

This parasite was discovered by Shein in 1908 in the buffalo in Nha-Trang in Indo-China, and is seen in two forms—an ovoidal, which is most frequently met with, and a bacillary. Its mode of transmission is unknown.

Genus Nicollia Nuttall.

Definition.—Oval or pear-shaped parasites, with an oval nucleus with two karyosomes, one near the centre and another close to the surface of the body, with quadruple division.

Nicollia quadrigemina Nicolle, 1907.

This parasite is found in *Ctenodactylus gondii* in North Africa, and Nuttall and Graham-Smith point out that its method of division and its chromatin are so peculiar that its position is doubtful.

Genus Nuttallia França, 1909.

Definition.—Oval or pear-shaped parasites with multiplication in the form of a cross.

Type Species.—*Nuttallia equi* Laveran, 1899.

Nuttallia herpetedis França, 1908.

N. herpetedis is found in considerable numbers in *Herpestes ichneumon* L., the mongoose, as small spheres, with the chromatin arranged as a cross, or as pyriform shapes, or in fours arranged in cross form.

Nuttallia equi Laveran, 1899.

Synonym.—*Piroplasma equi* Laveran, 1899.

Nuttallia equi is the parasite of piroplasmosis in horses, mules, donkeys, and zebras in Africa, Germany, Italy, and Venezuela.

The disease appears to have been first differentiated by Wiltshire, in 1883, as anthrax fever, which name was changed to bilary fever by Hutcheon. The parasite was first seen by Guglielmi, in Italy, in 1899.

It differs from *P. canis* in existing in large and small spherical forms, in large and small pyriform shapes, in large and small rod-like bodies, in rosettes of four, and sometimes as free flagellate forms. Koch believes that this list includes two different types of parasite—one of parasites arranged in groups of four, and the other like *P. canis*.

It is very difficult to inoculate, and is believed to be spread by the blue tick (*Eurhipicephalus decoloratus*).

The incubation period is not known. The disease begins with high fever, but becomes subnormal before death. The appetite varies. The animal is very weak, and in the later stages becomes paralytic and comatose. Anæmia and jaundice are noted. The pulse varies, being often weak and irregular. The respirations are accelerated. Bowels often constipated; urine is highly coloured, and hæmoglobinuria may occur. The disease may be acute or chronic.

In acute cases death may take place in from two to five days, but the mortality is not high. Secondary and terminal infections may take place.

The post-mortem reveals emaciation and icteric staining, and anæmia of the tissues, enormous enlargement of the spleen, and thin, watery blood. The liver is yellow and congested; the kidneys are enlarged and anæmic; the lymphatic glands are hæmorrhagic, as may be the mucosa of the intestines. The heart is sometimes enlarged. The lungs are usually normal.

Other species are *N. ninensis* Yakimoff, 1910, in *Erinaceus europæus; N. muris* Coles, 1914; *N. decumani* Macfie, 1915; *N. microti* Coles, 1914.

Genus Smithia França, 1910.

Definition.—Pear-shaped forms, not in pairs, occupying the whole diameter of the corpuscles. Forms crosses.

Type Species.—*Smithia microti* França, 1910.

Other Species.—In addition to *Smithia microti* França, 1910, found in *Microtus arvalis*, there is *S. talpæ* Galli-Valerio, 1913, in *Talpa europæa*

Genus Anaplasma Theiler, 1910.

Definition.—Coccus-like parasites, round or oval in form, apparently consisting wholly of chromatin, and devoid of cytoplasm. Flagellate forms said to exist.

Dias and Aragão consider these organisms to be degenerations of red cells.

Type Species.—*Anaplasma marginale*.

Anaplasma marginale Theiler, 1910.

Coccus-like parasites situated near the margin of the corpuscles.

Morphology.—Round or oval parasites consisting only of chromatin substance, sometimes situated in a paler zone of the corpuscle. Multiply rapidly, and invade 40 to 50 per cent. of the corpuscles.

Life-History.—It is spread by the ticks *Eurhipicephalus decoloratus* and *E. simus*, and possibly passes through the egg.

Cultivation.—Veglia claims to have cultivated this organism on defibrinated blood media.

Pathogenicity.—It causes a disease like red water, but different therefrom in that animals immune against red water are susceptible to it. Clinically, it causes a severe type of illness, with fever, anæmia, and diarrhœa, with yellow fæces and urine. The blood shows anisocytosis, poikilocytosis, polychromasia, and basophilia. The post-mortem appearances are anæmia with jaundice, enlarged and yellow liver, inspissated bile, and enlarged spleen.

Anaplasma marginale var. centrale Theiler, 1912.

Like *A. marginale*, but situate towards the centre of the cell. Type of illness milder than the above form.

Anaplasma canis Basile, 1912.

Cocci-like forms and crescent-shaped bodies free and enclosed in corpuscles found in peripheral blood, liver, spleen, and lungs of dogs around Messina. Large form 4·9 by 2·3 μ observed, provided with a flagellum measuring 5 μ.

Pathogenicity.—Causes canine anaplasmosis.

Genus Achromaticus Dionisi, 1898.

Definition.—*Piroplasmidæ* with easily visible but not voluminous cytoplasm, sickle shaped, pyriform or rounded. Schizogony in red cells. Many merozoites. Large solitary parasites.

Type Species.—*A. vesperuginis* Dionisi, 1898.

Achromaticus vesperuginis Dionisi, 1898.

This parasite was found by Dionisi in the noctule in 1898. Sambon classifies it as a Piroplasma but this is doubted by Nuttall and Graham-Smith, as well as by Dionisi, though they report pyriform endocellular parasites from blood films from bats of the genus *Vesperugo*, and Nuttall and Graham-Smith report four pyriform parasites in a corpuscle. Gonder, however, believes that it is in some intermediate position between the Plasmodidæ and the Piroplasma, and Nuttall and Graham-Smith consider that further investigations are necessary before it can be classified. We agree with Gonder, and consider the parasite to be neither a Piroplasma nor a plasmodium, and therefore return to Dionisi's original idea of a separate genus. Recently it has been studied by Yakimoff, Stolnikoff, and Kohl-Yakimoff, who believe that it is a true Piroplasma. Another species is *A. gibsoni* Patton, 1910.

Genus Rangelia Carini and Maciel, 1914.

Definition.—Piroplasmidæ, often in pairs, with rounded, oval, or pyriform appearance, with easily visible cytoplasm. Schizogony in endothelial cells in internal organs. Merozoites very numerous.

Type Species.—*Rangelia vitalli* Pestana, 1910.

Rangelia vitalli Pestana, 1910.

This is the cause of a disease in dogs in Brazil called nambiavú

Genus Rossiella Nuttall, 1910.

Definition.—Piroplasmidæ of unusual type with voluminous cytoplasm, not pigmented; rounded form and rounded nucleus, which is not peripherally placed. Schizogony in red cells, division first into two and subsequently in more merozoites.

Type Species.—*Rossiella rossi* Nuttall, 1910.

Rossiella rossi Nuttall, 1910.

Parasite of *Canis adustus* in Africa.

Genus Elleipsisoma França, 1910.

Definition. Piroplasmidæ of unusual type, with voluminous cytoplasm, not pigmented; living in red blood cells which become dehæmoglobinized. Schizogony in the lungs.

Type Species.—*Elleipsisoma thomsoni* França, 1910.

Elleipsisoma thomsoni França, 1910.

Parasite of *Talpa europæa* and *T. cæca*.

Genus Bartonella Strong, Tyzzer, Brues, Sellards, and Gastiaburu, 1915.

Definition.—Piroplasmidæ with rounded or rod-shaped dividing forms, sometimes in chains; reproduction by binary division, cytoplasm and chromatinic substance often differentiated with difficulty. Motile. Habitat, red blood-corpuscles.

Type and Only Species.—*Bartonella bacilliformis* Strong, Tyzzer, Brues, Sellards, and Gastiaburu, 1915.

Bartonella bacilliformis Strong, Tyzzer, Brues, Sellards, and Gastiaburu, 1915.

Definition.—*Bartonella* with the characters of the genus.

History.—In 1901 and 1902 Barton found an organism in Oroya fever which Tamayo and Gastiaburu identified as belonging to the paratyphoid group.

In 1905 Barton described bacillary-like bodies in the red cells of persons suffering from malignant fever. In 1909 he noted these bodies in fourteen additional cases, and stated that they were protozoa, and probably the cause of the disease. In the same year Gastiaburu and Rebagliati confirmed these findings and regarded the organism as the cause of Oroya or Carrion's fever. In 1915 Strong, Tyzzer, Brues, Sellards, and Gastiaburu, confirmed and enlarged these discoveries and named the parasite.

Morphology.—In fresh blood-films the parasite appears as a rounded or rod-shaped body, 0·5-1·0 microns in diameter in the former case, and 1·5-2·5 microns in length in the latter. They are very abundant in severe cases, and are endowed with a definite motility which is totally distinct from pedesis. They glide slowly about the cell. Sometimes a dot or bead-like body can be seen at the two poles.

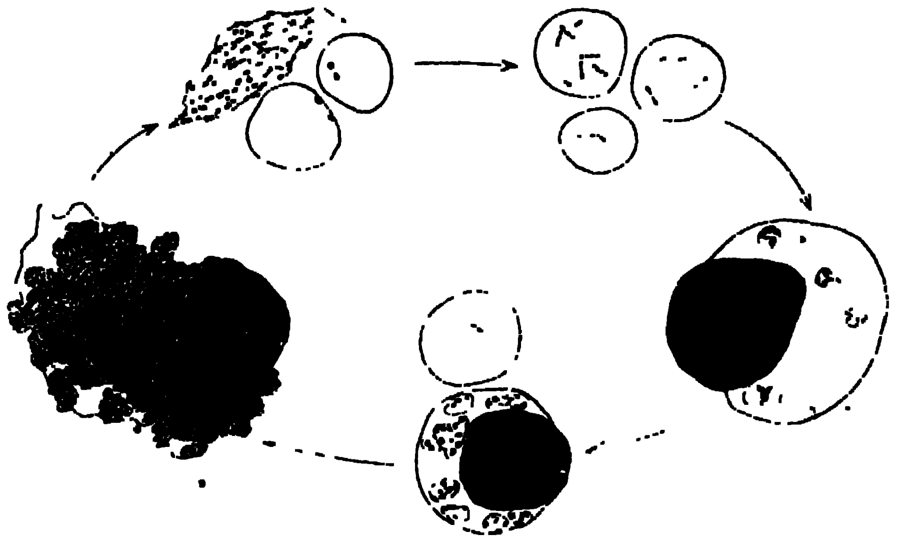

FIG. 165 - LIFE-CYCLE OF *Bartonella baccilliformis* STRONG, TYZZER, BRUES, SELLARDS, AND GASTIABURU, 1915

(Constructed from the illustrations in the Report of the First Expedition of the Harvard School of Tropical Medicine to South America in 1913)

When stained they are seen to be slightly curved, and to be present as single individuals, pairs, or in chains of three to five. V and Y forms are not uncommon, and are considered to represent dividing forms. Cross forms are rare, and due to organisms being superimposed.

The ends of the rods are more intensely coloured than the rest of the organism.

Some forms are rounded, oval, or almost pyriform. As many as ten parasites may be found in a single cell, which they apparently destroy.

Life-Cycle.—They are also to be found in large swollen endothelial cells, free or attached to the vessel wall, in the spleen and the lymph glands. An endothelial cell may be so distended with rounded and rod-shaped parasites as to occlude a vessel. In these cells the parasite, when coloured by Giemsa's stain, appears as rounded bodies, composed of bluish cytoplasm and containing small granules of chromatin, which vary in number from one to many, and it is suggested that the parasite breaks up into a large number of minute elements, each of which possesses a chromatin granule. These elements grow and become rods, which are set free by rupture of the enclosing sphere, and so fill the endothelial cells, from which they escape also by rupture. The rods are looked upon as gametocytes, rather than merozoites, and are considered to be the forms seen in the red cells.

Comparison.—The organism is believed to resemble *Theileria parva.*

Inoculations.—Attempts to transmit the parasite to inoculated animals failed. The animals used were rabbits and monkeys.

Cultivation.—So far the organism has not been cultivated.

Transmission by Insects.—Experiments have been performed with the mosquito *Phalangomyia debilis* Dyar and Knab, but no evidence of the presence of the parasites in the stomach or salivary glands could be obtained.

Pathogenicity.—It is believed to be the causal agent of Oroya fever.

FAMILY PLASMODIDÆ LUHE, 1906.

Synonyms.—*Gymnospondia* Labbé, 1894, *Acytosporidia* Wasielewski, 1896; *Hæmamœbida* Ross, 1899, *Acytosporea* Minchin, 1903.

Definition.—Hæmosporidia with hæmozoin. The trophozoite grows into the schizont, containing hæmozoin, which breaks up into a number of merozoites, which are usually said never to be flagellate. The oökinete encysts and forms a typical oöcyst, which breaks up eventually into sporozoites.

Classification.—The genera of the Plasmodidæ are: *Plasmodium* Marchiafava and Celli, 1885, *Laverania* Grassi and Feletti, 1889, *Hæmocystidium* Castellani and Willey, 1904.

These genera may be distinguished as follows:—

A. Size large. Schizogony binary or at times quaternary, in general circulation *Hæmocystidium.*
B. Size small. Schizogony into more than four merozoites—
  I. Without crescent bodies—*Plasmodium.*
  II. With crescent bodies—*Laverania.*

Genus Plasmodium Marchiafava and Celli, 1885.

Synonyms.—*Oscillaria* Laveran, 1881; *Hæmatomonas* Osler, 1887; *Hæmatophyllum* Metchnikoff, 1887; *Hæmamœba* Grassi and Feletti, 1889; *Laverania* Grassi and Feletti, 1889; *Cytamœba*, Danilewski, 1890; *Proteosoma* Labbé, 1894; *Hæmosporidium* Lewkowicz, 1897; *Cytosporon* Wasielewski, 1901.

Definition.—Plasmodidæ, in which the gametocytes resemble more or less the schizonts by being round in shape. Schizogony in the peripheral blood.

Nomenclature.—Some remarks are perhaps necessary on the nomenclature. Laveran first used the term *Oscillaria* because he saw the flagellate form, which at that time was thought to be a

Polymitus form because of its flagella. Later Laveran repudiated this term, which, indeed, could not be used, because it had already been applied to a plant. He then suggested the term 'hæmatozoön,' but this is objectionable, because the hæmatozoa are a group of parasites, and not a single genus. Metchnikoff suggested the term *Hæmatophyllum malariæ*, which is equally impossible; therefore the earliest distinctive term is 'plasmodium' which was used by Marchiafava and Celli in 1885.

It is not a good term, because a plasmodium is generally considered to be a mass of protoplasm with several nuclei representing, not one single animal, but several.

General Account.—The malarial parasites may be taken as the typical examples of the Plasmodidæ.

The malarial parasite exists in nature outside the human body in certain species of different genera of the family Anophelinæ, a type of mosquito which is somewhat easily identified by its habit of projecting at almost right angles from the surface on which it stands. In the salivary glands of infected insects the malarial parasites are found as fine fusiform bodies, about 10 to 20 μ in length, and 1 to 2 μ in breadth, lying in the cells or in the duct. These fusiform bodies are called sporozoites, and consist of cytoplasm containing a central nucleus composed of chromatin.

The ends of the parasite are pointed, one being sharper than the other. They are capable of movement forwards, and of flexion into loops or curves. It may be that the sporozoites represent male, female, and indifferent parasites, or they may not; the question is still undecided.

When inoculated into man by a mosquito, they penetrate into the red blood cells, and develop into small endo-corpuscular parasites called the trophozoites, which at first are composed of cytoplasm and a nucleus.

This young trophozoite grows, throwing out pseudopodia for the purposes of nutrition, and presently a vacuole appears, converting the small parasite into a ring form, which, according to Schaudinn, is of benefit in enabling it to absorb nutriment quickly.

The vacuole does not keep pace with the growth of the parasite, and finally in the old form disappears. Early in the ring forms there appear granules of a black pigment, which used to be called melanin, but which has by no means the chemical characteristics of true melanin, as will be described under Malaria. This pigment has been named by Sambon 'haemozoin'—a name which appears to us to be peculiarly suitable, and will therefore be used in this work. It is really of an excrementitious nature. The fully-grown trophozoite now ceases to be amœboid, and, becoming rounded off and full of pigment granules, is called the schizont, which has a subcentral nucleus. This nucleus now divides, so that parasites may be seen with two, three, four, five, six, up to twenty-four nuclei. The cytoplasm around these nuclei segments into small bodies called merozoites, each with a nucleus, but an unsegmented portion containing the hæmozoin, and called the residual mass, or ***nucleus de reliquat***, is always left unsegmented.

The blood-corpuscle now breaks up, and the merozoites, residual protoplasm, and pigment are liberated into the blood stream, where the effete matter and some merozoites are taken up by the leucocytes and destroyed.

The merozoite usually tries to enter a red blood cell and to start again as a trophozoite, thus completing a cycle in the blood of the human being who is acting as host. This cycle is called the *cycle of Golgi*, or *schizogony*. Sometimes more than one merozoite will enter a cell, thus giving rise to multiple infection. In such a case they are generally of the same age, but this is not invariable. In the red cell, under these conditions of multiple infection, some observers have thought that the young trophozoites might conjugate; but this, together with the suggestion of further division of the merozoite, we believe to be incorrect, though it must be admitted that forms with a double nucleus can be seen. When such a binucleate form is seen nowadays, it makes the observer think seriously of a possible flagellate origin, and inclines him to support Sambon and Hartmann's classification, but never, as far as we know, has anyone seen a flagellate merozoite in human malaria.

It will be seen that in going through the process of schizogony one sporozoite becomes several merozoites, and that each of these may again become several merozoites, so that the infection grows unless kept in check by phagocytosis, and perhaps chemical action or quinine treatment.

Each parasite means a red cell destroyed and so much toxin liberated into the blood stream. Hence in a certain number of days (eight to twelve, as a rule) the parasites will have increased to such a degree that their collective toxins, acting upon the organs of the body, upset the metabolism and produce an attack of fever. This period of eight to twelve days is the incubation period of the disease.

It is possible that all the sporozoites develop into schizonts, and there is at present no evidence that they develop into male or female forms directly. If they do not do this, then the merozoites must differentiate sexually; for in about a week male and female forms can be seen in the blood stream, and, moreover, very young stages can be observed.

The earliest form of a sexual parasite is like an ordinary merozoite, but it grows very slowly, and it never possesses a vacuole, and as it grows its protoplasm becomes heavily pigmented and granulated in the female, and lighter and clear in the male. The result is to produce a female type of parasite called the macrogametocyte, or a male type of parasite, the microgametocyte. So that there are three types of parasite - the indifferent or schizont, the female, and the male.

The macrogametocyte is characterized by possessing a small, more or less rounded nucleus excentrically placed and poor in chromatin, and a cytoplasm full of granules and pigment.

The microgametocyte is characterized by having a large nucleus extending like a band across the cytoplasm, and much chromatin, a clear protoplasm, and less pigment.

The macrogametocyte and microgametocyte are the means of propagating the parasite in the mosquito, and if they fail to reach the gut of this insect the microgametocytes die off.

The macrogametocytes, on the other hand, are extremely persistent, and can wait in the body for a long time until some chill or accident lowers its resistance, when they become active and develop merozoites by parthenogenesis, thus accounting for the relapses and the recurrences of malaria, even months and years after having left a tropical country. Hence in malaria there is a latent phase which is capable of lasting an unknown time -at least one to three years, perhaps longer; but upon this subject more will be said later, and, indeed, more information is urgently needed.

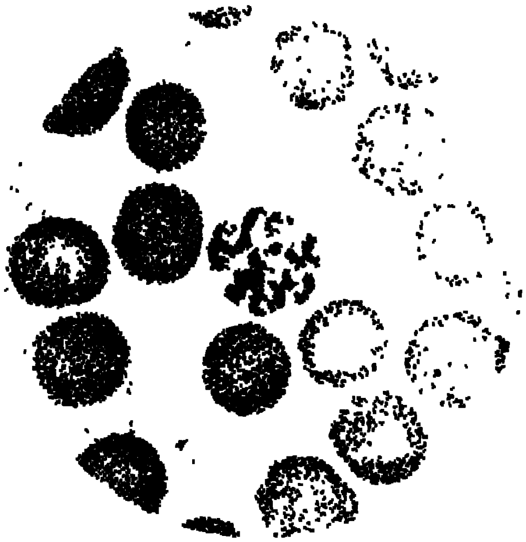

FIG. 166.—SCHIZOGONY IN *Plasmodium vivax* (GRASSI AND FELETTI, 1890). (× 1,000 DIAMETERS)

(By Norman; given us by J. J. Bell.)

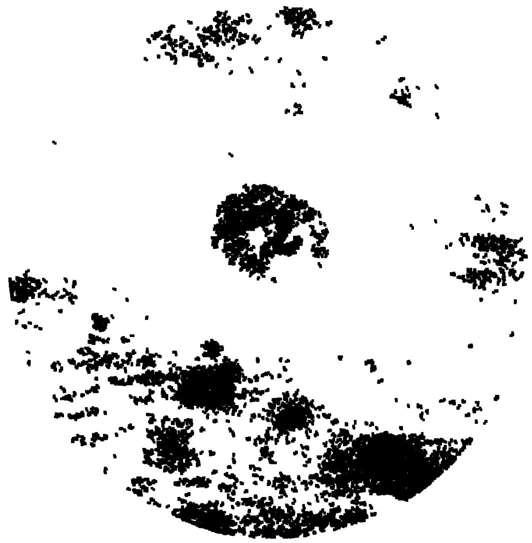

FIG. 167 OÖCYST IN STOMACH OF ANOPHELINE MOSQUITO. (× 1,000 DIAMETERS)

(By Norman, from a preparation by James.)

In developing parthenogenetically, the nucleus of the macrogametocyte divides into two portions, one rich and the other poor in chromatin. The pigment granules gather round the pale nucleus, and with it the surrounding cytoplasm and hæmozoin form a sort of *nucleus de reliquat*. The rest of the protoplasm, rendered clearer by loss of its hæmozoin, contains the nucleus rich in chromatin, which now divides like the nucleus of a schizont, and forms merozoites, which, escaping from the red cell, infect red corpuscles, and start the cycle of schizogony anew.

Etheogenesis is unknown in the malarial parasite.

If a female mosquito (the male does not suck blood) belonging to certain of the genera of the Anophelinæ sucks the blood of a person in whom both macro- and micro-gametocytes are to be found, a new cycle is started in that mosquito. This cycle is sporogony, which is characterized by being a sexual process. Changes now appear in the macro- and micro-gametocyte, which are thought by Schaudinn to be brought about by the alteration in temperature.

The macrogametocyte, escaping from its red cell, undergoes reduction by division of its nucleus once or twice, forming polar bodies. The reduced gametocyte is now called the macrogamete.

Similarly the microgametocyte undergoes changes, for chromidial masses separate from its nucleus and travel to the periphery of the parasite, from which thin threads of protoplasm now project.

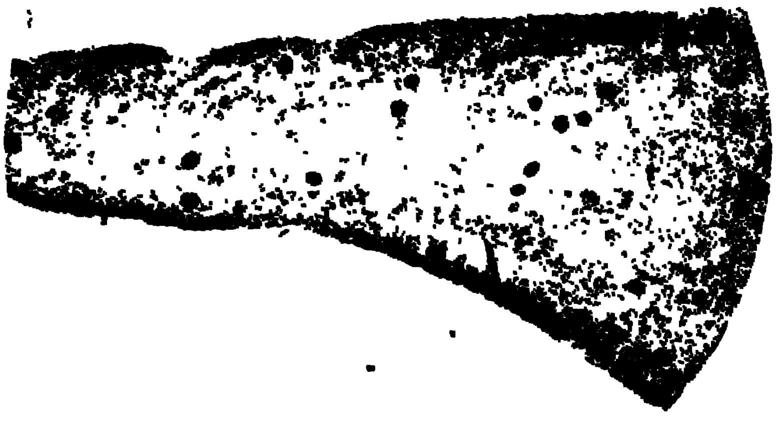

FIG. 168. SPOROCYSTS IN STOMACH OF ANOPHELINE MOSQUITO. (× 1,000 DIAMETERS.)

(By Norman from a preparation by James.)

These threads, which vary from four to six in number, lash about vigorously, moving the whole parasite, which therefore whirls about, and it and its processes, called flagella, were looked upon as a polymitus; hence this stage is often called the polymitus stage.

The threads break off, and are now called microgametes. Each microgamete is composed of a long, tapering thread of protoplasm capable of bending and moving rapidly. Its chromatin is spread along it in dots or bars, and hence the whole structure somewhat resembles a spirochæte, but there is no undulating membrane.

A microgamete now conjugates with a macrogamete, the male and female pronuclei fusing to form a synkaryon, and the resulting zygote is called an oökinete. This zygote elongates, and its anterior extremity, which is more or less clear of hæmozoin, becomes pointed; the nucleus lies in the middle, and the posterior end contains most of the pigment, which may be largely cast off or may be retained.

It now pierces the epithelium of the mosquito's stomach, below which it comes to rest, and forms a thin cyst-wall, and is called the oöcyst. This now grows rapidly, and its nucleus divides into a large number of daughter nuclei, around each of which the protoplasm gathers, forming the sporoblasts, which are somewhat connected together (Fig. 169).

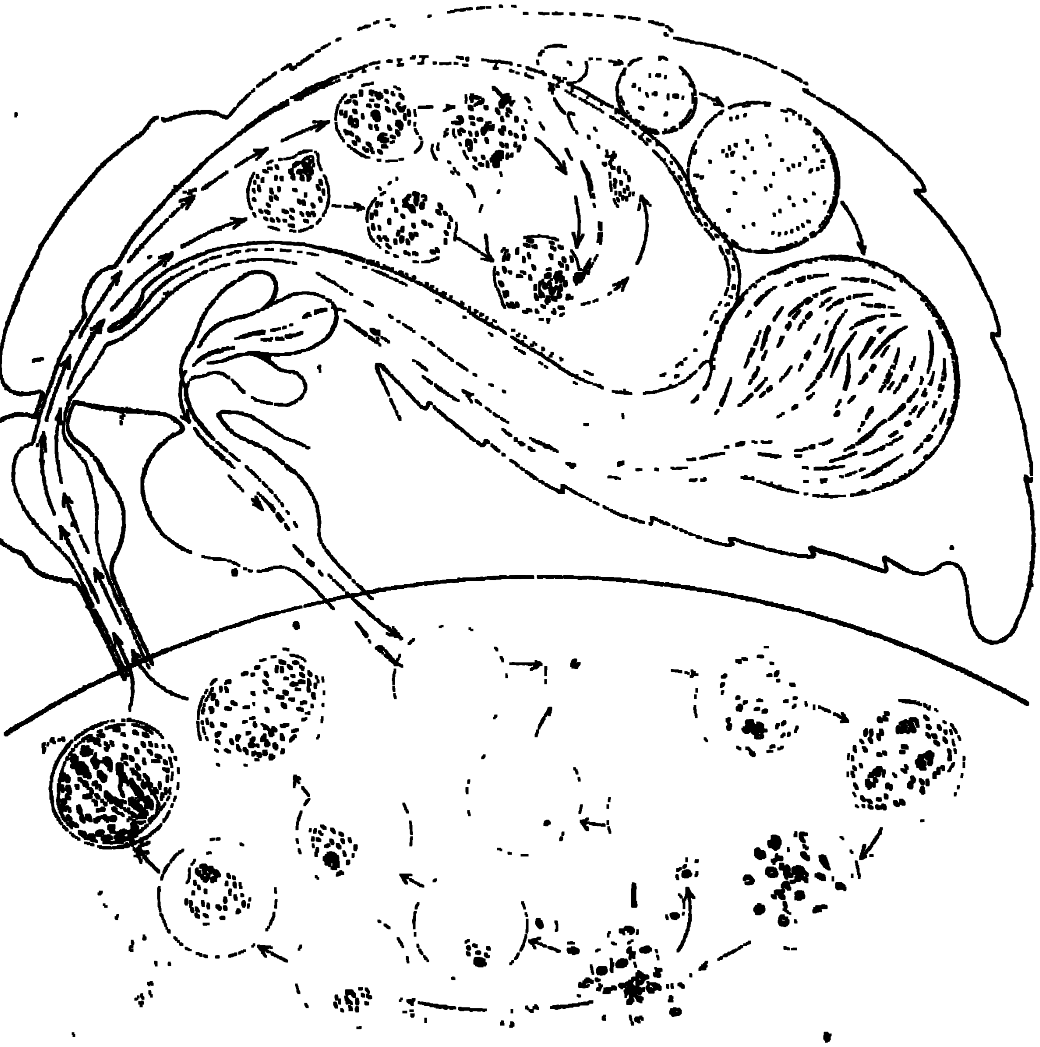

FIG. 169.—DIAGRAM OF THE LIFE-CYCLE OF *Plasmodium vivax* (GRASSI AND FELETTI), IN MAN AND THE ANOPHELINE MOSQUITO.

The nucleus of each sporoblast now divides into several small nuclei. These travel to the periphery, which grows out into a series of small projections, each of which takes a chromatin particle with it. Each of these projections is a sporozoite, so that each sporoblast forms a large number of sporozoites, and leaves a residual mass of pigment and cytoplasm undivided. The cyst, now enormously enlarged, bursts, and the sporozoites escape into the cœlome of the insect, which in this case is a hæmocœle, and therefore they enter the blood, and are carried by it probably all over the insect's body. Certainly they are seen in the thoracic muscles, but finally they find their way to the salivary glands, and so to a new host, or according to Schaudinn to the eggs, and so probably to a new generation of mosquitoes.

Sporogony takes about ten to twelve days, during which the mosquito will have sucked blood three or four times.

Abnormal Forms.—In mosquitoes, whether infected by malarial parasites or by Proteosoma, peculiar bodies, called 'black spores' by Ross, are sometimes found in the stomach wall, which are now known to be protozoal parasites of the genus *Nosema*, which have invaded the oöcysts, and are therefore hyperparasites.

Cultivation. *Plasmodium malariæ*, *P. vivax*, and *Laverania malariæ* were first cultivated by Bass, alone and with John. They grow anaerobically in blood mixed with dextrose at 41° C., but the blood must have no leucocytes if more than one generation is to be cultivated. The whole asexual cycle of *P. vivax* and *L. malariæ* has been completed *in vitro* in the corpuscles of human blood. Forms suggesting parthenogenesis were seen.

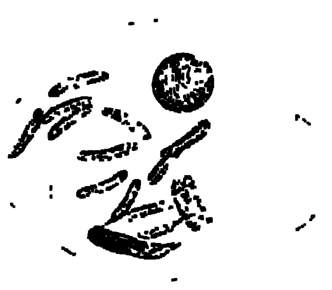

FIG. 170.—AN OÖCYST SHOWING ROSS'S 'BLACK SPORES,' NOW KNOWN TO BE PROTOZOA BELONGING TO THE GENUS NOSEMA

(After Grassi.)

Animal Hosts.—Although species of Plasmodium exist in animals, still there is no evidence that the human parasites live in any other animal than man. Fermi and Lumbau in 1912 have tested this with regard to bats, sparrows, owls, quails, and frogs, with negative results.

Classification.—A number of species, increasing gradually, belong to this genus, among which are two of the malarial parasites, *P. vivax* and *P. malariæ*.

Plasmodium vivax Grassi and Feletti, 1890 (Plate I.).

Synonyms. *Hæmamœba vivax* Grassi and Feletti, 1890; *H. malariæ* var. *magna* Laveran, 1900; *H. malariæ* var. *tertianæ* Laveran, 1901; *Plasmodium malariæ* var. *tertianæ* Celli and Santelice, 1891; *P. malariæ tertianum* Labbé, 1899; *Hæmosporidium tertianum* Lewkowicz, 1887.

Plasmodium vivax is the parasite of tertian malarial fever, and derives its specific name from its energetic amœboid movements, which probably take place for purposes of nutrition.

Its schizogony has been well studied by Golgi and Schaudinn, and its sporogony by Grassi, Bignami, and Bastianelli.

The whole process of the schizogony of *P. vivax* can be summarized as follows:—During the first twenty-four hours after the entry of the sporozoite or merozoite into the red cell the little trophozoite, which at the beginning is about one-third the size of the erythrocyte, grows rapidly, absorbing nutriment from the red cell by its pseudopodia and by the large surface of cytoplasm exposed, owing to the size of the vacuole.

Hence, not merely does it increase in size, but it acts deleteriously upon the enclosing cell, which loses its hæmoglobin, turns pale and degenerates, as is evident by its becoming swollen owing to the absorption of fluid, and by showing, on staining with any modification of Romanowsky, a dotted appearance due to red granules called Schüffner's dots. These dots can be seen in red cells affected by other plasmodia—*e.g.*, *P. canis* in the dog. In growing, it gives rise to a quantity of hæmozoin, which appears as fine, reddish-brown granules, often seen in active movements due to currents in the cytoplasm of the parasite. In about thirty hours it becomes rounded off as the schizont (Fig. 44, p. 294), 8·5 μ in diameter.

From the thirtieth to the forty-eighth hour the fully-grown schizont undergoes sporulation, when it will be noticed that fifteen to twenty merozoites are formed, while the hæmozoin granules are packed together, either into the centre or towards the periphery of the parasite. It will also be noted that the red cell is now considerably swollen and almost colourless.

About the forty-eighth hour the remains of the corpuscle disintegrate, and the merozoites (size 1·5 μ), hæmozoin, etc., escape.

So that *P. vivax* occupies forty-eight hours in the process of schizogony. As curiosities, it may be mentioned that a trophozoite or a schizont may be seen in the same red cell as a gametocyte.

Sporogony.—The development in the mosquito was first worked out in *Anopheles claviger*.

The development of the gametes, and the fertilization of the macrogamete, and the structure of the oökinete, have been carefully described and figured by Schaudinn (*vide* Figs. 45, 46, and 47, p. 294). In about forty hours after the mosquito has been fed, the oöcyst can be found as a round transparent body with strands of yellowish hæmozoin scattered throughout it, lying in the stomach wall beneath the epithelium, and covered over by the musculo-elastic layer of the gut. Its wall is seen to be well defined—*i.e.*, the oökinete has become encysted. By this time the chromatin will have divided into small masses.

On the third day it will have become from one-third to one-fourth larger, and the cyst-wall will be more distinct, and the imperfect segmentation of the protoplasm around the nuclei can be seen. The hæmozoin is seen gathered into little masses lying between the segments of the cytoplasm, which are the sporoblasts. The first stages of the formation of sporozoites may also be observed.

During the fourth day the size increases about a fourth, and the nuclei and their surrounding protoplasm will have formed some twenty to thirty sporoblasts, whose periphery will be marked by a palisade of forming sporozoites.

Between the fourth and fifth day the cysts (50 μ in diameter) full of sporozoites (size 14 μ) will be seen to be projecting into the cœlome.

After the seventh day the oöcyst ruptures, and the sporozoites escape and find their way to the salivary glands, in the cells of which they lie, mainly in those of the mid or poison gland. Thus, about the tenth to the twelfth day after infection the mosquito is ready to spread the disease by its bite, and the cycle of sporogony is complete. It must be remembered that Schaudinn observed infection of the mosquito's egg, but whether the parasite penetrates into the larva, and from that to the pupa, and thus into a second generation, is not known.

Plasmodium malariæ Laveran, 1881 (Plate I.).

Synonyms.—*Hæmamœba malariæ* Grassi and Feletti, 1890; *H. laverani* var. *quartana* Labbé, 1894; *H. malariæ* var. *magna* Laveran, 1900; *H. malariæ* var. *quartanæ* Laveran, 1901; *Plasmodium malariæ* var. *quartanæ* Celli and Sanfelice, 1891; *Hæmosporidium quartanæ* Lewkowicz, 1897; *Plasmodium malariæ quartanum* Labbé, 1899; *P. golgii* Sambon, 1902; *Laverania malariæ* Jannesco, 1905; and *Oscillaria malariæ* Laveran, 1881.

Schizogony.—The young trophozoite, which is smaller than *P. vivax*, forms a compact ring, which lies in an unaltered erythrocyte, and shows, as a rule, but little pseudopodial activity. Very soon hæmozoin appears in the form of dark rodlets.

After the first twenty-four hours the parasite is found to be much larger, and the hæmozoin more abundant. The granules of pigment will be noticed to be gathered at the periphery, and to be very dark in colour, and non motile. The red cell tends, if anything, to become smaller and darker. In about sixty hours the trophozoite will have become the full-grown schizont, which is a large, round, pigmented body surrounded by a rim belonging to the corpuscle. During the next twelve hours its nucleus divides up into six or twelve nuclei, around which the cytoplasm gathers, while the hæmozoin is driven into the centre, and the appearance of a daisy is produced by the central block of hæmozoin and the regular arrangement of the merozoites around it (size 6 μ).

The merozoites (size 1·75 μ) are now set free, and, as a rule, many of them appear to be killed off, and not to be able to affect the red cells. More rarely they go on increasing in number, and recently have been said to cause death in a case (Leishman), but a severe infection is not usual.

The whole schizogony takes place in the peripheral blood, and occupies seventy-two hours.

Sporogony.—Gametocytes are very rarely seen, and only after the disease has lasted a long time, but Vida has recently described all stages of their development as seen in the peripheral blood.

They begin as small forms, with a central nucleus but no vacuole, and soon become pigmented, the fully-grown macrogametocyte being a little larger than a normal corpuscle. Its dark cytoplasm is heavily pigmented, especially at the periphery, at which the nucleus is also placed. The corpuscle forms but a small rim around the parasite.

The microgametocyte shows the usual structure already described, but is less pigmented, and has a clearer cytoplasm. The corpuscle is not enlarged, as in the case of the macrogametocyte, and much more of it is visible around the parasite. The formation of the microgametes has been observed, but the infection of the mosquito is difficult to bring about, though the development in the mosquito has been traced by Bignami and Bastianelli. The oöcyst is characterized by the pigment, which is black, coarse, and gathered into a clump. The cycle of development is the same as in *P. vivax*, but takes about eighteen to twenty-one days to be completed after infection in mosquitoes which were kept at a temperature of about 22° C. This appears to be the degree of heat at which the process takes place best. At the end of that time the completely developed sporozoites can be seen.

Pathogenicity. Causes quartan fever

Plasmodium tenue Stephens, 1914, is an extremely amœboid form, with scanty cytoplasm and much chromatin, found first in blood films from India, but known also in Africa. It may be *Laverania malariæ*. *Plasmodium caucasicum* Marzinowsky, 1916, found on the Black Sea littoral, may also be *Laverania malariæ*.

Plasmodium danilewskyi Grassi and Feletti, 1890.

Synonyms. -*Laverania danilewskyi* Grassi and Feletti, 1890; *Hæmamœba relicta* Grassi and Feletti, 1891; *Cytosporon malariæ avium* Danilewskyi, 1891; *Proteosoma grassii* Labbé, 1894; *Plasmodium relictum* Sergent, 1907.

This parasite was discovered by Grassi in the blood of birds in Italy, and causes death in partridges in Hungary. It affects sparrows in India, and is the form in which Ross first traced the development of a plasmodium in a mosquito. It occurs in Ceylon, and is common in Africa.

The young trophozoite becomes pigmented, and, displacing the nucleus, grows into the schizont, which forms about nine merozoites.

The macrogametocyte has but little chromatin in its nucleus, which is rounded, while the microgametocyte has an elongated, darkly-staining nucleus.

These develop in *Culex fatigans*, *C. nemorosus*, or some other species, when in about twelve to fifteen hours ookinetes are seen, and in about one to two days well-developed oocysts are present in the stomach in the form of round, transparent cysts, with hæmozoin scattered through them.

In three to four days the oöcysts have increased in size, and sporoblasts have appeared, and even sporozoites are forming.

In nine to ten days the oöcyst has become fully developed and bursts, and the sporozoites can first be seen in the muscles of the thorax, and then in the salivary glands, in which they lie principally in the central or poison lobe. The black spores already mentioned can be noted in the stomach, and, according to Stephens and Christophers, in either the thoracic muscles or in the salivary glands.

No traces of parasites have been found in the larvæ or second generation of *Culex*.

PLATE I.

MALARIAL PARASITES.

(Coloured by Leishman's stain.)

Geo Waterston & Sons, Ltd Edin

To face page [illegible]

Plasmodium kochi Laveran, 1899.

This plasmodium is found in chimpanzees (*Anthropopithecus troglodytes* Gm.), and in monkeys in Africa and in Ceylon; in the latter it causes illness and death. The spleen and bone-marrow are found pigmented. It is said not to be inoculable.

Plasmodium pithoci Halberstaedter and Prowazek, 1907.

Found in the ourang-outang (*Simia satyrus*) and the chimpanzee, in which the trophozoites resemble *P. vivax* and the gametes *P. malariæ*. Schüffner's dots can be seen.

Plasmodium inui Halberstaedter and Prowazek, 1907.

In *Macacus cynomolgus* L. and *M. nemestrinus* L. It is like *P. pitheci*, but the hæmozoin is in the form of fine yellow granules. Merozoites, twelve to sixteen in number. Schüffner's dots absent.

Plasmodium cynomolgi Mayer, 1907.

In *M. cynomolgus* L. Merozoites, eight to thirteen. Schüffner's dots present.

Plasmodium bovis Kolle, 1898.

In cattle in South Africa, in which they produce remittent fever and severe anæmia.

Plasmodium canis Castellani and Chalmers, 1910.

This parasite, which is very common in pariah dogs in Ceylon, was discovered by us in 1908. It resembles *P. vivax*, entering the red cell as a small round merozoite, and growing into a pigmented plasmodium, and finally dividing into a number of merozoites. Schüffner's dots are also present. Fig. 171 shows the schizogony of this parasite, and Fig. 172 the gametocytes. The macrogametocyte has a small rounded nucleus and the microgametocyte an elongated narrowish nucleus extending across the parasite.

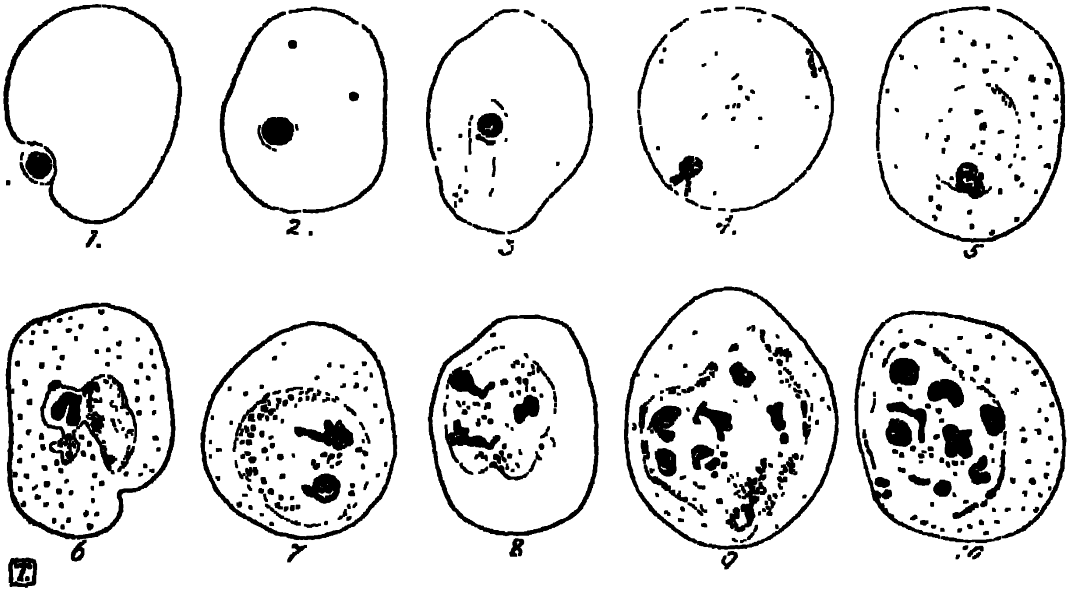

FIG. 171.—*Plasmodium canis* CASTELLANI AND CHALMERS.

1-2, Merozoite entering the corpuscle; 3, young trophozoite (the red cell shows Shüffner's dots); 4-6, trophozoites, enclosing cells showing Shüffner's dots; 7-10, schizonts showing various stages of nuclear division prior to the formation of the merozoites.

Plasmodium equi Castellani and Chalmers, 1913.

Found by us in a horse in Ceylon. It closely resembles *P. canis*.

Plasmodium brasilianum Gonder and Gossler, 1908.

Resembles the human quartan parasite, but found in *Brachyurus calvus* in Brazil.

Plasmodium vassali Laveran, 1905.

Synonym.—*P. vassali* Sambon, 1907.

Found by Vassal in a squirrel—*Sciurus griseimanus*.

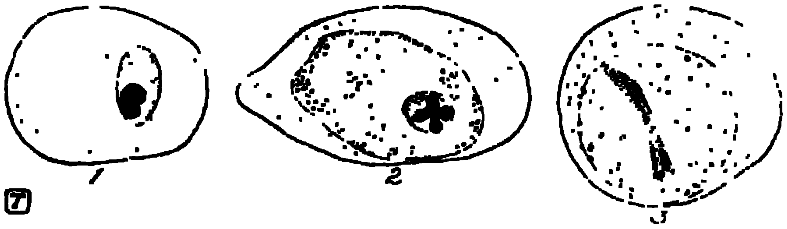

FIG. 172.—*Plasmodium canis* CASTELLANI AND CHALMERS.
1. Young gametocyte; 2. Microgametocyte; 3. Macrogametocyte.

Other Forms.

In Mammals. *Plasmodium murinum* Dionisi, 1898, in *Myotis myotis*, *P. monosoma* Vassal, 1907, in *Vesperugo abramus*.

In Birds.—*P. majoris*, in *Parus major*, *P. vaughani* Novy and MacNeal, 1904, in *Merula migratoria*.

In Lizards. *P. diploglossi* Aragão and Neiva, 1909, in *Diploglossus fasciatus*. *P. tropiduri* Aragão and Neiva, 1909, in *Tropidurus torquatus* Wied in Brazil.

Genus Hæmocystidium Castellani and Willey, 1904.

The characters of this genus resemble those of the genus *Plasmodium*, but the parasites are generally larger, and according to Dobell, the schizogony is very simple, there being as a rule binary and occasionally quaternary division, which takes place in the general circulation. Woodcock, however, considers the forms which Dobell describes as binary fission to be fusion forms of the parasites. Pigment present.

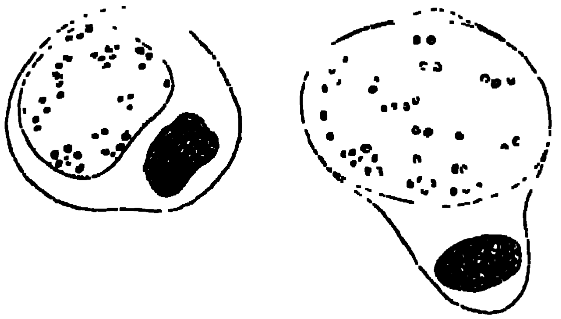

FIG. 173.—*Hæmocystidium simondi* CASTELLANI AND WILLEY.
(After Castellani and Willey.)

Hæmocystidium simondi Castellani and Willey, 1904.

This parasite was found in *Hemidactylus leschenaultii* Gray in Ceylon.

Other species: *H. metschnikovi* Simond in *Chitra indica* Gray in India; *H. mesnili* Bonet in *Naja* sp. (?) in West Africa, *H. roumei* Bonet in *Cinyxis belliana* Gray in West Africa, *H. testudinis* Laveran in *Testudo pardalis* in South Africa; *H. najæ* Wenyon in *Naja haje*, and in *Naja nigricollis* in Khartoum.

Genus Laverania Grassi and Feletti, 1890.

Definition. Plasmodidæ, in which the gametocyte is dissimilar from the schizont, appearing in the form of a crescent. Schizogony in the red blood cells in internal organs.

Laverania malariæ Grassi and Feletti, 1890 (Plate I.).

Synonyms. *Hæmamœba malariæ* Laveran, 1890; *H. præcox* Grassi and Feletti, 1890; *H. laverani* Labbé, 1894; *H. immaculata* Grassi and Feletti, 1891; *Plasmodium malariæ* var. *quotidianæ* Celli and Sanfelice, 1890; *P. præcox* Doflein, 1901; *P. immaculatum* Schaudinn, 1902; *P. falciparum* Blanchard, 1905; *Hæmomonas præcox* Ross, 1899; *Hæmosporidium undecimanæ* Lewkowicz, 1892; *H. sedecimanæ* Lewkowicz, 1892; *H. vigesimotertianæ* Lewkowicz, 1892; *Hæmatozoon falciparum* Welch, 1897.

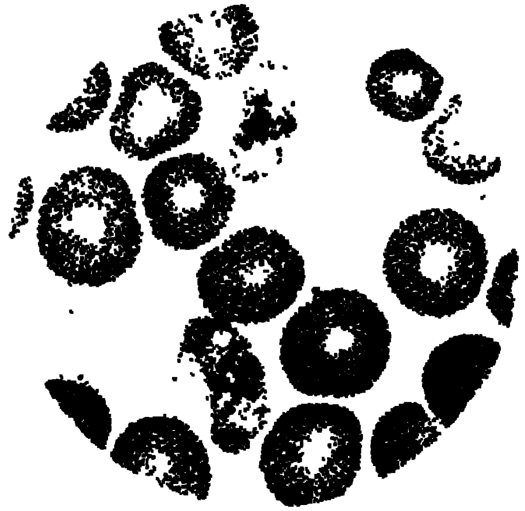

FIG. 174.—MALE CRESCENT OF *Laverania malariæ* (GRASSI AND FELETTI, 1890). (×1,000 DIAMETERS.)

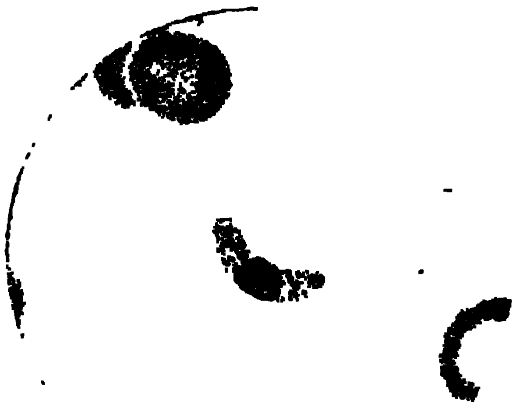

FIG. 175.—FEMALE CRESCENT OF *Laverania malariæ*. (×1,000 DIAMETERS.)

(By Norman, through the kindness of J. J. Bell.)

The young trophozoite begins as a very small parasite, which quickly forms a ring, of which the size is only one-sixth to one-seventh of the diameter of the enclosing red cell. This quickly grows into an oval form, which becomes pigmented, while the enclosing erythrocyte in stained preparations may show the so-called Maurer's dots, the significance of which is not understood.

The fully-grown schizont (size 4·5 μ) is but rarely seen in the peripheral blood, and the segmentation into merozoites (size 0·7 μ) nearly always takes place in the internal organs, when eight to ten or fifteen are formed. When this is in progress there is a great tendency for the red corpuscles to cling together and to the wall of the vessel, and hence to give rise to obstruction of the circulation, which produces the perniciousness of the fevers due to this parasite.

Character	*P. malariæ.*	*P. vivax.*	*L. malariæ.*
Schizogony ..	Completion in seventy-two hours.	Completion in forty-eight hours.	Completion in forty-eight hours or less.
Young trophozoite	Young trophozoite, smaller than *P. vivax*, larger than *L. malariæ*, movements rather slow; pseudopodia not marked or long	Young trophozoite, large; very actively motile, long pseudopodia.	Young trophozoite, small; actively motile.
Hæmozoin ..	Granules coarse, sluggish; peripherally arranged; dark brown.	Granules fine; movement marked	Granules fine and scanty; often motionless.
Schizont ..	Smaller than red corpuscle	Larger than red corpuscle.	Much smaller than red corpuscle.
Merozoites ..	Six to twelve, regularly arranged in a rosette	Fifteen to twenty regularly arranged	Eight to fifteen, arranged irregularly.
Gametocytes ..	Resemble sporonts, but larger.	Resemble sporonts but larger.	Crescentic in shape.
Erythrocytes ..	Almost normal.	Pale and swollen.	May be small and dark.

Schizogony takes from thirty-six to forty eight hours to be completed.

The gametocytes are characterized by being crescent-shaped and large, with the remains of the red cell stretched round them. The hæmoglobin of the cell is often seen lying in juxtaposition to the parasite, while the remaining portion of the corpuscle is almost colourless.

The macrogametocyte is characterized by its long thin shape.

FAMILY HÆMOPROTEIDÆ Sambon 1906.

Definition. Hæmosporidia with hæmozoin, but with oökinete which does not encyst.

Genus Hæmoproteus Kruse, 1890.

Synonyms. *Halteridium* Labbé, 1894; *Laverania* Laveran, 1899; *Trypanosoma* Schaudinn 1904; *Trypanomorpha* Léger, 1906.

Historical.—These parasites were first described by Grassi and Feletti in the blood of birds in 1890 as *Laverania*, a term altered by Labbé in 1894 to *Halteridium danilewskyi*. In 1904 came Schaudinn's paper showing that they were stages in the life history of trypanosomes, which has been supported by the work of the Sergents, and has been severely criticized by Novy, McNeal, Ross, and Thiroux who believe that Schaudinn made a mistake, and that the flagellates and intracorpuscular parasites are quite distinct. In 1908 a paper by Aragão appeared on *H. columbæ*, which certainly does not support Schaudinn's views; but in 1909 Woodcock's researches, as already mentioned, strongly support that distinguished protozoologist; however, later researches have all tended to indicate that Schaudinn was wrong and that his now celebrated life-cycle for *Hæmoproteus noctuæ* is a mixture of the life-cycles of a hæmoproteus and a trypanosome We, however, at present still give Schaudinn's account, pending confirmation of the recent work on the subject. At all events, the question as to whether Schaudinn was right or wrong cannot, impartially, be said to be settled one way or the other.

Hæmoproteus noctuæ Celli and Sanfelice 1891.

H. noctuæ goes through the cycle of schizogony in *Glaucidium noctuæ* Retz, the little owl, and its sporogony in *Culex pipiens* Linnæus.

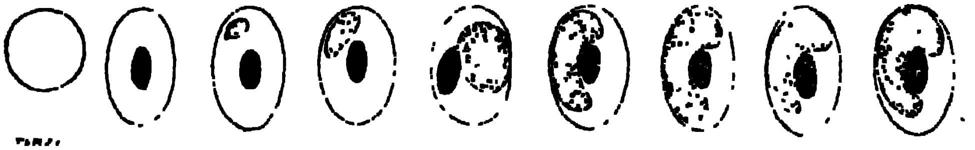

FIG. 176.—*Hæmoproteus mansoni* SAMBON SHOWING THE DEVELOPMENT OF THE GAMETOCYTES.

(After Sambon.)

When this gnat sucks the blood of a little owl infected with hæmoproteus, two halteridial forms in the owl's corpuscles are seen to undergo development in its stomach. These two forms are the microgametocytes and the macrogametocytes.

Microgametocyte.—The microgametocyte appears as a typical halteridium parasite enclosed in an erythrocyte, and possessing pale clear cytoplasm, with coarse hæmozoin granules and a large single nucleus, which is composed of eight groups, each containing trophic and kinetic elements

Macrogametocyte.—The macrogametocyte is a typical halteridium, laden with food granules, lying in a pale disorganized erythrocyte It has a rather small trophonucleus, alongside of which is a small kinetonucleus.

In the Mosquito.—When these gametocytes reach the alimentary canal of *Culex pipiens*, they escape from the erythrocytes, and appear free in the lumen of that canal, and proceed first to reduction and then to zygosis, with the formation of a zygote.

The whole process has been carefully worked out by Macallum in another species of halteridium, and is confirmed by Schaudinn in the present species.

Formation of the Microgametocyte.—The microgametocyte is a clear hyaline body, which, on escaping from the red blood-corpuscles, throws out active flagella, which, after beating about a little, break loose, forming the free microgametes. Schaudinn studied the cytological processes underlying these grosser changes, and found that the trophonuclei were reduced to four chromosomes, while the eight kinetonuclei remain, and, separating from the parent nucleus, form microgametes in the way presently to be described for the development of a male oökinete into a male trypanosome.

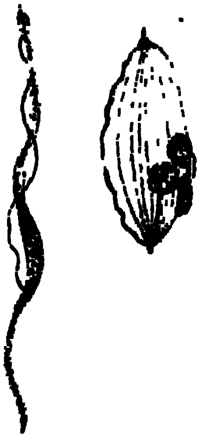

FIG. 177.—*Hæmoproteus noctuæ* CELLI AND SANFELICE.

(After Schaudinn.)

On the left is the microgamete, and on the right a scheme showing the arrangement of the nuclei centrosomes, undulating membrane, and myonemes.

The Microgamete. The microgamete is very thin, and tapering at the posterior extremity where it ends in a tail-like prolongation of the cytoplasm containing a portion of the trophonucleus. The anterior end is acutely conical.

The trophonucleus is elongated into a long thread, extending from the anterior to the posterior end of the body and carrying four chromosomes in the form of dots at regular intervals.

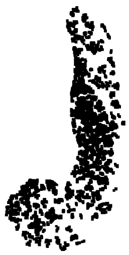

FIG. 178.—*Hæmoproteus noctuæ* CELLI AND SANFELICE: THE OÖKINETE.

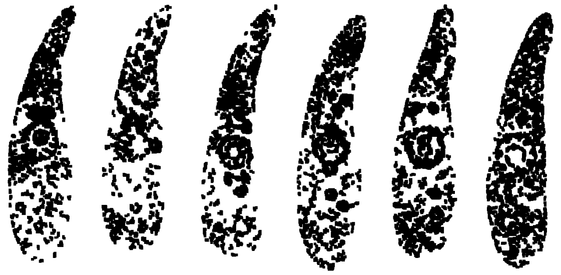

FIG. 179.—*Hæmoproteus noctuæ* CELLI AND SANFELICE: MATURATION OF THE OÖKINETE.

(After Schaudinn.)

The kinetonucleus is situate in the posterior third of the cytoplasm and consists of a rather elongated mass, with eight chromosomes and one intranuclear centrosome.

In addition to this centrosome there are two others—an anterior, situate just at the base of the anterior conical projection, and a posterior, situate just anterior to the tail, being connected with the trophonucleus by a chromatin bar. The undulating membrane runs from the anterior to the posterior centrosome, and is strengthened by eight myonemes.

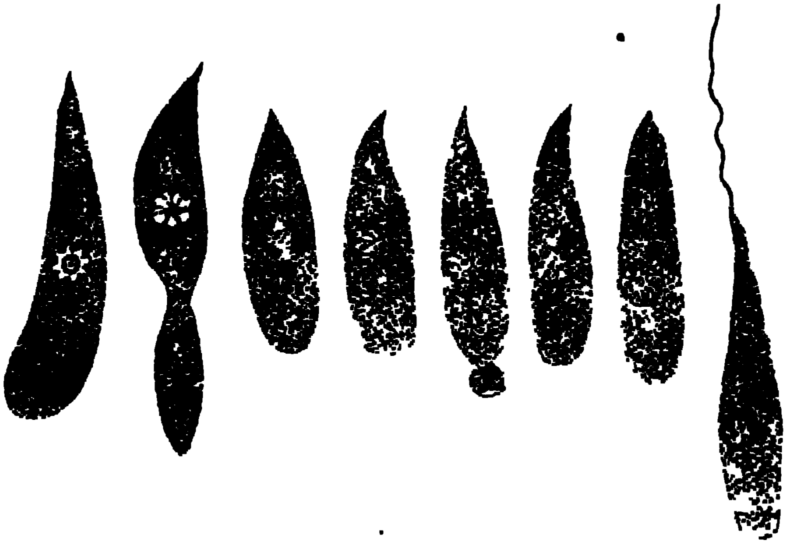

FIG. 180.—*Hæmoproteus noctuæ* CELLI AND SANFELICE.

(After Schaudinn.)

Formation of the indifferent oökinete and its development into the indifferent trypanosome.

Formation of the Macrogamete. The macrogametocyte becomes rounded and ruptures the remains of the erythrocyte, and is set free. The centrosome of the trophonucleus disappears, and the chromatin forms a spiral thread, which separates by longitudinal and transverse divisions into four tetrads. The kinetonucleus first forms a spindle, and then divides, causing the first reduction, which results in four dyads, and then a second division follows, leaving four monads or single chromosomes. The kinetonucleus now returns to its old position outside and close to the trophonucleus, and the macrogamete is fully developed.

Schaudinn was not able to trace out the reduction of the kinetonucleus, but it ultimately consists of four chromosomes and a centrosome, which, Woodcock points out, are not wholly sexual.

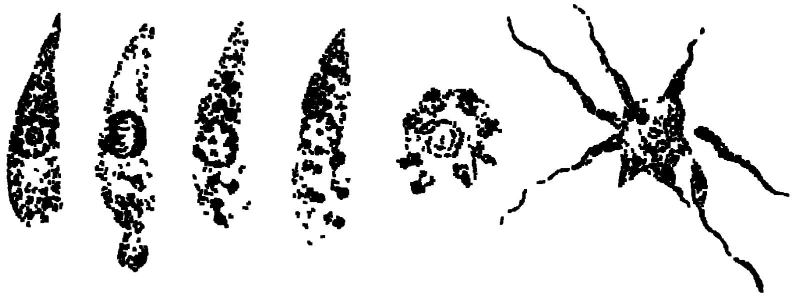

FIG. 181.—*Hæmoproteus noctuæ* CELLI AND SANFELICE.
(After Schaudinn.)
Formation of the male oökinete, and its development into the male trypanosome.

Zygosis.—This consists in the penetration of a microgamete into a receptive cone, which has arisen from the cytoplasm of the macrogamete on the side where the nuclei are situated.

The only parts which enter are the male trophonucleus, which is reduced, and the male kinetonucleus, which is not reduced, but which now undergoes two divisions. The trophonuclei of the male and female elements fuse and form the fusion spindle, at either end of which the kinetonuclei take up positions, and thus the zygote is formed.

Oökinete.—While zygosis is proceeding, and even before the complete formation of the synkaryon, the zygote becomes vermiform and motile, and is therefore called an oökinete. It consists of an anterior, hyaline, changeable end, which is followed by a region of cytoplasm with vacuoles, then by a denser region with the nuclear spindle just described, and finally a rounded posterior end full of granules and hæmozoin. From this posterior end a portion of cytoplasm enclosing granules and hæmozoin, etc., is cut off, thus freeing the oökinete of waste material. The spindle of the synkaryon now consolidates to form eight chromosomes, which will constitute the trophonucleus, while the two kinetonuclei at either end of the spindle, meeting together, form a single kinetonucleus, which takes up a central position inside the trophonucleus, and divides into eight chromosomes, with a centrosome in its centre. The nucleus of the oökinete, therefore, consists of a central centrosome, with eight surrounding chromosomes, around which lie another eight chromosomes, bordering the periphery.

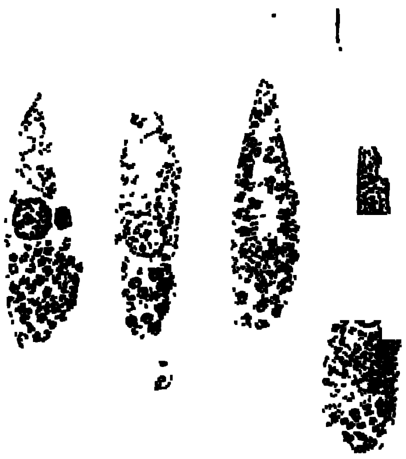

FIG. 182.—*Hæmoproteus noctuæ* CELLI AND SANFELICE: DEVELOPMENT OF THE FEMALE OÖKINETE AND THE FEMALE TRYPANOSOME.

(After Schaudinn.)

But oökinetes are not all alike. On the contrary, Schaudinn describes three kinds:—

1. *Indifferent Oökinete.*—Cytoplasm clear, and staining faintly, with one or two large vacuoles anteriorly, and having some granular material and hæmozoin still left.

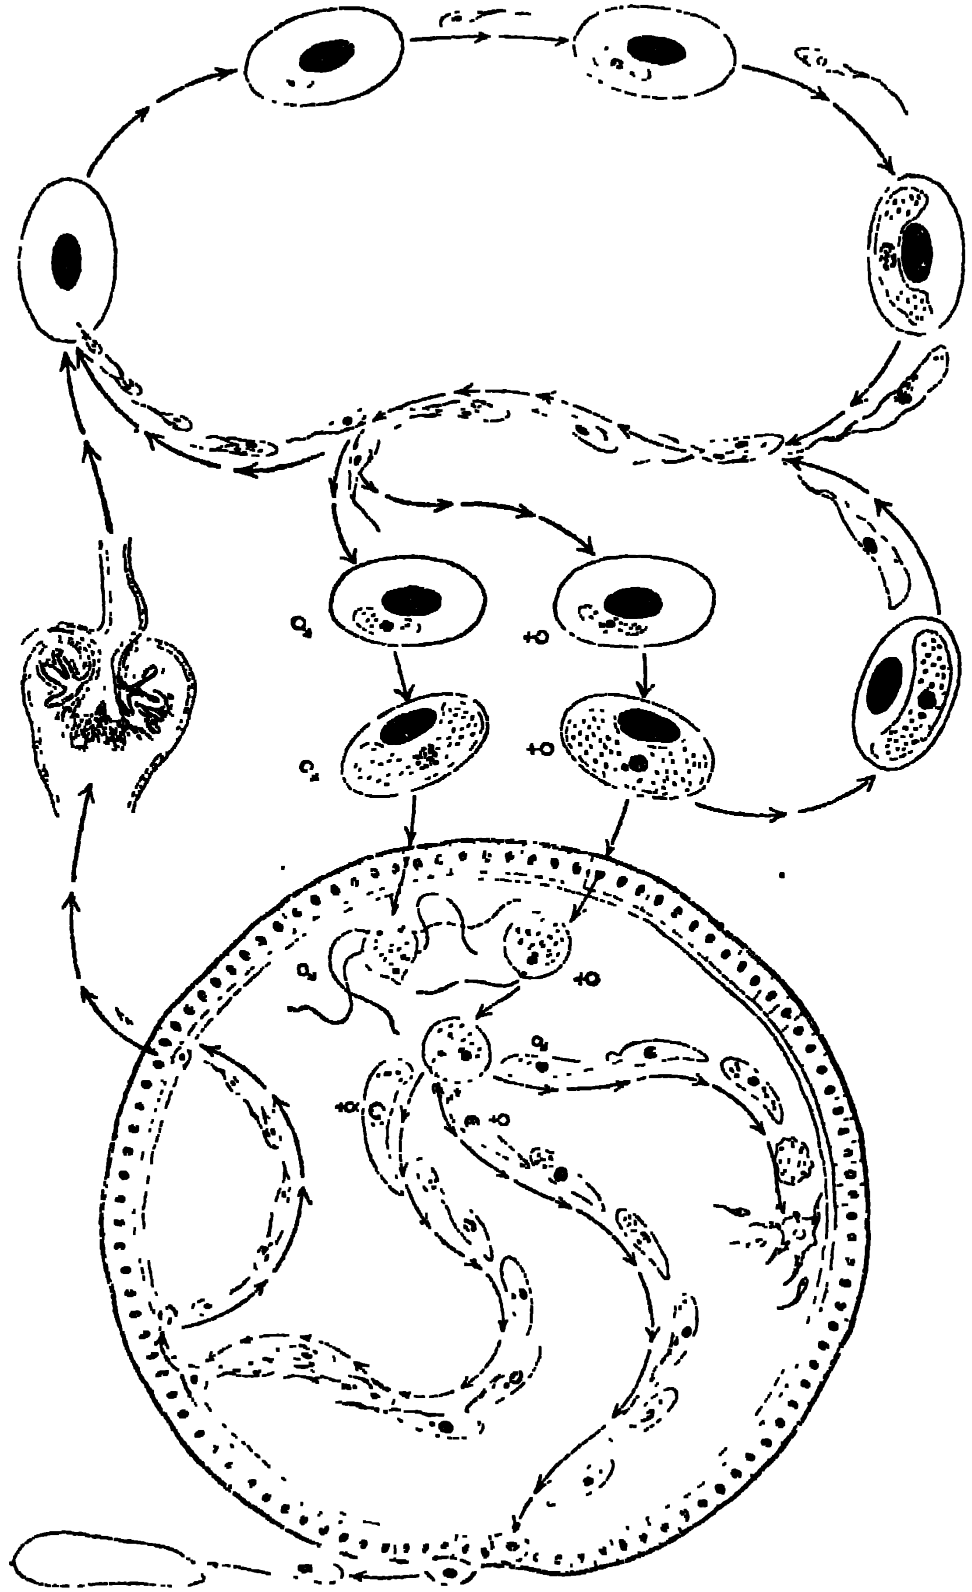

FIG. 183.—DIAGRAM SHOWING THE LIFE-CYCLE OF *Hæmoproteus noctua* CELLI AND SANFELICE.

(After Sambon and Terzi.)

Many authorities consider this life-cycle to be made up of the cycles of a halteridium and a trypanosome, which are believed to be quite distinct.

2. *Male Oökinete.*—Smaller than the indifferent or female forms, with cytoplasm almost hyaline, and much clearer than that of the indifferent form, with granular material completely lacking, nucleus large and rich in chromatin.

3. *Female Oökinete.*—Cytoplasm fairly dense, with plenty of granules, with a nucleus smaller than in the indifferent form.

The Indifferent Oökinete.—The indifferent oökinete starts its development by expelling for a second time a quantity of hæmozoin, while its kinetonucleus unites with the trophonucleus, so that the nucleus now possesses eight compound chromosomes.

The centrosome becomes dumb-bell shaped, and forms an axial spindle, around which the chromosomes are arranged. These now divide, and form a diaster by the different portions passing to either end of the spindle, which is heteropolar, the smaller half being kinetic in function. The nucleus now divides into a larger portion, the trophonucleus, and a smaller, the kinetonucleus. The former enters on a resting stage, while the latter proceeds to the periphery, and forming another axial spindle at right angles to the length of the parasite, divides into two portions by its centrosome forming the axial spindle and the chromosomes the two ends of a diaster. One of these daughter kinetonuclei lying in the ectoplasm is attached to the other, lying in the endoplasm, by means of the axial spindle. The ectoplasmic kinetonucleus forms another spindle, with a longitudinal axis, which grows backwards along a fold of the ectoplasm, expanding it as it goes, to the hinder end of the body. In this way an undulating membrane is formed, which, therefore, contains eight chromosomes—the myonemes—on each side of the folded ectoplasm, while the axial spindle, becoming excentric, forms the flagellum. At the posterior end of the undulating membrane the flagellum joins with the chromosomes, and grows out of the body to form the free flagellum, along which the ectoplasm is drawn for a short distance.

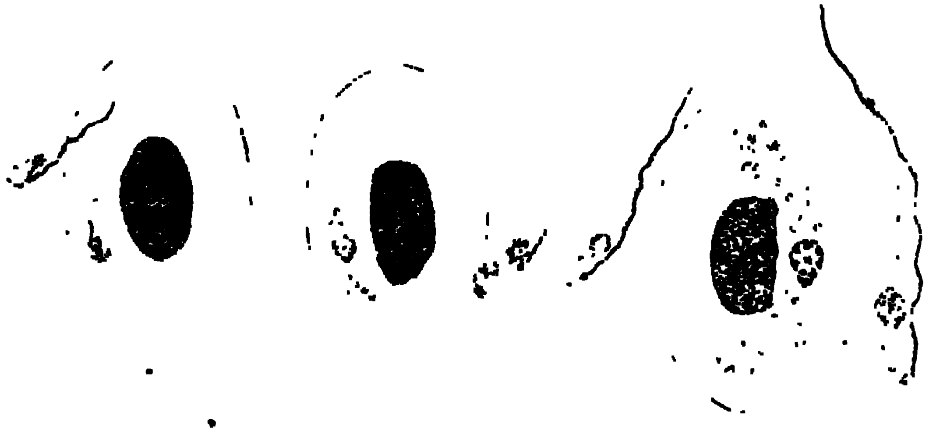

FIG. 184.—*Hæmoproteus noctuæ* CELLI AND SANFELICE.
(After Schaudinn.)

On the left a small trypanosome is seen entering a red corpuscle in the blood of the little owl, and in the corpuscle is seen the first endocellular stage. The second corpuscle shows a more advanced endocellular stage and the act of liberation into the liquor sanguinis. Farther to the right is seen a medium-sized trypanosome. The third corpuscle shows the fully-grown halteridial form, while on the extreme right a fully-grown trypanosome is depicted.

Of the two centrosomes of this spindle, the distal one disappears, while the proximal one forms the blepharoplast at the root of the flagellum.

The endoplasmic daughter kinetonucleus becomes the kinetonucleus of the trypanosome, and thus is formed the indifferent trypanosome, which now multiplies by binary division. After some time it takes on a gregariniform phase, and becomes attracted to an epithelial cell in the stomach of the mosquito by its flagellum, which is reduced to a short rod. While so attached it may multiply by binary division, and may also penetrate in between the cells of the stomach and encyst, losing its flagellum.

After a period of rest the trypanosome can become active again, but after a time it must either (1) pass into the blood of the little owl, (2) become a male or female form, (3) die out.

The Male Oökinete.—The male oökinete forms a heteropolar diaster, but with a subdivision of the elements into male and female instead of into kinetic and trophic.

The larger or female portion disappears, while the smaller or male portion forms eight double nuclei with kinetic and trophic elements, which are distributed throughout the cytoplasm.

The oökinete now becomes rounded, while the eight double nuclei travel to the periphery, which grows out into little elevations, each with a double nucleus. Each little elevation grows into a little male trypanosome in the same manner as in the indifferent form, and breaks off from the 'rest body' (*nucleus de reliquat*) of the parent cell. These male trypanosomes, according to Schaudinn, simply die off.

The Female Oökinete.—In this form the same changes take place as in the male oökinete, but it is the small male nucleus which degenerates, after dividing into a number of forms, while the large female nucleus, which consists of the trophic and kinetic elements, remains, and forms a trypanosome in the same manner as in the indifferent form.

The female trypanosome is slow moving and does not divide, but can become gregariniform and lie quiescent between the epithelial cells for a time. It can also pass into the ovaries and eggs, and lie dormant during the winter.

The female oökinete, however, undergoes parthenogenesis by losing its flagellar apparatus and developing a trophonucleus with a kinetonucleus in contact with it. The kinetonucleus now divides, and undergoes reduction, while the trophonucleus also divides, one portion being lost. The reduced kinetonucleus, which has divided into two, now enters the trophonucleus from opposite sides, and fusing forms the synkaryon of an oökinete, which may become an indifferent, a male, or a female trypanosome.

In the Owl.—The male, female, and indifferent trypanosomes may be injected into the owl during the process of biting by the mosquito, but the majority are of the indifferent type. The male trypanosomes, if they enter, die off. The indifferent trypanosomes divide in the blood until a small size is reached, when they enter the erythrocytes and become a young halteridium by the flagellar apparatus disappearing and the kinetonucleus approaching the trophonucleus.

In twenty-four hours this parasite, which now contains hæmozoin, becomes active, and, re-forming its flagellar apparatus, leaves the blood cell usually at night as a typical *Trypanosoma noctuæ*. After a short period of activity it enters another erythrocyte and grows till the next night, when it again becomes free. This process takes place six times before the trypanosome attains its full size, when it undergoes repeated division until again small, thus completing the cycle of schizogony. The small extracellular forms may be looked upon as the merozoites, and the intracellular forms as trophozoites, and the large extracellular form as a schizont. The sexual forms are developed from the merozoites, i.e., the very young indifferent trypanosomes, which enter the red cells, and become microgametocytes and macrogametocytes, thus completing the cycle of sporogony.

Remarks.—Novy and many others are convinced that Schaudinn is entirely wrong, and that he was dealing with a double infection of a halteridium and a trypanosome, both of which probably develop in entirely different ways. We are also convinced that these parasites are Hæmosporidia.

Hæmoproteus columbæ Celli and Sanfelice, 1891.

Hæmoproteus columbæ is the halteridium of *Columba livia* L. Its life-history is not exactly known at present, but has been studied by Ed. and Et. Sergent and by Aragão. According to the latter observer it would seem to have the usual two life-cycles of schizogony and sporogony joined into one, taking place in *Columba livia* and in *Lynchia maura* or *L. brunea* (*lividicolor*) Oliv.

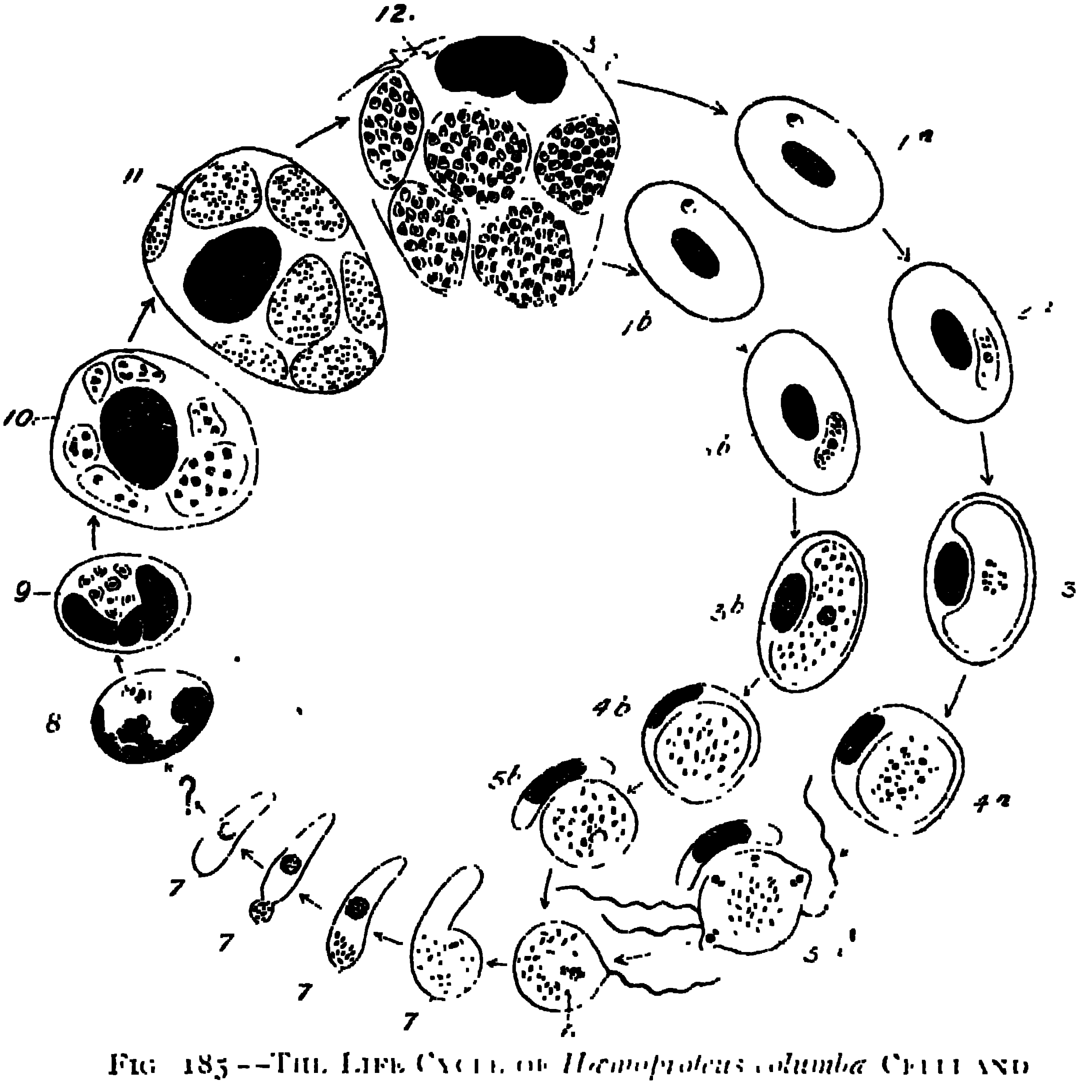

FIG. 185.—THE LIFE CYCLE OF *Hæmoproteus columbæ* CELLI AND SANFELICE.

(According to the researches of Aragão. After Aragão from *Archiv f. Protistenkunde*.)

Starting with the macro- and microgametocytes, which are of the same appearance as in *H. noctuæ*, and which enter the gut of the *Lynchia* along with the blood sucked from the pigeon, the usual processes of reduction, with the formation of microgametes and macrogametes and ookinetes, and the clearance of waste matter from these latter, are gone through. The further changes undergone by the ookinete are at present unknown.

After the *Lynchia* bites a pigeon, a small uninuclear parasite is to be found in a leucocyte, first at the site of the bite and later in the lungs, where the further development takes place. First the small parasite divides into a number of mononuclear forms, which, along with the leucocyte, grow enormously, and form large parasites, at first full of nuclei, and later of mononucleated merozoites, the whole process taking some twenty-six or more days. The minute merozoites now enter the red corpuscles and grow into typical Halteridia. It appears that there are no trypanosome stages, and, indeed, the only form of that nature met with was *Trypanosoma avium* Novy and McNeal.

This is quite a different history from that of Schaudinn for *H. noctuæ*, but it must be observed that it is incomplete, and, therefore, deductions cannot safely be drawn from it.

Other Species.—A large number of species are described by Celli and Sanfelice, Novy and McNeal, and others, which have been found in birds as well as in some reptiles.

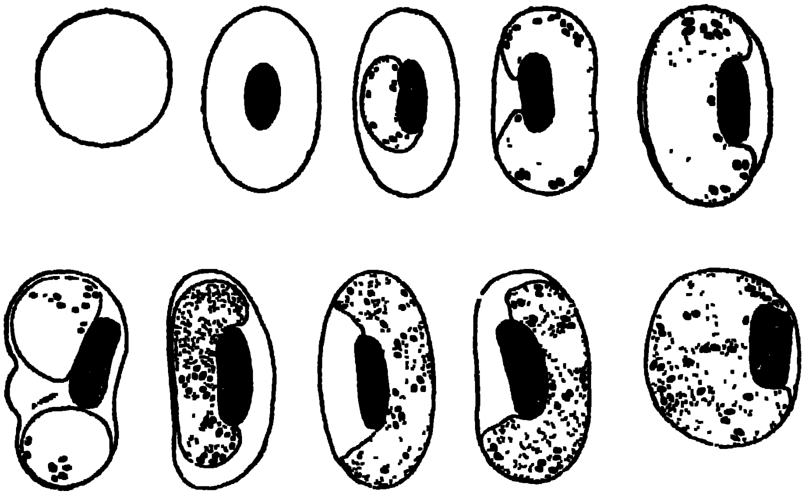

FIG. 186.—*Hæmoproteus columbæ* CELLI AND SANFELICE. (After Sambon.)

Sambon has described, under the name of *Hæmoproteus mansoni* (Fig. 176), a new species found in the red grouse (*Lagopus scoticus*), the gametocytes of which are not closely adherent to the nucleus of the erythrocyte, as is usually the case, and sporogony takes place in a parasitic fly of the grouse (*Ornithomyia lagopodis*), in the stomach of which oökinetes were found.

Anschütz has described a schizogony of *H. oryzivoræ* taking place in the circulating blood of *Padda oryzivora*.

CHAPTER XXII

NEOSPORIDIA

Neosporidia—Myxosporidia—Actinomyxidia—Sarcosporidia—Haplosporidia—Protozoa incertæ sedis—Chlamydozoa—Filterable viruses—References.

NEOSPORIDIA Schaudinn, 1900.

Definition.—Parasitic plasmodromata, without motile organs, in which spore-formation and trophic growth proceed simultaneously.

Remarks.—The Neosporidia are protozoa in which reproduction and growth go on together. In the Telosporidia the trophozoite grows into the schizont, which divides into spores; in the Neosporidia growth and spore formation go on together; but, as in the case of all attempts at classification, there are exceptions, for the trophozoite may grow into the schizont, and then divide.

It appears as though the Neosporidia were evolved from a sarcodinal ancestor.

They are divided into four orders: (1) Myxosporidia, (2) Actinomyxidia, (3) Sarcosporidia, (4) Haplosporidia; and, in addition, there are a number of parasites belonging evidently to the protozoa, which cannot easily be classified, and are therefore placed in an addendum to the Neosporidia as *Protozoa incertæ sedis*.

ORDER I. MYXOSPORIDIA Butschli, 1881.

Neosporidia with spore-formation commencing early in the amœboid trophozoite. Each spore has one or more polar capsules.

The Myxosporidia are subdivided into:—

Suborder I. Phænocystes Gurley, 1893. **Synonym.**—Myxosporidia (*sensû stricto*). Spores with two to four large, clearly visible polar capsules.

Suborder II. Cryptocystes Gurley, 1893. **Synonym.**—Microsporidia (Balbiani). Spores with one minute polar capsule, which is only rendered visible by treatment with reagents.

SUBORDER I. PHÆNOCYSTES Gurley, 1893.

Phænocystes comprise the true Myxosporidia, being usually found in Teleostean fish, though they may occur in elasmobranchs, amphibia, and reptiles.

In fish they have long been known as psorosperms, being found in the bile-passages, the urinary organs, the muscles, and the nervous system.

The amœboid trophozoite has a differentiation of its cytoplasm into endo- and ecto-plasm, and moves about by pseudopodia. Spore-formation begins early by a concentration of the cytoplasm around one of the nuclei of the trophozoite. This concentrated area is marked off by a capsule, and is the pansporoblast. The nucleus of the pansporoblast divides repeatedly, after which the cytoplasm splits into two masses—the sporoblasts—each of which is covered by a cuticle and contains three nuclei.

The cytoplasm of the sporoblast now divides into three areas around the nuclei. One of these areas is large, and is called the sporoplasm, while the other two are small, and form the polar capsules. Each spore, therefore, contains two polar capsules and one mass of sporoplasm, which represents a single sporozoite. Each polar capsule develops a spirally coiled thread. A spore escapes when the parent trophozoite dies, and then finds its way out of its host by the bile or urine, or through the tissues into the alimentary canal. For further development it must be swallowed by another host, in whose alimentary canal the threads of the polar capsules are extruded, fixing the little spore, which bursts and allows the amœboid sporozoite to escape and go on its travels in search of a suitable tissue. Perhaps *en route* it conjugates with another sporozoite; if so, this is not known. While sporogony is preparing, schizogony may take place by plasmotomy, which is the division of the multinuclear trophozoite into two or more forms.

It will thus be seen that growth, plasmotomy (schizogony), and spore-formation (sporogony) go on simultaneously.

Classification.—*Disporea* Doflein, 1899.—Phænocystes with two spores.

FAMILY.—*Ceratomyxidæ* Doflein, 1901.

Genera.—*Ceratomyxia*, *Leptotheca.*—Parasitic in fish and frogs.

Polysporea Doflein, 1899.—Phænocystes with more than two spores.

FAMILY 1.—*Myxidiidæ* Auerbach, 1910.

Genera.—*Sphærospora*, *Myxidium.*

FAMILY 2.—*Chloromyxidæ* Thélohan.

FAMILY 3.—*Myxobolidæ* Gurley, 1893.

SUBORDER II. CRYPTOCYSTES.

This order is divided by Doflein and Perez into:—

Tribe 1. *Monosporogenea* Perez.—Trophozoite becomes a single pansporoblast (sporont), which produces a single spore.

Tribe 2. *Oligosporogenea* Doflein, 1899.—Trophozoite becomes a single pansporoblast (sporont), which produces four to eight spores.

Tribe 3. *Polysporogenea* Doflein, 1899.—Trophozoite becomes numerous pansporoblasts (sporont), which produce many spores.

TRIBE 1. MONOSPOROGENEA.

This tribe includes *Nosema bombycis* Nägeli, 1857, which is the cause of pébrine, the silkworm disease. *N. apis* Zander, 1909, was shown to be the cause of microsporidiosis in bees in England by Fantham and Porter.

TRIBE 2. OLIGOSPOROGENEA Doflein, 1899.

This includes the genera *Gurleya* Doflein, *Thélohania* Henneguy, and *Pleistophora* Gurley.

TRIBE 3. POLYSPOROGENEA Doflein, 1899.

This includes the genera of *Glugea* Thélohan, and *Myxocystes* Mrazek, of which *Glugea anomala* Moniez is a parasite of the stickleback.

Microsporidium polyedricum Bolle, a doubtful species, is said by Perroncito to occur in man.

ORDER II. ACTINOMYXIDIA Stolc, 1899.

These are parasites in the Tubificidæ of the oligochæte worms, and need not concern us.

ORDER III. SARCOSPORIDIA Bütschli, 1882.

Definition.—Neosporidia in which the young trophozoite is, with rare exceptions, found in the muscle-fibre of warm-blooded animals. Spore-formation commences early, and proceeds during the whole growth of the trophozoite, which may attain a very large size, when it is covered by two coats, the inner of which is prolonged internally through the parasite, dividing it into a series of chambers.

Remarks.– The Sarcosporidia, discovered by Miescher in 1843, are very common parasites, and in the form of *Sarcocystis tenella* may be seen by the practitioner in the tropics in meat sent as food to gaols and hospitals.

Two families are known: (1) *Sarcocystidæ*, (2) *Rhinosporidiidæ*.

1. Sarcocystidæ Poche, 1913.

Definition.—Sarcosporidia found in muscle fibres, and divided into chambers by septa.

Sarcocystis Lankester, 1882.

Synonym.—*Gastrocystis* Chatton, 1910.

Definition.—Sarcocystidæ with outer radially striated and inner homogeneous coat and poles of undifferentiated protoplasm.

Type Species.—*Sarcocystis miescheriana* Kuhn, 1865.

Though a common parasite, its life-history is by no means well known. The youngest form is the trophozoite described by Bertram, which lies in a muscle-fibre, and consists of cytoplasm united by a cuticle, and containing several mononuclear pansporoblasts. The next stage is more advanced, for in this the trophozoite has grown considerably, and now consists of two coats—an outer, radially striated, and an inner, homogeneous, which is prolonged externally into filaments and internally into a series of septa, marking out chambers, each of which contains one pansporoblast. Internal to this coat is a layer of cytoplasm forming the endoplasm of the parasite.

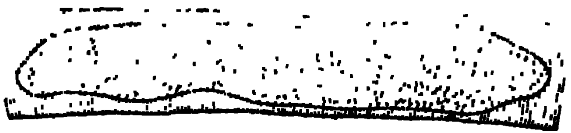

Fig. 187.—*Sarcocystis tenellæ bubali*: Young Form.

The poles of the parasite consist of undifferentiated endoplasm, and form the areas of growth of the young trophozoite. The pansporoblast breaks up into a large number of spores.

The third stage is reached when the parasite has grown so much that it has stretched the muscle-fibre, in which it is lying, into a thin sheath covering it, and therefore now appears to lie between the muscle-fibres. The endoplasmic layer extends all round the interior of the parasite, so that the pansporoblasts are formed from the whole periphery, and therefore the youngest forms are in this position, while, farther in, chambers with the fully-developed pansporoblasts are found, and, still farther in, is the centre of the parasite, filled by a granular substance formed from broken-down and dead spores which have been too long in existence.

As to the spores, a curious point to be noted is that some observers only describe gymnospores, while others only describe chlamydospores. Minchin suggests that this is because parasites in different stages of their life-history have been examined, and he looks upon the gymnospores as merozoites and the chlamydospores as spores, and these views are strongly supported by Korté's description of a form in *Macacus rhesus*.

The merozoites are crescent-shaped, naked spores, from 1 to 21 μ in length, according to the species, consisting of a finely granular protoplasm with a nucleus, some granules, and one or two vacuoles. They are thought to be the means by which the parasite spreads itself in its host, especially as they are motile by gliding, corkscrew, or amœboid movements.

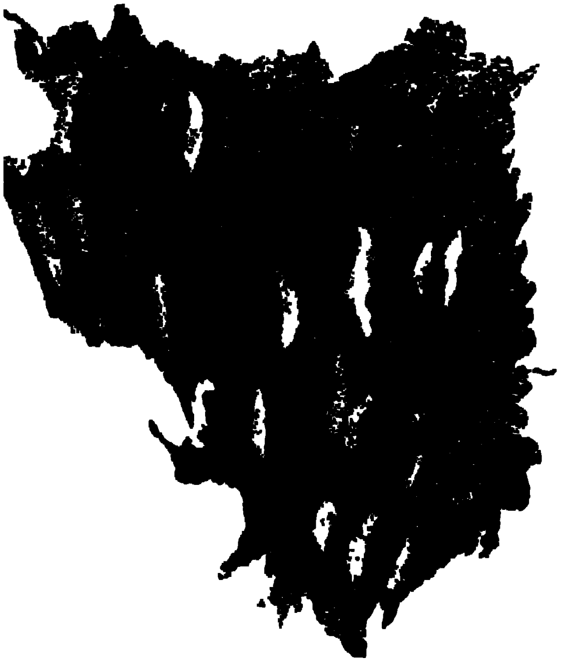

FIG. 188.—*Sarcocystis tenellæ bubali* IN MEAT.

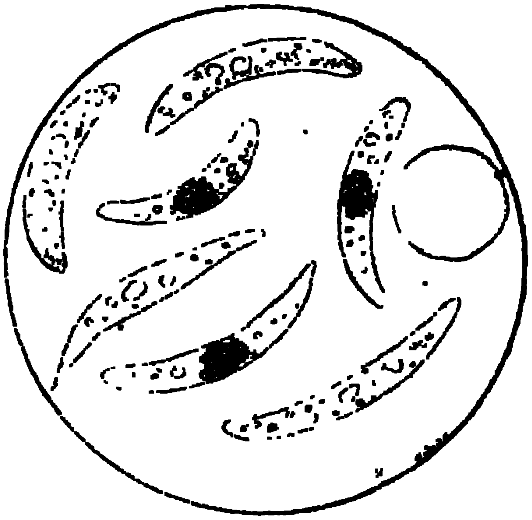

FIG. 189.—SARCOCYSTIS SPORES FOUND IN THE BLOOD OF *Bos indicus* BY CASTELLANI AND STURGESS.

The spores are from 3 to 14 μ long in *Sarcocystis tenella*, with one extremity rounded and the other pointed. They are curved, and surrounded by a thin membrane. The pointed third of the spore is spirally striated, due to fine folds in the outer capsule, while the blunt third contains a nucleus. It is obvious that this resembles the spore of a myxosporidian, and, in fact, Van Eecke says that one, two, or even three filaments issue from a spore. The spores can be seen in the peripheral blood at times.

It is thought that these spores spread the infection to another host, but in what manner is not clear. Perrin has recently suggested that the parasite may be transmitted by the larvæ and imagines of the blow-fly (Calliphora) or the flesh-fly (Sarcophaga).

It is true that Smith has infected (after a long incubation) mice by feeding them on the flesh of infected mice, but that, of course, might simply be by the merozoites, and would in any case not explain how herbivorous animals are infected. Our feeding experiments with a dog were not successful.

Erdmann says that the spore germinates in the intestine of the host, and liberating the toxin—sarcocystin—which may come from the polar capsule, causes the epithelium to be shed, while the little amœba coming out from the spore is able to penetrate the denuded area and to get into the lymph spaces of the intestine, where it lives about a month and then passes on to the muscles.

Crawley considers that the spore bores its way into the intestinal cells where it appears to undergo some form of schizogony. At all events it disappears in twenty-four hours, but later he thought that he had noted sexual differentiation in these spores in the cells, and the formation of a zygote.

Pathogenicity.—*Sarcocystis tenellæ bubali* is very common in the buffalo-meat in Ceylon, and frequently causes inquiries to be made. It appears as white particles, called by the native butchers 'milk nerves,' lying among the muscular fibres of tongue, larynx, diaphragm, and skeletal muscles. This ingestion of infected meat has apparently no deleterious effect on man, but the spores may be the cause of irregular fever.

Classification.—A number of species are recognized:—

1. *Sarcocystis miescheriana* Kühn 1865, found in the pig.

2. *S. bertrami* Doflein, 1901, in the horse.

3. *S. tenellæ* Railliet, 1886, in the sheep. *S. tenellæ bubali*, in the Ceylon buffalo. Vuillemin has described a case of this infection in man.

4. *S. blanchardi* Doflein, 1901, in cattle.

5. *S. lindemanni* Rivolta, 1878. This species has been found in man. They were first described indefinitely by Lindemann in 1868, in the myocardium and on the valves of the heart of a person who had died of dropsy. They were said to be 3 millimetres in length and 1·5 millimetres in breadth, but it is very doubtful what these really were.

Rosenberg in 1892, reports a most doubtful case of a cyst in a papillary muscle in a person who died from pleuritis and endocarditis. Kartulis described them in the muscular system and liver (most doubtful) of a person who died from multiple abscesses in the liver and muscles. The man was a Sudanese. Koch, in 1887, described an undoubted case in Egypt.

Baraban and St. Remy, in 1894, described them in the laryngeal muscles of a man who had been executed. This description is not to be doubted. The parasite is described as being 1·6 millimetres long, and about 0·17 millimetre in width. Vuillemin in Nancy and Darling (1909) in Barbados have recorded cases.

6. *S. hueti* Blanchard, 1885, in the seal.

7. *S. kortei* Castellani and Chalmers, 1909.—This parasite, found by Korté in the thigh muscles of *Macacus rhesus*, is peculiar in that the inner coat was not continued into the cytoplasm of the trophozoite, and the endoplasm contained only gymnospores (merozoites), and no pansporoblasts or alveolar network. The spores contained nothing but a nucleus, no cell membrane or other structure being visible. There were no signs of any reaction on the part of the tissues.

8. *S. aramidis* Splendore, 1907.—Parasite in *Aramidis saracura*, a Brazilian bird.

9. *S. ammodromi* Splendore, 1907.—*Miescheria ammodromi* Splendore, 1907. Mesnil says it is not generic, and perhaps not specific. It is found in a Brazilian bird, *Ammodromus manimbe*.

10. *S. leporum* Crawley, 1914, in American rabbits.

11. *S. setophaga* Crawley, 1914, in American redstarts.

12. *S. muris* Blanchard, in rats.

2. **Rhinosporidiidæ** Poche, 1913.

Definition.—Sarcosporidia found in connective tissue and not divided into chambers by septa.

Rhinosporidium Minchin and Fantham, 1905.

Definition.—Rhinosporidiidæ with well-defined sporoblast.
Type Species.—*Rhinosporidium seeberi* (Wernicke, 1900).

Rhinosporidium seeberi Wernicke, 1900.

Synonym.—*Rhinosporidium kinealyi* Minchin and Fantham, 1905.

Rhinosporidium was discovered in 1896 by Dr. Guillermo Seeber in Buenos Ayres in a nasal polypi in a young man of nineteen years of age. In 1900 he published a description of the parasite, and in the same year Wernicke gave it the name of *Coccidium seeberi*.

Kinealy, in 1903, reported to the Laryngological Society a peculiar case of polypus growing from the septum of the nose of an Indian in Calcutta as a pedunculated vascular growth resembling a raspberry in appearance by having whitish spots on the general red surface. On section, this tumour was found to have peculiar bodies embedded in it.

It was then carefully examined and described by Minchin and Fantham, who came to the conclusion that it was a haplosporidian, and named it *Rhinosporidium kinealyi*.

In 1905 Nair of Madras came across a similar polypus in several people who all came from the small native State of Cochin on the west coast of India. These polypi have been carefully described by Beattie in 1906. Castellani and Chalmers have found it in polypi in Ceylon.

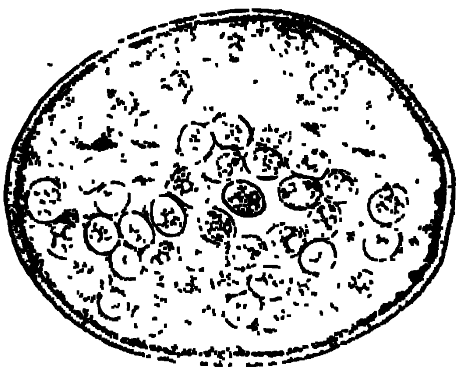

FIG. 190.—*Rhinosporidium seeberi* WERNICKE.
(From a nasal polypus in a case in Ceylon; schematic, and highly magnified.)

Morphology.—On cutting into the polypus it is noticed that there are minute dots visible to the naked eye, and capable of being dissected out. These dots are cysts.

When examined with the microscope, it is seen that the growth is covered by stratified pavement epithelium, which shows signs of proliferation and invasion by polymorphonuclear leucocytes. Under this epithelium there is a stroma formed of delicate fibrous tissue, myxomatous in places, and cellular at other spots. The cysts were found to be oval, round, tubular, branched or irregular bodies, lying below the epithelium principally, but also found in hæmorrhages and in cell collections. The wall of the cyst is generally thin, and has either an opening or a conical elevation at one point. It consists of two layers—a thinner external and thicker internal coat. The smaller cysts, from 10 to 30 μ in diameter, contained undifferentiated protoplasm with a vesicular nucleus containing a nucleolus. The larger cysts had one or more definite chromatic masses. A fully-developed cyst is lined with protoplasm, in which young pansporoblasts are forming, while the centre of the parasite is full of old pansporoblasts, separated from one another by an indefinite framework continuous with the capsule. A young pansporoblast is seen to be a small oval or rounded mass of cytoplasm with a single nucleus. This body grows, and becomes surrounded by a membrane, while its nucleus divides by amitosis into four to sixteen spores, each of which has a very thin wall and a central nucleus. The pansporoblasts and spores are set free by rupture of the cyst, and may be surrounded by polymorphonuclear leucocytes, thus forming minute abscesses, or may be engulfed by mononuclear leucocytes, or may grow into parasites, or escape from the host in the nasal secretion. The method of infection is not known.

The framework inside the cyst separating the pansporoblasts indicates that *Rhinosporidium* belongs to the Sarcosporidia, and not to the Haplosporidia.

Pathogenicity.—The pathology appears to be a proliferation of the submucosa and mucosa of the nose, brought about by the irritation of the parasite (see p. 1578).

ORDER IV. HAPLOSPORIDIA Caullery and Mesnil, 1899.

Synonym.—*Haplosporidiidea* Poche, 1913.

Neosporidia with very simple life-history and undifferentiated cell-plasma, without septum and with spores of simple structure, with one nucleus, and no polar capsules.

The Haplosporidia are characterized by the simplicity of their life-cycle, which begins with a mononuclear or binuclear trophozoite, which may encyst, and in any case grows larger and larger, while its nucleus divides into several nuclei, so that a multinucleated mass or schizont is formed. This escapes from its cyst and divides up into merozoites, either directly or after plasmotomy, each of which becomes a trophozoite, thus completing schizogony. Sporogony is unknown.

They are parasites of fishes and invertebrates.

Classification.—Family 1. Haplosporidiæ Caullery and Mesnil.—Spores with double envelope and opening.

Genus 1. *Haplosporidium.*—Spores closed by a valve. In annelids.
Genus 2. *Urosporidium.*—Spores open. In annelids.

Family 2. Bertramiidæ Spore envelope without opening.
Genus 1. *Bertramia.*- Stomach of fish.
Genus 2. *Ichthyosporidium.* In tumours of fish (Figs. 191-196).

Family 3. Cœlosporidiidæ.- Spores nude.
Genus 1. *Polagarynum.*
Genus 2. *Blastulidium.*

Protozoa Incertæ Sedis.

Cytoryctes variolæ Guarnieri, 1892.

Synonym.—*Strombodes jeuneri* Sjöbrung, 1902.

In 1892 Guarnieri described peculiar parasitic bodies in lesions of smallpox, and in those produced by vaccination of the cornea of rabbits, etc. Pfeiffer, in 1893, confirmed these findings, as did Jackson Clarke in 1894, and Wasielewski in 1897. Councilman, Magrath, and Calkins, in 1903, published the full account of the life-history of the parasite, and their findings have been confirmed—in part, at least—by De Korté in 1905.

In its youngest form *Cytoryctes variolæ* is seen in the cells of the skin as a minute spherical homogeneous body, 0·7 μ in size. No differentiation into nucleus and cytoplasm is possible, as the organism appears to be all nucleus. The parasite grows to 3 μ, and then shows a vacuolization in the centre, with sometimes a central dot. The periphery next shows minute unstained dots, which, when they become larger, take on the green of a Borrel's stain. The red staining material is called by Calkins protogonoplasm.

The organism can now change its shape and throw out pseudopodia, and lives in a vacuole near the nucleus; there is no ectoplasm or endoplasm, no vacuoles, but only chromatin granules of protogonoplasm. Volpino has described minute motile granules in the epithelial cells, which he considers to be the true parasites.

Auto-Infection.—In a large parasite to 14 μ) the protogonoplasm is distributed through the body in minute spherical granules lying in a minute vesicle, forming granules from 0·7 to 1 μ in diameter, which are liberated by disintegration of the framework of host cell, while the rest of the cytoplasm form a *nucleus de reliquat*.

Sexual Development.—The homogeneous granules or gemmules may start the cycle of cytoplasmic organisms again, or may become germ-cells in the nucleus. The gemmules reach the nucleus, but they now stain uniformly and become minute, clearly-defined, homogeneous bodies—female gametocytes. Sometimes they fail to reach the nucleus and remain in the cytoplasm, in which they can only partially develop. Within the nucleus Calkins thinks they form male and female gametocytes, homogeneous granules, or the gemmules become spherical, with central red masses, and later red masses at the periphery—the male gametes. No conjugation has been observed.

The zygote is an amœboid body lying in the nucleus, and staining deeply. This zygote becomes a pansporoblast and the mother-cell of the sporoblasts. The spore is very minute, and contains a vacuole; it migrates, and may travel into the nucleus and form secondary sporoblasts.

Cytoryctes (Doubtful Species).

This organism can be found as corroid bodies in the smears taken from the heart muscle of animals suffering from foot and mouth disease.

Neuroryctes hydrophobiæ Calkins, 1907. •

Neuroryctes hydrophobiæ, better known as the Negri bodies, because they were discovered by Negri in 1903 as round or oval bodies, 1 to 23 μ in length, in the nerve-cell of the brain, especially the *Cornu ammonis*, of animals suffering from hydrophobia, are now generally accepted as the cause of the disease. Hydrophobia is so common in India and Ceylon that a knowledge of its parasite is necessary to the practitioner in that part of the tropics.

Some authorities consider these bodies to be cell-structures, but in our opinion there cannot be any doubt that they are parasites, especially after the further investigation of Negri, amply confirmed by Williams, Lowden, and Calkins, who named it *Neuroryctes hydrophobiæ* Calkins, 1907. Prowazek believes them to be Chlamydozoa. When stained by Giemsa the protoplasm takes on a bluish tinge like the malarial organism, while there is a central

(From drawings by Miss Robertson.)

body like a nucleus, composed of a periphery of chromatin, and containing a central chromatic particle staining red. Negri, Williams, and Lowden give drawings indicating the rapid division and growth of the organism, which apparently as it grows divides, until finally large forms result whose chromatin breaks up into minute masses.

They consider that the parasite reaches the nervous system by spreading along the nerves, which it does more quickly than travelling by the blood

Cyclasterella scarlatinalis Mallory (**Doubtful Species**).

In 1904 Mallory described round and elongated bodies, sharply stained with methylene blue, 2 to 7 μ in size, lying in the epithelium of the epidermis, together with radiate bodies, composed of a central spherical body with ten to eighteen segments radiating away from it, in epithelial cells and lymph-spaces of the epidermis of people suffering from scarlet fever.

This discovery has since been confirmed by Field and Duval, both during life and in post-mortems.

Further research is needed before the nature of these bodies can be definitely settled.

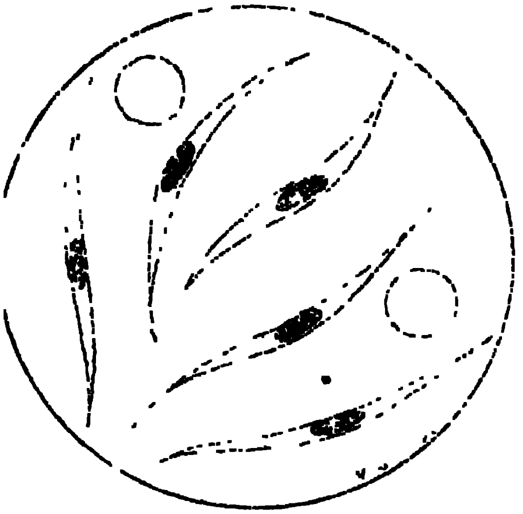

Fig. 197.—*Sergentella hominis* Brumpt.

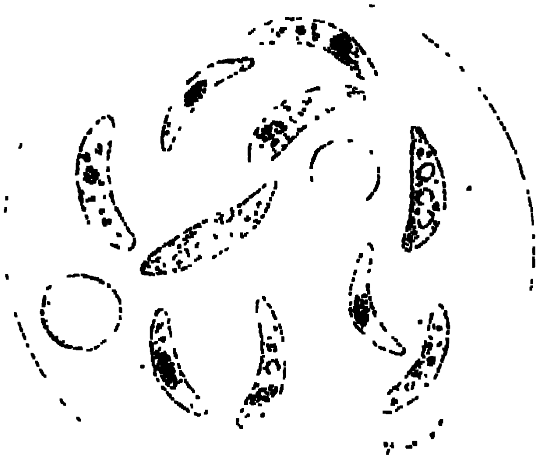

Fig. 198.—Sarcocystis Spores found in the Blood of Man by Castellani and Willey.

Coccidioides immitis Rixford and Gilchrist, 1897 (**A Fungus**).

Synonyms.—*C. pyogenes* Rixford and Gilchrist, 1897; *Coccidium posades* Caxton (?), 1898.

These parasites were first seen by Wernicke and Possadas in Buenos Ayres, and later in the United States by Rixford and Gilchrist, Montgomery, Moffit, and Ophuls, where they cause an infection producing nodules in the skin, liver, kidney, genitalia, and lymphatic glands.

This so-called protozoon is a fungus (see p. 985)

The Bodies of Ureteritis Cystica (**Doubtful**).

In this disease the kidney is hydronephritic and the ureter and bladder are cystic.

The cysts contain large and small oval and irregular cells with bright globules, variously interpreted as Coccidia, Myxosporidia, and cell inclusions.

Sergentella hominis Brumpt, 1910.

Et. and Ed. Sergent in 1903 reported a vermiform body, 40 μ long by 1 to 1·5 μ broad, pointed at each end, with a nucleus in the middle, in the blood of a person suffering from night-sweats and nausea.

Bodies found by Sambon in Pseudochirus peregrinus.

Sambon has found bodies in a lemur which may have some relationship to the spores of Sarcocystis, but this is doubtful.

Bodies described in Man by Castellani and Willey.

These bodies were found and described in 1905 in two patients suffering from irregular fever. They generally have a crescentic shape, 10 to 30 μ in length, and 1.5 to 4 μ in breadth. They often present vacuoles, and a nucleus may be seen in some specimens, but not in all. The whole body stains bluish, while here and there granules of chromatin can be seen. They cannot be compared with malarial crescents, as they never contain pigment. These bodies may be spores of Sarcocystis.

Protozoal Bodies found in Dysentery.

In 1914 Castellani described a peculiar protozoal organism (*Entoplasma Castellanii* Paul 1914) which he found in three cases of dysenteric colitis, in which amœbæ and dysenteric bacilli were absent. One of the cases had been infected in Burma, and the other two probably in Ceylon.

In fresh preparations the organisms appeared as large pear-shaped or flask-shaped bodies, 60-80 microns in diameter, actively motile, and showing only slight changes of shape while moving, and no pseudopodia.

The anterior portion at its upper part was shaken by very rapid vibratile movements, as though produced by a flagellum. No such organella could be seen in fresh or stained preparations by Castellani or any other observer. The cytoplasm was very vacuolated. In stained preparations a group of granular bodies could be seen and were thought by Mesnil to be a diffuse nucleus.

FIG. 199. —*Entoplasma Castellanii* PAUL, 1914.

Chlamydozoa Prowazek, 1907.

Definition.—The Chlamydozoa are a collective group of minute parasites, which either live extracellularly, when they are capable of passing through the usual filters, or intracellularly, when they excite a reaction upon the part of the enclosing cell which produces a substance which encloses them as it were with a mantle, thus forming a cell inclusion.

Remarks.—This collective group was formed by Prowazek to embrace a number of minute parasitic forms which become enclosed in a cellular product as with a mantle. The general tendency is to range these forms among the Protozoa. The minute granules are the parasites, and the surrounding substance is either plastin or chromatin from the nucleus, or a fatty substance. The name Chlamydozoa is derived from the Greek ζῷον, an animal, and χλαμύς, a mantle. At the present time doubt is expressed as to causal action of the Chlamydozoa as well as to their parasitic nature.

History.—In 1907 Prowazek and Halberstaedter, on examining trachoma smears stained by Giemsa's method, found dark blue granular inclusions in the protoplasm of the epithelial cells. These granules were at first round or oval, and increased in size, at the same time becoming less dark, while minute red dots appeared, which increased rapidly in numbers, while the blue masses gradually disappeared. The granules formed *cell inclusions*, and the blue masses were considered to be a reaction product on the part of the cell, and were thought to be composed of plastin, while the minute red dots were considered to be the virus. The reason why they considered the blue granules to be distinct from the red points was because the blue gradually disappeared, while the red points, or *elementary bodies*, could be seen extracellularly situated. They inoculated anthropoid apes successfully with trachoma, and found the same bodies in this infection. These researches were confirmed by Greef in the same year, and were extended in 1908 by Stargardt and Schmeichler in 1909, who described a conjunctivitis neonatorum non-gonorrhoica with typical Chlamydozoa. In 1909 Heymann found the same bodies in four cases of gonorrhœal conjunctivitis in newly-born infants. This discovery was of the greatest importance, because since the days of Kroner it had been known that the conjunctivitis of the new-born was not always due to the gonococcus. Linder, in 1909, and Wolfrum, in 1910, showed that there were two forms of blennorrhœa--viz., a conjunctivitis neonatorum caused by the gonococcus, and a second caused by Chlamydozoa, this latter disease being termed by Linder 'inclusion-blennorrhœa' in contradistinction to gonoblennorrhœa. Linder maintains that the same virus produced trachoma, inclusion-blennorrhœa, and that this virus can be found in the male and female genital passages, and he bases his opinion on the facts that he has been able to produce trachoma in monkeys inoculated from a case of non-gonorrhœal urethritis in a man, from two such cases in women, and from several cases of inclusion-blennorrhœa in infants. Further investigations have shown that inclusion-blennorrhœa is histologically similar to trachoma.

Later, Leber and Prowazek in 1911 found a similar organism, *Lyozoon atrophicans* in epitheliosis desquamativa, and in the same year Uhlenhuth found inclusions in swine pest, and Botteri in spring catarrh.

In the meanwhile Halberstaedter and Prowazek had in their first paper grouped with these cell inclusions the forms described in smallpox, hydrophobia, molluscum contagiosum, epithelioma contagiosum, and Lipschütz grouped the causes of dermotropismus, or human dermatoses, under the subhead Strongyloplasmata. Finally the whole subject was gathered together and reviewed by Prowazek in 1911 in his 'Handbuch der Pathogenen Protozoen.' Somewhat similar bodies have been seen by Castellani in sprue in cells from the oral mucosa, although most of these inclusions are non-granular, and he doubts their parasitic nature. He has observed somewhat similar bodies in conjunctivitis and in urethritis of a non-gonorrhœal nature.

Morphology.—On examining the cells from a case of urethral discharge of non-gonorrhœal origin, or the cells from the discharge in certain forms of conjunctivitis, they can be seen to contain peculiar masses of granules which are grouped into oval or roundish bodies, measuring 2 to 6 μ in transverse or maximum diameter. The individual granules measure 0·5 to 1 μ in diameter, and stain a purplish-red colour with Giemsa or Leishman's preparations. These granules appear to be embedded in a pale bluish matrix.

Life-History.—The smallest form or *elementary body* is merely a minute speck of chromatin, apparently without any cytoplasm, which lives extracellularly, but may enter a cell. This entry into the cell is not a process of phagocytosis, as may be shown by the absence of the usual vacuole, and by the fact that they do not show the usual yellow coloration when stained by neutral red. Inside the cell the elementary body grows in size, and becomes the *initial body*, which becomes surrounded by the mantle, and thus forms the *cell inclusion*. This body now breaks up into a number of small bodies called *initial corpuscles*, which divide by simple division—*i.e.*, by the formation of dumb-bell forms, the two ends of which simply move apart until the connecting thread is broken. The result of the division of the initial corpuscles is the *elementary body*. In this way the life-cycle is completed.

Comparison.—It will thus be seen that the Chlamydozoa are the granules inside the body of the *Cytoryctes variolæ* or the *Neuroryctes hydrophobiæ*, and that the whole organism of these two forms corresponds to the mantle and parasite of the chlamydozoon.

Pathogenicity.—They are believed to be the cause of smallpox, vaccinia, trachoma, Samoan epitheliosis, hydrophobia, scarlet fever, etc.

Classification.—The Chlamydozoa are classified into:—

A. *Chlamydozoa vera.*

Chlamydozoa, which commences as elementary bodies from cell inclusions.

1. Cytoryctes group—cause destruction of the cell.
2. Cytooikon group—cause proliferation of the cell.
3. Gelbsucht group—cause gelbsucht in the Lepidoptera.

B. *Chlamydozoa strongyloplasmata.*

Chlamydozoa, which always remain as elementary bodies—*e.g.*, the forms in the peripneumonia of cattle and the diphtheria in birds.

Only the Cytoryctes and Cytooikon groups concern us.

The Cytoryctes Group.

It is important to distinguish between the Chlamydozoon of such a disease as smallpox and the parasite *Cytoryctes variolæ*. The Chlamydozoon is one of the chromatic particles of *C. variolæ*, the protoplasm of which forms the mantle. The Cytoryctes group includes the parasites of:—

1. Vaccinia.
2. Variola.
3. Scarlet fever.
4. Hydrophobia.

The Cytooikon Group.

The Cytooikon group includes:—

1 *Lyozoon atrophicans* Leber and Prowazek.
2. Trachoma bodies.

The former group have been described above, and the latter group will be dealt with in the chapter dealing with the diseases of the special senses.

The Filterable Viruses.

By the term 'filterable virus' is meant micro-organisms so small that they will pass through the pores of filters which are too small to allow the passage of bacteria. The term 'ultramicroscopic' is also used for filterable viruses, but is not free from objection.

History.—In 1892 Iwanowski demonstrated the filterability of the mosaic disease of the tobacco plant, and in 1898 Löffler and Frosch discovered that the virus of foot and mouth disease would pass through the pores of the finest porcelain filter. Shortly afterwards Beijerinck confirmed Iwanowski's observations, and since then numerous observations have been made.

IN MAN.—*Yellow fever* virus by Reed and Carroll in 1901, destroyed it heated to 53° C. for ten minutes; *Molluscum contagiosum*, by Julius Véry in 1905; *Dengue fever* by Ashburn and Craig in 1907; *Three days' fever* by Doerr in 1908; *Poliomyelitis* by Lentz, Landsteiner, Levaditi, Flexner, and Lewis in 1909; *Typhus* by Nicolle in 1910; *Measles* by Goldberger and Anderson in 1911, as well as *Trachoma*, *Scarlatina*, *Verruca vulgaris*, and, according to Nicolle, *Influenza*.

ANIMALS AND MAN.—*Foot and Mouth Disease* by Löffler and Frosch in 1898; *Vaccinia* by Siegel in 1905, *Variola* and *Rabies*.

Besides these filterable viruses others have been found in diseases of birds and one in plants.

Cultivation.—The virus of pleuro-pneumonia of cattle, of fowl pest, fowl diphtheria, epithelioma contagiosum, and of Novy's rat disease have been cultivated. The organism of pleuro-pneumonia is a very small spirochæte, but the organisms of the other disease are only evident by the fact of their infectivity in subcultures carried beyond any reasonable limit of dilution from the original.

Immunity.—In nearly every case the immunity produced by a filterable virus is complete and of long duration.

Secondary Infections.—Secondary infections with bacteria are common, and it is thought that many of the so-called typical symptoms of the disease may be due to the secondary agent.

Methods of Infection.—The methods of infection are various: (1) By blood-sucking insects—*e.g.*, *Stegomyia calopus* and yellow fever, etc.; (2) by entry through an abrasion—*e.g.*, *Molluscum contagiosum ;* (3) by contact—*e.g.*, fowl pest; (4) by unknown methods —*e.g.*, Novy's rat disease.

Nature.—The nature of the viruses is unknown; some, especially those spread by blood-sucking agents, are probably protozoal, but others may be bacterial.

Classification.—The filterable viruses may be divided into—

1. Filterable viruses associated with no known organism.
2. Filterable viruses associated with some known organism.

1. *Filterable Viruses associated with No Known Organism.*

Under this heading come the viruses of several diseases of importance in tropical medicine—*e.g.*, the virus of yellow fever, of dengue fever, of pappataci fever, of typhus fever.

Yellow Fever.—The virus is found in the blood only during the first three days of the fever. It can pass through Berkefeld and Chamberland B filters, and can be destroyed by heating to 55° C. for ten minutes, or by a temperature of 24° to 30° C. for forty-eight hours. It is conveyed by *Stegomyia calopus* after an interval of twelve days from the time of the infective feed.

Dengue Fever.—The virus is in the blood during the fever, and can be filtered through Berkefeld filters impermeable to *Micrococcus melitensis*. It is spread by *Culex fatigans*.

Pappataci Fever. The virus exists in the blood during the first day of the fever, and can be filtered through Berkefeld filters, and is spread by *Phlebotomus papatasii* after an interval of seven days from the date of the infective feed.

Typhus Fever.—The virus exists in the blood, and can be filtered through *the coarser* Berkefeld filters. It is destroyed by a temperature of 52° to 55° C.; it is spread by *Pediculus vestimentorum* L.

Verruga Peruviana.—The experiments of Strong, Tyzzer, Brues, Sellards, and Gastiaburu tend to show that the virus of this disease is a filterable virus, and distinct from that of Oroya fever. It appears to be similar in many respects to the virus of smallpox. It can be inoculated successfully into monkeys, but only a modified form of the disease appears, the lesions regressing in four to five weeks (analogy with inoculated smallpox). It has also been transmitted to rabbits and dogs. It has not yet been demonstrated that *Phlebotomus verrucarium* or any other insect does transmit the disease, but it is believed that some arthropod is the carrier.

2. *Filterable Viruses associated with Some Known Organism.*

Borrel has clearly shown that a minute flagellated organism (*Micromonas mesnili*) exists in the filtrates of sheep-pox, and it is quite possible that all filtrates contain these minute organisms, and, further, there is reason to suppose that certain larger organisms possess these minute forms in some stage of their life-cycle—*e.g.*, the organisms of trachoma, variola, and vaccinia.

Bradford, Bashford and Wilson have described minute bodies which they state to have cultivated, using Noguchi's method, from cases of acute infective polyneuritis, influenza, trench fever, typhus, and other conditions.

Trachoma.—The virus passes through the Berkefeld filters, and can be successfully inoculated into monkeys.

Variola and Vaccinia.—The virus passes through Berkefeld and *the coarser* Chamberland filters, and is destroyed by heating to 57° to 58° C. in fifteen minutes, or by almost any disinfectant, by saponin, vicin, bile, taurocholic acid, and sodium oleate.

CHAPTER XXIII

HETEROKARYOTA

Preliminary—Heterokaryota—Ciliata—Balantidium—Nyctotherus—References.

DIVISION B. HETEROKARYOTA Hickson, 1903.

PHYLUM V. CILIATA Perty, 1852.

The Ciliata are free-living or parasitic Heterokaryota, found principally in water, where they exist upon small animal and vegetal organisms and the débris of decomposing plants and animals. Some of them can live in the alimentary canal of man and animals, obtaining their food from its contents, and increasing to such numbers as to cause irritation of the intestine.

Their movement is by cilia, but always with one end, the anterior, in front. They turn round when desiring to progress in a different direction. This anterior end may be similar morphologically to the posterior, or may be characterized by being more pointed, by having a mouth, or by peculiar sensory cilia (Hypotricha), or by a peristome of long cilia (Heterotricha). The body, which may be spherical or flattened, is divided into an ectoplasm (the cortex) and endoplasm (the medulla). The ectoplasm may simply be a clear outer layer of the protoplasm, or it may be differentiated into three layers. The first is very thick and very tough; the next, called the alveolar sheath, is marked by vertical parallel lines, which are the contractile myoneme threads; while the innermost layer next to the endoplasm consists of clear transparent ectoplasm.

The semifluid endoplasm is in constant rotatory motion, containing food vacuoles, contractile vacuoles, nuclei, pigment granules, colourless granules, crystalline bodies, and smaller particles. The cytostome or mouth is present in all except the parasitic Opalinæ. It is a slit in the cortex at the anterior end of the body, which can be opened for the reception of food, but is usually kept closed. It may be on the surface or may be carried inwards by a funnel-shaped depression in the ectoplasm called the vestibule, which may be lined by cilia specialized for the capture of food.

A cytopyge, or cell anus, occurs in *Nyctotherus*, but as a rule no definite opening appears, and the undigested food is simply pushed through the cortex.

Two wholly distinct nuclei exist in the Heterokaryota, a mega- or macro-nucleus and a micronucleus. They are not merely different in size, form, structure, and appearance, but also in function; for the macronucleus is somatic and trophic in its function, while the micronucleus is purely sexual. They are not comparable to the tropho- and kineto-nuclei of the trypanosomes.

The macronucleus is generally well marked, but breaks down into granules before or after conjugation. It consists of an achromatic portion, with a chromatic portion in the form of a close-meshed network of fibrils, but whether there is a definite surrounding membrane or not is doubtful.

The micronucleus, when at rest, is a minute irregular granule of chromatin lying in the centre of a perfectly clear achromatic area. Probably there is only one in each animal, and the appearance of two or more is due to reproductive phases which are just finishing.

The Ciliata are characterized by the presence of protoplasmic processes projecting all over the body. These are fine, short whips, called cilia, which in places are transformed into thick processes called cirri or flat membranes in certain species. The cilia are processes of the pellicle, but they appear to be supported by a thread of specialized ectoplasm. The short, fine cilia are for motion, and the long, motionless cirri for the purpose of entangling food-particles. The membranes are supposed to be formed of fused cilia. Trichocysts exist in the Holotricha, and an excretory organ has recently been described by Metcalfe in certain species of Opalina, parasitic in frogs, while other Ciliata have a contractile vacuole.

Reproduction may take place asexually by (1) transverse or longitudinal division; (2) gemmation, simple or multiple, (3) encystment and spore-formation, or sexually by conjugation.

1. **Fission.**- There is no morphological distinction between longitudinal and transverse fission, in which the following changes take place: (1) A second mouth is formed; then comes (2) enlargement and division of the micronucleus, followed by (3) enlargement and division of the macronucleus; and, finally, (4) division of the cytoplasm.

2. **Encystment and Spore-Formation.**- The animal encysts and breaks up into a number of small individuals.

3. **Conjugation.**- Conjugation has been best described by Calkins and Caullery in *Paramæcium aurelia*. Two conjugating cells about the same size are placed so that the mouths are directly opposed The micronucleus swells, its chromatin becomes granular, elongated, crescentic, fusiform, and finally forms two nuclei, each of which at once divides into two. Of these, two degenerate, while the other two divide to form a migratory, or male, and a stationary, or female, pronucleus. The male interchange and fuse with the opposite female nuclei, and then the organisms separate. The macronucleus fragments and disappears, and the synkaryon breaks up into eight micronuclei.

Four of these swell, and are changed into macronuclei; so that four micro- and four macro-nuclei are in the same cell, which divides into two very small cells with two macro- and micro-nuclei each. These cells grow to nearly full size, and then divide, giving rise to the typical protozoon, with one macronucleus and one micronucleus.

Parasitism.—A great many species of the Ciliata are parasitic in the intestine or bladder of other animals, and some are epizoic.

The latter will often be met with as *Vorticellæ*, living on *Anopheles* and *Culex* larvæ. The former are found largely in the Orthoptera, the Amphibia, and in herbivorous mammals—*e.g.*, horse and cow.

In man a few have been recorded: *Chilodon dentatus* Dujardin, 1842; *C. uncinatus*, *Colpoda cucullus* Schutz, 1889; *Balantidium coli* Malmsten, 1857; *B. minutum* Jakobi and Schaudinn, 1898; *Nyctotherus faba* Jakobi and Schaudinn, 1898; *N. giganteus* Krause, 1906; *N. africanus* Castellani, 1905.

Parasitism does not appear to affect the structure of the animal, unless the loss of the cytostome in Opalina, parasitic in frogs, is considered to be due to this cause.

Pathogenicity.—The ciliate parasites, as a rule, appear to cause but little effect, unless they are present in large numbers, when diarrhœa, often severe and long-persisting, may result.

Classification.—The Ciliata are classified into four orders:—

Order I. Holotricha Stein, 1859.—Mobile Ciliata without special oral cirri (*Chilodon*, *Colpoda*).

Order II. Heterotricha Stein, 1859.—Mobile Ciliata with special oral cirri (*Balantidium*, *Nyctotherus*).

Order III. Hypotricha Stein, 1859.—Mobile Ciliata with well-developed dorsal and ventral surfaces. Not known to be parasitic in man.

Order IV. Peritricha Stein, 1859.—Fixed Ciliata. Not known to be parasitic in man.

ORDER I. HOLOTRICHA Stein, 1859.

Definition.—The Holotricha are free-moving Ciliata, in which all the cilia are of approximately equal length and thickness, and never possessing cirri.

Remarks.—It is divided into two suborders:—

Suborder 1, *Gymnostomata*.—Mouth closed when ingesting food.

Suborder 2, *Hymenostomata*.—Mouth always open, and provided with an undulating membrane.

SUBORDER GYMNOSTOMATA Butschli 1889

Family Chlamydodontidæ Stein.—In this family there is a genus *Chilodon* Ehrenberg, 1833, which includes oval, strongly dorso-ventrally compressed Chlamydodontidæ, commonly found in infusions, of which one species, *C. dentatus* Dujardin, 1842, was found in great abundance by Guiart in the motions of a woman suffering from severe dysentery in Paris. Manson and Sambon have described a case of chance-parasitism due to another species, *C. uncinatus* Blochmann, in a patient from tropical South Africa.

They noted that the parasites were only found in the mucus, never in the fæcal masses. They were present in very large numbers, and were found to be all gametes, some of which were conjugating. It appears probable that Guiart's parasites may really have been *C. uncinatus*, and not *C. dentatus*.

SUBORDER HYMENOSTOMATA Hickson, 1903.

FAMILY CHILIFERIDÆ Bütschli.—The genus *Colpoda* Müller, 1773, includes the kidney-shaped Chilifera, with rows of cilia twisted from left to right, commonly found in hay infusions, of which one species, *Colpoda cucullus* Schutz, 1899, commonly found in the water of marshes, was noticed in a brickmaker attacked with dysentery in Berlin. *Uronema caudatum* Dujardin, 1841, has been found in the motions of cases of diarrhœa in man.

ORDER II. HETEROTRICHA Stein, 1859.

The Heterotricha are free-moving Ciliata, with strong cirri or membranellæ, forming an adoral ring enclosing a space, the peristome, at one part of which the mouth opens. The order is divided into Polytricha, Oligotricha.

Polytricha Hickson, 1903.—Heterotricha in which the surface of the body is covered with rows of short cilia.

FAMILIES.—*Plagiostominidæ* Claparède and Lachmann, *Bursarinidæ* Bütschli, *Stentorinidæ* Stein, *Gyrocorynæ* Stein.

y BURSARIDÆ Kent, 1880.

Synonym.—*Bursarinidæ* Butschli.
This family includes the genus *Balantidium*.

Genus Balantidium Claparède and Lachmann, 1858.

Definition.—*Bursarinidæ* with a large peristome and a well-marked anal aperture.

Remarks.—Balantidium is common in the rectum of pigs, and is sometimes found in the intestines of man. Cyst 80-100 μ in diameter.

Balantidium coli Malmsten, 1857.

Synonyms.—*Paramæcium coli* Malmsten, 1857; *Plagiostoma coli* Claparède and Lachmann, 1858; *Leucophrys coli* Stein, 1860; *Balantidium coli* Stein, 1867; *Holophrya coli* Leuckart, 1863.

Balantidium coli is constantly found in pigs, and has been found in the colon and the dejecta of man in cases of cholera and diarrhœa.

In shape it is oval, slightly pointed anteriorly, but this depends upon whether the peristome is funnel-shaped or contracted. It is covered with cilia arranged in parallel rows, which give it a striated appearance.

It is 0·06 to 0·1 millimetre in length by 0·05 to 0·07 millimetre in breadth, and possesses a bean- or kidney-shaped macronucleus, and a globular micronucleus situated near it. It develops asexually by transverse division or by conjugation. It can encyst, and in this condition pass from pigs to man. *B. coli* lives in the rectum of pigs, and is transferred by its cysts to man.

It was discovered by Malmsten in a man who had had cholera, and was suffering from diarrhœa and ulcer of the rectum The ulcer had nothing to do with the disease, as it healed, while the diarrhœa was probably due to the parasites.

Casagrandi and Barbagallo produced catarrhal enterocolitis in young cats by means of this parasite.

Strong has investigated, in a masterly manner, the enterocolitis produced by *B. coli* in the Philippine Islands.

Balantidium minutum Schaudinn, 1899.

The body is shortly oval, with a pointed anterior extremity. Length, 20 to 32 μ; breadth, 14 to 20 μ.

The peristome extends into the centre of the body, and has the right lateral border fringed with cilia, and the left lateral border terminates in a hyaline membrane which can pass over to the right side, and has a row of cirri. The cysts are oval.

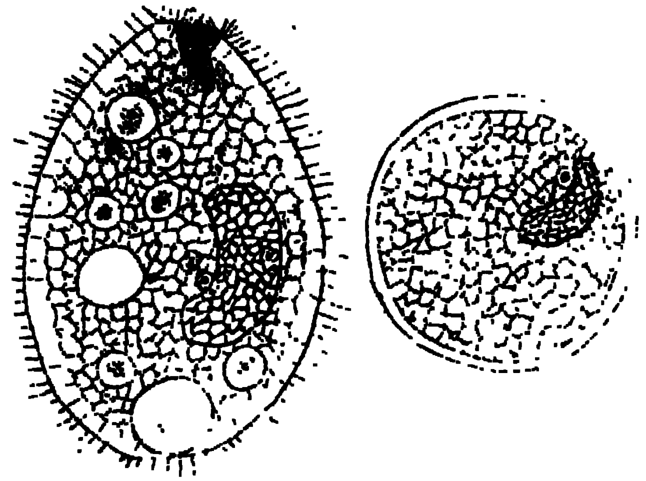

Fig. 200.—*Balantidium coli* Malmsten.

(After Hartmann. From the *Archiv für Schiffs- u. Tropenhygiene.*)

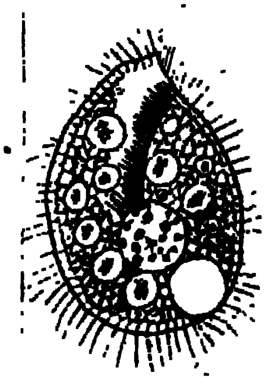

Fig. 201.—*Balantidium minutum* Schaudinn.

(After Hartmann. From the *Archiv für Schiffs- u. Tropenhygiene.*)

This parasite (along with *Nyctotherus faba*) was found by Schaudinn in a German who had often stayed in North America. The symptoms were constipation alternating with diarrhœa associated with abdominal pain.

Balantidium minutum var. **italicum** Sangiorgi and Ugdulena, 1917.

This parasite, which was found by Sangiorgi and Ugdulena in human fæces, differs from *B. minutum* in that the nucleus is excentric, and in the peculiar orientation of the micronucleus.

Genus Nyctotherus Leidy, 1849.

Definition.—Body bean- or kidney-shaped, with a large peristome on the concave side extending from the anterior end up to the middle of the body, from where a curved cytopharynx or œsophagus extends inwards. The macronucleus is large, and situated almost in the centre.

Remarks.—The species are mostly parasitic in the intestine of Amphibia, Insecta, and Myriapoda.

Species known in man: *Nyctotherus faba* Schaudinn, 1899; *N. giganteus* Krause, 1906; *N. africanus* Castellani, 1905.

Nyctotherus faba Schaudinn, 1899.

N. faba is flattened dorso-ventrally, and is 26 to 28 μ in length, and 16 to 18 μ in breadth, and 12 μ in thickness. The cilia on the peristome are of two kinds, those on the right side, of the size of the body, being true cilia, and those on the left side being cirri.

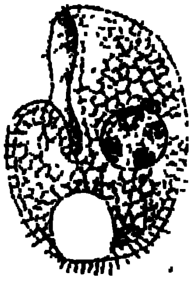

Fig. 202.—*Nyctotherus faba* Schaudinn.

(After Hartmann. From the *Archiv für Schiffs- u. Tropenhygiene.*)

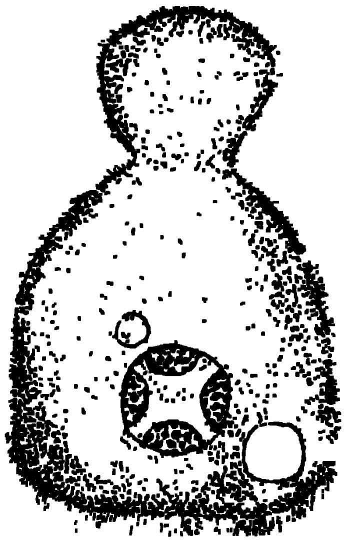

Fig. 203.—*Nyctotherus africanus* Castellani

The contractile vacuole is large, and situated posteriorly. The macro-nucleus is in the centre, and is peculiar in having four or five large collections of chromatin at its periphery. The micronucleus lies close by. The cysts are oval.

This species was discovered by Schaudinn in the same patient as *Balantidium minutum*.

Nyctotherus giganteus P. Krause, 1906.

Synonym.—*Balantidium giganteum* P. Krause, 1906.

This organism, along with *Trichomonas intestinalis*, was found by Krause in the dejecta of persons suffering from typhoid in Breslau.

It is shaped like a truncated cone, with the anterior end narrowed, and the posterior broad. Length, 90 to 400 μ; breadth, 60 to 150 μ. Surface covered with cilia. The peristome is situated laterally, and from it a cytopharynx leads inwards.

The macronucleus is large and bean-shaped, while the micronucleus is small and round. One or two vacuoles can be seen. The cytopyge is situated posteriorly.

In the fæces the parasite becomes rounded off and encysted, and then divides into four.

Nyctotherus africanus Castellani, 1905.

Found by Castellani in a Baganda native. *N. africanus* is hourglass shaped, with the anterior portion much less developed than the posterior. Length, 40 to 50 μ; breadth, 30 to 40 μ. The surface is covered with very minute cilia, which are generally more evident on the posterior portion, being almost invisible on the anterior.

The peristome is short. The cytoplasm is finely granular throughout. The nucleus is situate far posteriorly, near the contractile vacuole. The micronucleus is very small, and situated close to the macronucleus. No food vacuoles are to be seen.

Neither division, conjugation, nor encystment are known.

The patient, who had diarrhœa alternately with long periods of constipation, was suffering from sleeping sickness.

The cæcum contained many parasites, as did other parts of the bowel. The mucosa of the cæcum, colon, and rectum were slightly congested, but not ulcerated. Castellani originally considered this parasite to belong to the genus *Nyctotherus*, but more complete investigations will probably show that it constitutes a new genus.

SUBORDER HYMENOSTOMATA Butschli, 1889.

Genus Uronema Dujardin 1841.

Definition. Hymenostomata ovate or elongate with one or more caudal setæ.

Type Species. - *Uronema marinum* Dujardin, 1841

Uronema caudatum.

Found in a case of diarrhœa.

CHAPTER XXIV

TREMATODA

Metazoan parasites—Platyhelmia—Trematoda—Classification—Malacotylea—Digenea—Prosostomata—Paramphistomoidea—Fascioloidea—Schistosomidae—References.

SUBKINGDOM II. METAZOA.

Definition.—Metazoa are free-living or parasitic, multicellular animals, characterized by a physiological division of labour among their cells.

Remarks. Tropical medicine is only concerned with parasitic Metazoa, and chiefly with those which affect man. Parasitic Metazoa may be ectoparasites—as, for example, many species of the Insecta—or endoparasites—as, for example, many worms. The ectoparasites can cause disease by introducing toxins, protozoa, or bacteria into the tissues, and in this way they are of the utmost importance as the spreaders of disease, for, as is generally recognized, a disease is very often limited by the special œcological conditions of the animal which spreads its germ. Many of the ectoparasites, such as mosquitoes, are temporary, or, like ticks, periodic; while others, like lice, are permanent parasites.

With regard to the endoparasites, their ill effects on the host depend upon many factors which have been recently studied in considerable detail.

The effects of metazoan parasites on their hosts depend upon the species of the parasites, their condition, the number present, their presence in certain organs, bacterial infection, their migration in the body, the loss to the host in feeding them, the damage caused by their toxins and the condition of the host.

1. The Species of Parasite.—*Filaria* may exist in a host without apparent ill effect, but *Ankylostoma* will produce anaemia, œdema, and perhaps death.

2. The Condition of the Parasite. The dead eggs of *Filaria* are believed to block the lymph channels, and give rise to swelling and rupture of these vessels, thus bringing about lymphangitis and elephantiasis, while the living larvæ apparently do no harm.

3. The Number of Parasites.—A few Ascarides may cause no symptoms, while a large number may lead to serious disease.

4. The Organ Affected.—Ascarides in the alimentary canal are not nearly so virulent as in the liver, while *Paragonimus ringeri* in the lungs will cause a disease somewhat resembling phthisis.

Ascarides may cause serious mischief in the pancreas, as observed by Chalmers; and may cause appendicitis, as noted by Blanchard, Metchnikoff, Castellani, and others.

5. Bacterial Infection caused by the Parasite.—*Trichuris trichiura* may be a harmless parasite in itself, but it is quite capable of introducing bacteria into the mucosa of the vermiform appendix and causing appendicitis, for, as is well known, it burrows in the mucosa. The fever so often found in patients suffering from ankylostomiasis is probably caused by intestinal bacteria entering the small wound produced by the ancylostome.

This method of producing ill effects upon the host appears to us to be of the greatest importance in the tropics, and is, we fear, often overlooked.

6. Migration of the Parasite in the Body.—The larvæ of *Ancylostoma* as they enter the skin cause a dermatitis known as Cooly itch, sore feet, ground itch, etc., which may be primarily due to the irritation of the worm, or secondarily to bacteria introduced into the skin by its agency. The wanderings of the larvæ of *Trichinella spiralis* through the muscles cause the severe symptoms of trichiniasis.

Sambon has pointed out that much that is obscure in the pathogenesis of various forms of helminthiasis might be elucidated by a better knowledge of the migrations of the entozoa in their immature stages from the time they attack the host to that of their settlement in their selective anatomical habitat. He believes that many forms do not go directly to the part in which they are usually found, but may take a very different route from that generally accepted, and may even live for a length of time in other structures before reaching such organs as the alimentary canal or nasal fossæ, which are only sought in order to enable the young to escape from the host. During these wanderings mechanical injury may be caused to the host, and pathogenic micro-organisms may be carried from one part of the body to another.

7. The Absorption of Food.—Leuckart estimates that a *Dibothriocephalus latus* gives off in a year proglottides to the weight of 140 grammes; *Tænia saginata*, 550 grammes; and *Ascaris lumbricoides*, 42 grammes of eggs in the same period.

If the number of these parasites is great, the drain on the host must be considerable, especially in children who need food for growth.

8. Toxins.—This subject has already been dealt with (p. 205).

9. The Condition of the Host.—The condition of the host is also a factor in the diseases produced by these parasites, for though Ascarides may be harmless in a healthy intestine, they may perforate a typhoid or dysenteric ulcer, or a traumatic lesion of the bowel, and cause fatal peritonitis.

With regard to the question as to whether parasites ever benefit human beings, reference can be made to the belief that the development of the *Bacillus tuberculosis* Koch is delayed by the presence of entozoa in the bowels, a view which, with our Eastern experience, we are unable to support.

The old idea that worms were good for children has died out long ago, and we know of no cases of mutualism, or benefit to parasite and host, in the animal parasites of man.

True parasitism is found in those cases in which the parasite benefits and the host is injured. Chance parasites are animals which accidentally and temporarily become parasites.

The life-history of a parasite may be simple, being carried out in one host, or it may be complex, with one or more hosts for its larval stages and another for its adult condition.

Generally these hosts bear a direct relationship to one another, the intermediary host often being herbivorous, and thus becoming infected through eating fæcally contaminated food, and the definitive host being carnivorous or omnivorous, becoming infected through eating the herbivorous host of the larva.

Some parasites, particularly the Microfilariæ in the blood, show a remarkable periodicity in their habits, which appears to be associated with the means of escape from the definitive host by some intermediary host, such as a mosquito or a tick, whose habits agree with the periodicity of the parasite. Such correlations are very numerous in Nature—as, for example, the opening, or emitting of strong odours, by certain flowers at definite times of the day or night, which accords with the habits of insects which help on their fertilization.

Tropical countries are the home *par excellence* for parasites, as the means of infection by bad sanitation, biting flies, etc., are easily available. It is therefore obvious that, as there may be many methods of infection by the mouth, the skin, and the nose, prevention is not an easy matter. It depends upon two factors—personal and public hygiene. The question of personal hygiene is the more important and more easily applied, as only one person is concerned, while that of public hygiene is more expensive and not so easy to apply, as many people have to act in unison in order to produce any effect.

Personal hygiene includes such matters as personal and domestic cleanliness; protection of the skin against infection, by the use of mosquito curtains and boots; avoidance of infection from domestic pets, such as dogs and cats, by not too close association with them; the protection of articles of food against flies and vermin; and the careful cooking of food and filtering of water.

With regard to public rules, the first is the proper disposal of waste, particularly of fæcal matter; careful cattle and meat inspection in well-kept slaughter-houses; and the destruction of ownerless dogs by means of a lethal chamber, in which they are killed by gas.

Classification.—The metazoan parasites of man can be arranged into phyla as follows:—

Phylum I. Platyhelmia.
Phylum II. Nemathelmia.
Phylum III. Annulata.
Phylum IV. Arthropoda.

PHYLUM I. PLATYHELMIA Vogt, 1851.

Synonyms.—*Platodes* Leuckart, 1854; *Platyhelminthes* Gegenbaur, 1859; *Platyhelminthes* Minot, 1877.

Definition.—Platyhelmia are bilaterally symmetrical Metazoa, with dorso-ventrally flattened bodies, and without a true cœlom.

Morphology.—The Platyhelmia are flat-worms, with an oval or tape-like body, which is either covered by a ciliated epithelium, as in the free-living Turbellaria, or with a cuticle under which the surface epithelium has sunk into the parenchyma, forming the so-called subcuticular layer in the parasitic Trematoda and Cestoda. A well-developed musculo-dermal layer is present, but there is no cœlom.

The mouth is generally situated at the anterior end, when present, but it may be moved to the inferior surface, and opens, via a pharynx, into a forked or branched gut, which has no anal aperture. The alimentary canal may, however, be wanting (Cestoda). The excretory system begins in the so-called flame cells—*i.e.*, cells provided with a leash of cilia from which fine channels run, uniting together to form larger channels These ultimately empty into a pair of laterally placed canals, opening to the exterior separately or together, often through an excretory vesicle.

The nervous system consists of a large, bi-lobed, cerebral ganglion, with nerves running forwards and backwards.

The Platyhelmia are mostly hermaphrodite, but may rarely be unisexual; the ova are produced in the ovary, near which they are fertilized, and then, after obtaining food-yolk from the yolk reservoir, which has received it via the vitelline ducts from the yolk glands, they acquire a shell in a shell gland, and then enter a uterus, through which they slowly pass to the exterior.

The male organs consist of testes, vasa deferentia, vesicula seminalis, and a cirrus pouch, with a cirrus and a so-called prostate gland.

Classification.—The Platyhelmia are classified into:

Class I. Turbellaria. Free-living flat worms, covered with cilia.

Class II. Trematoda.—Parasitic flat-worms with an alimentary canal; cuticle non-ciliate.

Class III. Cestoidea.—Parasitic flat-worms without an alimentary canal; cuticle non-ciliate.

Class I. does not enter into the subject under discussion.

CLASS II. TREMATODA Rudolphi, 1808.

Synonyms.—Sucking Worms.

Definition.—The Trematoda are parasitic Platyhelmia, which retain the mouth and alimentary canal, but in which the epidermis not merely loses its cilia during development, but is sunk into the mesoblast after secreting the chitinous cuticle. Suckers are developed in the region of the mouth, and also on the ventral surface.

Remarks.—The knowledge of the Trematoda began in 1379, when

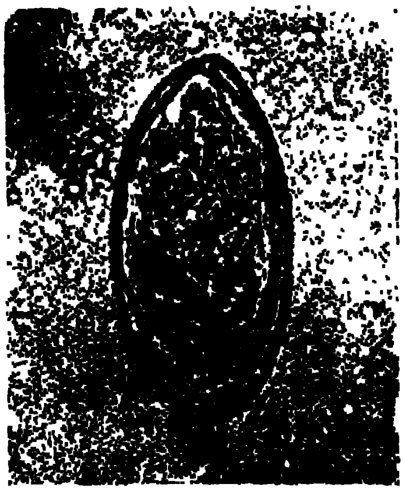

FIG. 209.—*Schistosoma mansoni.* (× 350.)

FIGS. 204-209.—EGGS OF VARIOUS TREMATODES FOUND IN HUMAN FÆCES.

(From photomicrographs by J. J. Bell.)

Jehan de Brie discovered the liver-fluke in the sheep, which was subsequently described by Gabucinus in 1547; but it was not till the time of O. F. Müller, in 1777, that any accurate idea of their form was obtained. Zeder in 1800 made the first attempt to classify parasitic worms, calling the Trematodes 'sucking-worms'; while in 1808 Rudolphi invented the name of the class, deriving it from the Greek τρηματώδης which means, 'pierced by holes.' After this date come many observers, among whom may be mentioned Laurer (whose canal still bears his name) in 1830, van Beneden in 1858, and Leuckart in 1867 (who divided them into Distomea and Polystomea), and Thomas in 1883, who worked out the development of *Fasciola hepatica*. In 1892 Monticelli revived an older classification of the group by Burmeister into three orders.

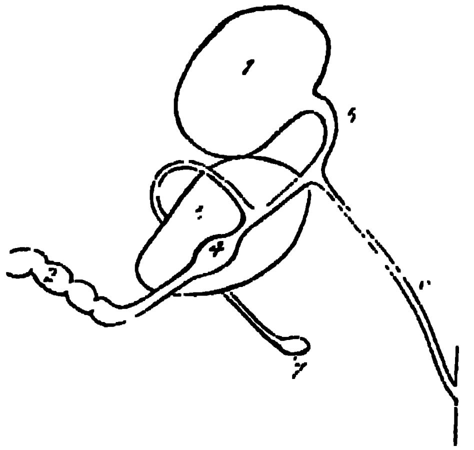

FIG. 210. DIAGRAM OF A TYPE OF THE FEMALE GENERATIVE APPARATUS OF A TREMATODE.

(After Stiles.)

1, Ovary, 2, uterus, 3, shell gland, 4, ootype, 5, ovarian duct, 6, Laurer's canal, 7, vitellarian duct.

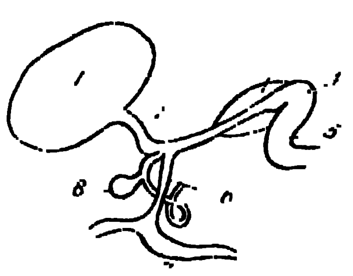

FIG. 211. DIAGRAM OF ANOTHER TYPE OF THE FEMALE GENERATIVE APPARATUS OF A TREMATODE.

1, Ovary, 2, ovarian duct, 3, shell gland, 4, ootype, 5, uterus, 6, Laurer's canal, 7, vitellarian duct, 8, receptaculum seminis.

In 1899 Looss completely revolutionized the whole classification. His work has since been extended by Leiper, Odhner, Lühe, and others. Of recent years our knowledge of the life history of these parasites has been extended in a remarkable manner by Leiper and numerous Japanese observers.

Morphology.—In shape the Trematoda are generally leaf-like or tongue-shaped, and but rarely cylindrical. They are provided with a cuticle, which may have spine-like scales, and with one or two suckers, oral and ventral (often called the 'acetabulum'), which are capable of fixing the parasites by the action of their equatorial, meridional, and radial muscular fibres to the lining of the alimentary canal, or such other organ as they may inhabit.

The mouth lies in the oral sucker, and leads to a pharynx. The œsophagus may be short or long, with or without a sphincter muscle, and is often provided with unicellular salivary glands. The intestinal tubules, which may be branched or simple, end blindly, there being no anal aperture. The food is composed of epithelial cells and blood.

The excretory system is well developed, commencing in special cells provided with cilia (flame cells), which communicate with excretory capillaries. These open into canals, which anastomose freely, and then join the gathering tubes, which open into an excretory vesicle. This vesicle, which may be long or short, pear-shaped or Y-shaped, generally opens posteriorly, but may open dorsally above the acetabulum.

The sexes are but rarely separate, hermaphroditism being usual. The male organs consist of testes, which may be simple or branched, and are, as a rule, situated posteriorly. The vas deferens leads forwards sometimes through a vesicula seminalis to the genital opening, below which a cirrus enclosed in a muscular pouch provided with glands, called the 'prostate,' may be found.

The female organs consist of an ovary, which may be branched and is usually situated in front of the testes, and an ovarian duct, which joins with the vitellarian duct from the yolk glands, making a tube, called the 'oötype,' surrounded by the shell gland, in which the egg is formed (Fig. 210).

A curious little canal, Laurer's canal, joins by its inner aperture the oötype near the uterine tube, while its outer aperture is found on the dorsal surface. The homology of this little canal is not quite clear; it may be a vagina. Sometimes a receptaculum seminis is present The ootype opens into the uterine tube, which is usually much coiled, and has its anterior portion thickened, to form the metatrema or vulva, which opens into the genital orifice (Fig. 211).

The genital pore varies in position, being situated in the mid-line in front of or behind the ventral sucker as a rule. Rarely it opens rather laterally and has a muscular depression of its own.

Life-History. -The full life-history of a number of forms has been worked out by Leuckart and Thomas for *Fasciola hepatica*, under which heading details will be given, by Looss for various amphistomes, by Leiper for the genus Schistosoma, and by numerous Japanese observers for other forms.

Typically there is an alternation of generations where one sexual generation is followed by two asexual generations. Two hosts are required for the whole life-cycle.

Leiper has given the following scheme for the development of a digenetic trematode: –

1. Definitive host	.. ..	Egg.
2. First transition	.. ..	Miracidium.
3. Intermediate host	Sporocyst Sporocyst and daughter cysts Sporocyst and Rediæ Sporocyst, Rediæ, and daughter Rediæ	*Cercariæ*.
4. Second transition	..	Free-swimming or encysted *Cercariæ*.
5. Definitive host	.. ..	Adults.

Luhe has provided the following classification of Cercariæ (slightly modified for convenience of reference):

A. Body without internal differentiation. With cuticular ala—*Lophocercariæ*.

B. Body with internal differentiation. Tails may or may not be forked: -
  I. Acetabulum absent- *Monostomes*.
  II. Acetabulum present -
    (*a*) Posteriorly situate- -*Amphistomes*.
    (*b*) Ventrally situate:—
      1. Mouth central—*Gasterostomes*.
      2. Mouth terminal—*Distomes*.

The *Distome cercariæ* may be identified as follows:—

- A. Tails absent—*Cercariæ.*
- B. Tails present:—
  - I. Tails stumpy—*Monocercous.*
  - II. Tails well developed:—
    - (*a*) Tails joined, forming colony - *Rattenkönig cercariæ.*
    - (*b*) Tails not so joined:
      - 1. Tails set with spines -*Trichocercous.*
      - 2. Tails not set with spines:—
        - (A) Tails forked at end -*Furcocercous.*
        - (B) Tails not so forked:—
          - (C) Base of tail forms space into which body can be drawn -*Cystocercous.*
          - (D) Base of tail forms no such space:—
            - (E) Tail as wide or wider than body—*Rhopalocercous.*
            - (F) Tail narrower than body—*Leptocercous.*

The *Leptocercous cercariæ* may be further differentiated as follows:—

- A. Body armed anteriorly:—
  - I. With collar and crown of thorns -*Echinostomes.*
  - II. With a stylet -*Xiphidiocercariæ.*
- B. Body unarmed anteriorly -*Gymnocephalous cercariæ.*

Habitat.—These parasites are found in all classes of the vertebrates, and may occur in any of the organs, but the most common in man are those of the liver, the intestinal tract, the lungs, and the urinary bladder. It is important to remember that the adult parasites may live in domestic animals, especially in cats, that they may affect pigs and cattle, that development takes place in snails, and that the cercaria are free-swimming, but encystment on grass, water-weeds, etc., must be borne in mind.

Pathogenicity.—Apparently the smaller forms can live in human beings without being suspected, but irritation of the bladder, liver, intestine, and lungs may result either as the effect of the eggs or of the parasite.

Diagnosis.—The systematic examination by the microscope of the fæces after centrifuging, especially in cases of diarrhœa, and of the urine and sputum, is the only certain method of diagnosis.

Treatment.—The treatment of infections by these animals is little studied, but Christopherson has lately recommended Tartar Emetic (*vide* Chapter LXXIX., and more especially Chapter LXXXII.). One may try to kill or expel the intestinal forms by chloroform mixed with eucalyptol or Chenopodium followed by purgation, as described in Chapter LXXV. (Ankylostomiasis), or by extract of male fern all in the same chapter (Tæniasis).

Prophylaxis.—We do not know enough about the life-cycles to lay down general rules about prophylaxis, but it will be obvious that the cat, the dog, the pig, and cattle are indirect sources of infection, while bathing, wading and drinking water as well as green vegetables, particularly those not cooked, must be regarded as definite sources of infection, and so must that delicacy the edible snail, which may not be properly cooked.

Classification.—The classification of the Trematoda is as follows:—

SUBCLASS I. HETEROCOTYLEA Monticelli.

Synonyms.—*Polystomea* Leuckart, *Pectobothrii* Burmeister, and *Monogenea* van Beneden.

These Trematodes are generally ectoparasitic, but may be endoparasitic in amphibia and tortoises.

SUBCLASS II. ASPIDOCOTYLEA Monticelli.

Synonym.—*Aspidobothrii* Burmeister.

These are lowly organized endoparasitic trematodes, with one large sucker occupying the whole ventral surface, found in tortoises, marine fish, and shellfish.

SUBCLASS III. MALACOCOTYLEA Monticelli.

Synonyms.—*Distomea* Leuckart, *Malacobothrii* Burmeister, and *Digenea* van Beneden, 1858.

Definition.—Typical endoparasitic trematodes with never more than two sucking-discs, oral and ventral, and a Laurer's canal.

Remarks.—The Malacocotylea include all the human trematode parasites.

Classification.—The Malacocotylea may be divided into orders as follows:

A. Development without alternation of generations—Order 1. *Monogenea* van Beneden, 1858.
B. Development with alternation of generations—Order 2. *Digenea* van Beneden, 1858.

We are only concerned with Order 2.

ORDER DIGENEA van Beneden, 1858.

Definition.—Malacocotylea with a single median anterior sucker, a vagina, and few eggs which develop by alternation of generations.

Classification.—This order is divided into several suborders, of which *Prostomata* concerns us.

Mouth surrounded by the anterior sucker—Suborder *Prostomata* Odhner, 1905.

SUBORDER PROSTOMATA Odhner, 1905.

Definition.—Digenea, in which the mouth is surrounded by the anterior sucker.

Classification.—The Prostomata are divided into superfamilies in the following manner:—

A. Acetabulum or posterior sucker caudoterminal, subterminal, or ventroterminal, and behind the genitalia or at the most embraced by the vitellaria —Super-family 1, *Paramphistomoidea* Stiles and Goldberger, 1910.

B. Acetabulum or posterior sucker ventral and separated from the posterior extremity by, at least, a part of the genitalia —Super-family 2, *Fascioloidea* Stiles and Goldberger, 1910.

SUPER-FAMILY PARAMPHISTOMOIDEA Stiles and Goldberger, 1910.

Synonym.—*Amphistomata* Rudolphi, 1801.

Definition.—Prostomata with acetabulum, caudoterminal or subterminal, or ventral close to the caudal end. Oral sucker and œsophagus present. Cæca two in number. Hermaphrodites with genital pore ventro-median, præ-equatorial, prætesticular, and præovarial, and with one or two præ-ovarial testes. Vitellaria paired.

Type Family.—*Paramphistomidæ* Fischoeder, 1901, restricted.

Classification.—*Paramphistomidæ* Fischoeder, 1901 restricted; *Gastrodiscidæ* Stiles and Goldberger, 1910; *Gastrothylacidæ* Stiles and Goldberger, 1910. The last-named family does not contain any human parasites.

FAMILY I. PARAMPHISTOMIDÆ Fischoeder, 1901, restricted.

Definition.—Pyriform paramphistomoidea with ventral pouches absent.

Type Genus.—*Paramphistomum* Fischoeder, 1901.

Classification.—The Paramphistomidæ are classified into the following subfamilies: *Paramphistominæ* Fischoeder, 1910, restricted; *Cladorchiinæ* Fischoeder, 1901; and *Diplodiscinæ* Cohn, 1904; but of these only the second concerns us.

These suborders may be recognized as follows:—

A. Oral sucker without evaginations *Paramphistominæ.*

B. Oral sucker with evaginations *Cladorchiinæ.*

SUBFAMILY CLADORCHIINÆ Fischoeder, 1901.

Definition.—Paramphistomidæ with oral sucker with evagination.

Classification.—The Cladorchiinæ can be subdivided into the *Stephanopharynginæ* Stiles and Goldberger, 1910, with circular evagination, and *Cladorchiinæ sensu stricto* Fischoeder, 1910, with paired evagination. This last subdivision contains the following genera: *Cladorchis* Fischoeder, 1901, which is the type genus; *Pseudodiscus* Sonsino, 1895; *Chiorchis* Fischoeder, 1901; *Tasiorchis* Fischoeder, 1901; *Pseudocladorchis* Daday, 1907; *Microrchis* Daday, 1907; *Pfenderius* Stiles and Goldberger, 1910; and *Watsonius* Stiles and Goldberger, 1910; of which the last is of importance in tropical medicine.

It may be remarked that this subfamily will probably soon be made a family, and its divisions subfamilies.

Watsonius Stiles and Goldberger, 1910.

Definition.—Cladorchiinæ without genital sucker, with lobate or lobulate testes, without cirrus pouch, and with each oral invagination single.

Species.—*Watsonius watsoni* (Conyngham, 1904) Stiles and Goldberger, 1910.

Watsonius watsoni (Conyngham, 1904) Stiles and Goldberger, 1910.

Synonyms.—*Cladorchis watsoni* (Conyngham, 1904), *Amphistomum watsoni* (Conyngham, 1904), *Paramphistomum watsoni* (Conyngham, 1904).

Definition.—Watsonius with the characters of the genus.

History.—*Watsonius watsoni* was first discovered in the duodenum and upper part of the jejunum of a negro who had come from Adamawa, in late German West Africa, to Northern Nigeria. Since its discovery it has been reported near Lake Chad. The type was first described by Conyngham, later by Shipley, and in 1910 by Stiles and Goldberger.

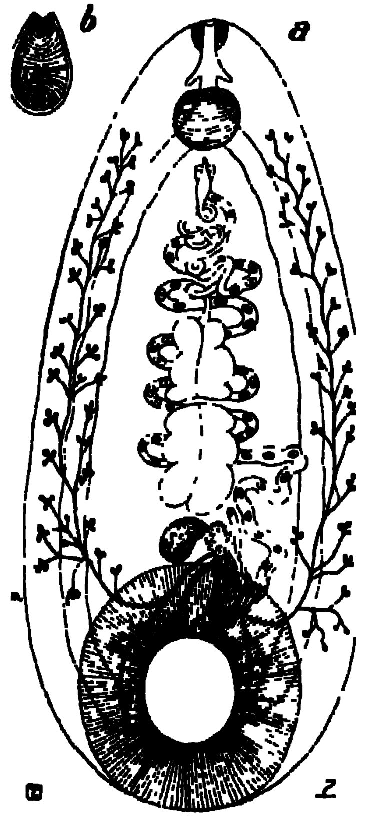

FIG. 212.—*Watsonius watsoni* (After Shipley, emended by Leiper.) *a*, Schematic; *b*, natural size.

Morphology.—The parasite is reddish-yellow when fresh, 8 to 10 millimetres in length by 4 to 5 millimetres in breadth. In shape it is oval or pyriform. The ventral sucker is large and situated posteriorly and subterminally, while the oral sucker is so small as to be hardly worthy of being considered a true sucker. It has a pair of lateral caudal irregularly globular suctional pouches. The pharynx is spherical, with two lateral diverticula, called the 'pharnygeal pouches.' The œsophagus divides into two long intestinal cæca about the level of the junction of the anterior third with the posterior two-thirds of the body, and is here surrounded by a sphincter muscle. The excretory pore opens slightly to the left of the middle line dorsal to the posterior sucker. The excretory vesicle is relatively small, and lies over that sucker. The genital papilla is situated in the mid-ventral line, about the junction of the anterior quarter with the posterior three-quarters of the body, and on it open the canal of the cirrus and the metatrema. The testes, which lie one behind the other, are deeply lobulated. The vas deferens runs into a vesicula seminalis, which opens into the cirrus canal, but has no true cirrus pouch.

The ovary lies close behind the testes, and rather to the right of the body. The ovarian duct curves backwards, and is almost at once surrounded by the shell gland, when it may be called the 'oötype,' which just behind the shell gland receives the vitellarian duct and the inner end of Laurer's canal. The uterus, full of eggs, coils over the testes and runs as far forwards as their anterior border, where it becomes thick and muscular, and is called the 'metatrema.' The eggs are large (122 to 130 μ in length by 75 to 80 μ in breadth).

Life-History.—The life-cycle is not known, but it is believed that the usual host is a herbivorous animal.

Pathogenicity.—It may perhaps cause diarrhœa and anæmia. A post-mortem showed the mucosa slightly congested.

Diagnosis.—By recognition of the eggs or adults in the fæces.

Treatment.—The eucalyptus and chloroform mixture advised for ankylostomiasis (Chapter LXXV.).

FAMILY II. GASTRODISCIDÆ Stiles and Goldberger, 1910.

Definition.—Paramphistomoidea with rather discoidal bodies divided by a transverse constriction into cephalic and caudal portions. Ventral pouch absent. Venter with many large papillæ. Acetabulum ventral at caudal end.

Type Genus.—*Gastrodiscus* Leuckart, 1877; the other genus is *Homalogaster* Poirier, 1883.

Gastrodiscus Leuckart, 1877.

Definition.—Gastrodiscidæ with bodies slender anteriorly and broadened posteriorly. The latter contains the genital glands. The acetabulum is small. The ventral pouch is absent. The oral sucker has paired evaginations, and leads into an œsophagus with muscular thickening. The cæca are long, not wavy, and end post-testicularly. Male organs:—These are two branched testes, and a cirrus pouch which is not completely closed. Female organs:—Ovary and shell gland are post-testicular; vitellaria are extracæcal; and the uterus intercæcal. Laurer's canal is prevesicular.

Type.—*Gastrodiscus ægyptiacus* Cobbold, 1876, in the horse.

Other Species.—*G. hominis* in man; *G. secundus* Looss, 1907, in the horse; *G. minor* Leiper, 1913, in the pig in Uganda and Nigeria.

Gastrodiscus hominis Lewis and McConnell, 1876.

Synonym.—*Amphistomum hominis* Lewis and McConnell.

Definition.—*Gastrodiscus* 5-8 mm. in length and 3-4 mm. broad.

History.—It was first described in 1876 by Lewis and McConnell, who found it in hundreds attached by its posterior sucker to the mucosa of the cæcum, vermiform appendix, and ascending colon of an Assamese. Since then it has been reported in natives of India, and perhaps it may be common. We have not met with it in Ceylon, though there was a small jar in the Medical College Museum labelled *Amphistomum hominis*, but without a history.

Leiper has made *G. hominis* the type of a new genus *Gastrodiscoides*, distinguished from *Gastrodiscus* by the absence of papillæ on the venter and the position of the genital pore on the cone.

Morphology.—The parasite is reddish-coloured, 8 to 10 millimetres in length and 4 to 5 millimetres in greatest breadth, tapering to 2·5 millimetres in front. The thickness is about 4 millimetres. The posterior end of the body presents a larger disc, on the hinder border of which lies the acetabulum. The rest of the body is thin, tapering to the mouth. The genital pore is at a level with the bifurcation of the intestine. The testes are double, with a sinuous vas deferens. The uterus and the yolk glands are situated laterally. The eggs are oval, 0·15 millimetre in length and 0·072 millimetre in breadth.

Pathogenicity.—It is not known whether these parasites cause any disease. It occurs in 5% of the pigs in French Indo-China.

SUPER-FAMILY FASCIOLOIDEA Stiles and Goldberger, 1910.

Synonym.—*Distomata* Retzius, 1782.

Definition.—Prostomata with acetabulum ventral and always separated from the posterior extremity by some part of the genital apparatus. Oral sucker present; cæca two in number. Hermaphrodites or with separate sexes.

Type Family. *Fasciolidæ* Railliet, 1895.

Classification.—The super family may be classified into the following families as follows:

A. *Hermaphrodites*:—
  I. Oral sucker without collar of strong pointed spines:—
    (*a*) Ovary in front of testes:—
      1. Genital pore in front of ventral sucker—*Fasciolidæ*
      2. Genital pore not in front of ventral sucker:—
        (A) Genital pore surrounded by a pseudo-sucker—*Heterophyidæ*.
        (B) Genital pore not so surrounded:—
          (C) Cuticle with pointed spines—*Troglotremidæ*.
          (D) Cuticle without pointed spines—*Opisthorchiidæ*.
    (*b*) Ovary behind testes—*Dicrocœliidæ*.
  II. Oral sucker with a dorsal and lateral, but not ventral, fold or collar bearing pointed spines—*Echinostomidæ*.
B. *Sexes separate*—*Schistosomidæ*.

FAMILY FASCIOLIDÆ RAILLIET, 1895.

Definition.—Fascioloidea, hermaphrodites with oral sucker without spiny collar, with ovary in front of the testes and genital pore behind the ventral sucker. Vitellaria well developed, extending dorsally and ventrally. Cirrus and vagina without spines. Uterus poorly developed. Excretory vesicle much branched. Eggs large.

Classification.—The Fasciolidæ are divided into two subfamilies as follows:—

A. Body with shoulder; receptaculum seminis absent; intestine branched—*Fasciolinæ*.
B. Body without shoulder; receptaculum seminis present; intestine not branched—*Fasciolopsinæ*.

SUBORDER FASCIOLINÆ Odhner, 1910.

Definition.—Fasciolidæ with a shoulder separating the head from the body, with a much branched intestine, without a receptaculum seminis.

Remarks.—This subfamily contains the genus Fasciola, which concerns us.

Fasciola Linnæus, 1758.

Definition.—Large Fascioloidea with leaf-like bodies, with the anterior end shaped into a conical head and with the ventral sucker situated near the mouth. Cuticle covered with spines.

Type Species.—*Fasciola hepatica* Linnæus, 1758.

Fasciola hepatica Linnæus, 1758.

Synonyms.—*Distomum hepaticum* Retz, 1786, *Fasciola humana* Gmel, 1789; *D. caviæ* Sons, 1890; *Cladocœlium hepaticum* Stoss, 1892.

Definition.—*Fasciola* with long cephalic cone, converging sides, small acetabulum situate some distance behind the oral sucker. Eggs 130-145 × 70-90 microns.

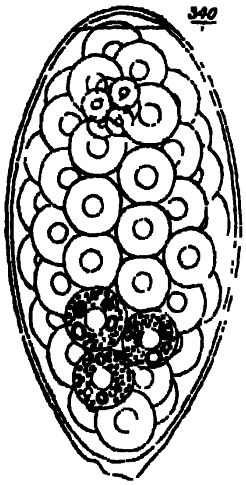

FIG. 213.—EGG OF *Fasciola hepatica*.

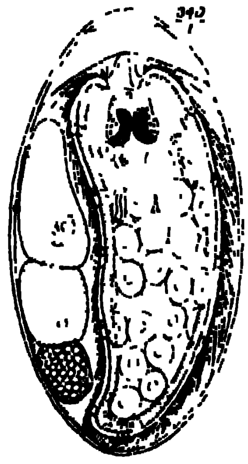

FIG. 214.—THE MIRACIDIUM OF *Fasciola hepatica*.

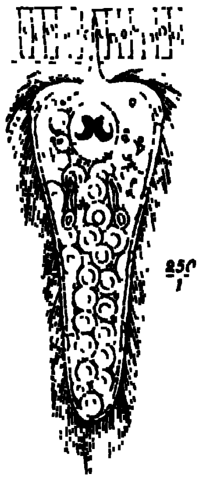

FIG. 215.—THE LARVA OF *Fasciola hepatica*.

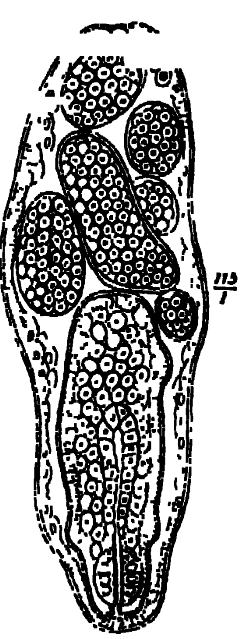

FIG. 216.—THE SPOROCYST OF *Fasciola hepatica*.

(After Thomas, from the *Quarterly Journal of Microscopical Science*.)

History.—*Fasciola hepatica*, the liver-fluke, is a parasite of sheep, oxen, goats, horses, and many other herbivorous animals, in Europe, North Africa, North and South America, Australia, Tasmania, Japan, China, Burma, and India. It is said to be extremely common in Burma and Egypt.

It has been found in man several times, and apparently usually in the liver, but it has been recorded in the bloodvessels, in a swelling on the sole of the foot, in abscesses about the head, and in a swelling in the right hypochondriac region. It is probable that *Distomum oculi humani* Ammon, 1833, and *Monostomum lentis* Von Nordmann, 1832, may have been young liver-flukes.

Morphology.—*Fasciola hepatica* is a flat, oval animal, with an anterior triangular projection. Length, 20 to 30 millimetres; breadth, 8 to 13 millimetres. The cuticle is covered with minute pointed scales directed backwards.

There are two suckers—an oral, which is situated at the anterior end of the animal and surrounds the mouth opening, and a ventral, the acetabulum, which is a muscular cap situated in the median line near the junction of the anterior projection with the rest of the body. The mouth leads into a muscular pharynx, which passes via a short œsophagus into the intestine, which divides just in front of the genital aperture into two tubes running to the posterior end of the body, giving off numerous branched cæca.

The excretory system starts with dilated tubules, into which project the cilia of the so-called flame cells. The ducts, which freely anastomose, open into a main duct, which runs directly backwards to open at a median pore at the posterior end of the body.

The two testes are much-branched tubes, lying in the middle of the body, of equal size, one lying in front of the other; from each a vas deferens runs as far as the ventral sucker, where it opens into an elongated sac, the vesicula seminalis, from which the ductus ejaculatorius runs to the end of a large muscular organ, called the cirrus which lies in a sac situate just in front of the ventral sucker. The genital opening through which the cirrus can be protruded is situated between the two suckers on the ventral surface.

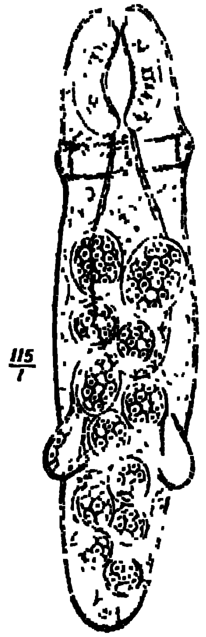

Fig. 217.—The Redia of *Fasciola hepatica*

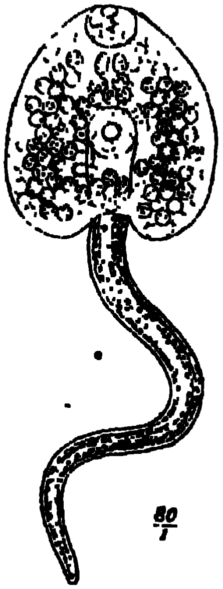

Fig. 218.—The Cercaria of *Fasciola hepatica*.

(After Thomas, from the *Quarterly Journal of Microscopical Science*.)

The branched and tubular ovary lies on the right, in front of the anterior testes. The ovarian ducts run backwards to join the middle line with the median vitellarian duct from the yolk reservoir, into which open the vitellarian ducts from the large branched yolk glands lying on either side of the body, from the level of the ventral sucker to the posterior extremity.

The junction of these two ducts is surrounded by the shell gland, and forms a much-convoluted tube, the uterus, which is joined close to its commencement by a little tube, Laurer's canal, opening on to the dorsal surface. The uterus, which is generally full of eggs, opens on the left side of the base of the cirrus.

The nervous system consists of a nerve collar around the pharynx, from which two nerve cords run backwards along the sides of the body.

Life-History.—The ovum starts from the ovary and travels along the ovarian duct, where it is fertilized, after which it is surrounded by a large number of yolk cells, and then by a shell formed from the secretion of the shell gland. The egg now passes forwards into the uterus, and is evidently deposited in the bile-passages and escapes in the fæces. It is oval, yellowish-brown, with a cap-like lid 0·13 to 0·145 millimetre in length by 0·07 to 0·09 millimetre in breadth, and is seen to enclose a mass of yolk cells with one ovum, which now segments and grows, using up the yolk cells, forming a young form, called a 'miracidium,' 0·13 by 0·027 millimetre, which in a few weeks escapes by the opercular opening if the egg is in water, and, being ciliated, swims about as a conical larva, with a little anterior papilla and two eye-spots. It has a cuticular epithelium, under which are muscular layers, and contains a simple sac, like an alimentary canal, a cerebral ganglion, and an excretory system. There is a segmentation cavity (forming a body cavity) between the alimentary canal and the body-wall.

It now bores its way into the pulmonary cavity of some snail by means of its anterior papilla; otherwise it dies in about eight hours. The varieties of snail hosts are: *Limnæa truncatula* Muller, in Europe, Asia, Africa; *L. oahuensis* in the Sandwich Islands; *L. viator* Orb in South America; *L. humilis* Say in North America, in which it loses all its organs, and increases in size rapidly, while cells grow from the wall into the primary body cavity, so that a cyst is formed, called the 'sporocyst.' This has an external cuticle, a thin muscular layer, and an epithelial lined cavity, containing collections of cells, which develop into cylindrical forms, possessing a simple, short, tube-like alimentary canal, with a pharynx, glands, and intestine, and a genital pore near the anterior end. These forms, which are called *Rediæ*, after the celebrated biologist Redi, force their way out of the sporocyst by making a wound, which heals readily, and then wander about the snail, being especially abundant in the liver. When fully formed they have a ridge running round the anterior end, and a pair of blunt processes for locomotion posteriorly.

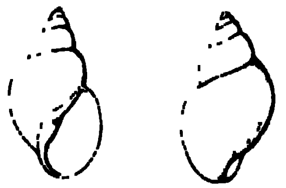

FIG. 219.—*Limnæa truncatula* MÜLLER.

Inside the *Rediæ* cells bud off from the body-wall and form the *Cercariæ* which are not unlike a young *Fasciola* with a tail

The *Cercariæ* possess cutaneous glands for the purpose of secreting the cyst-wall of the next stage. They escape from the *Rediæ* by means of the genital pore, and, leaving the snail, swim about in the water for some time, finally becoming encysted on grass or water-weeds, and are then eaten by sheep, inside which they escape from the cyst, and, working their way along the bile-ducts, develop in six weeks into sexually mature flukes.

Habitat.—The liver-fluke usually lives in the sheep, in which it causes the disease called '**sheep-rot**'; but infection can spread to man.

Pathogenicity.—It causes the disease 'Halzoun' in North Lebanon by entering the pharynx. It is probably *Hexathyridium venarum* Treutler, found in the anterior tibial vein, and the worms found in the portal vein by Duval at Rennes in 1842; by Vital from Constantia in 1874, by Giesler, in 1850, in a foot; by Harris, in Liverpool, in an abscess. It may be *Distomum oculi humani* Ammon, 1833; *Monostomum lentis* Von Nordmann, 1832; and the *Distomum ophthalmicum* Diesing, 1830.

Fasciola gigantica Cobbold, 1856.

Synonyms.—*Fasciola angusta* Railliet, 1895; *F. gigantea* Cobbold, 1858.

Definition.—Fasciola with short cephalic cone, almost parallel sides, large acetabulum situate close behind oral sucker. Eggs 150-190 × 75-90 microns.

Remarks.—*F. gigantica*, which is nearly allied to *F. hepatica*, is found in herbivora in Africa, and is believed to have occurred in a man, for a parasite somewhat resembling it was expelled from the lung during a fit of coughing associated with hæmoptysis, but there is some doubt as to whether it was not different from Cobbold's species. Its length was 26 to 28 millimetres and its breadth 6 to 8 millimetres, but it was contracted. It caused fever, cough, and slight hæmoptysis.

Subfamily Fasciolopsinæ Odhner, 1910.

Definition.—Fasciolidæ without shoulder between head and body, with simple zigzag intestines, and with a receptaculum seminis.

Type Genus.—*Fasciolopsis* Looss, 1896.

Fasciolopsis Looss, 1896.

Definition.—Fasciolinæ with large ventral sucker elongated posteriorly to form a sac. Cirrus pouch, long and cylindrical. Laurer's canal present.

Type Species.—*Fasciolopsis buski* Lankester, 1857.

Classification.—Four species are known to occur in man, and they can be recognized as follows:—

A. *Spines present on cuticle:*
  I. Vitelline acini very large—*Goddardi*.
  II. Vitelline acini not large—*Kwan's fluke* (?).
B. *No spines on cuticle:*—
  I. Cirrus sac conspicuous:—
    (*a*) Cirrus pouch very long, broad, convoluted, powerfully built—*Fülleborni*.
    (*b*) Cirrus pouch not so long, narrow, straight, not powerfully built—*Buski*.
  II. Cirrus sac inconspicuous—*Rathouisi* (?).

Fasciolopsis buski Lankester, 1857.

Synonyms.—*Distomum buski* Lankester, 1857; *D. crassum* Busk, 1859; *nec* v. Siebold, 1836; *Distomum rathouisi* Poirier, 1887.

History.—*Fasciolopsis buski* is a very large trematode, which was first discovered by Busk in the duodenum of a Lascar who died in the Seamen's Hospital in 1843. In 1857 it was named by Lankester, and in 1859 described by Cobbold.

It appears to be by no means uncommon in man and pigs in South China, and is known in Borneo, the Straits Settlements, Assam, and India. In 1910 *F. rathouisi* Poirier, 1887, was regarded as the same as *F. buski* Lankester, 1898, but at the present time some authorities go back to the older view that they are separate species—*e.g.*, Odhner says they are the same, and Ward that they are separate, because the cirrus sac is convoluted and not conspicuous while that of *F. buski* is straight and conspicuous.

Morphology.—It is a large, thick, brown, smooth trematode, 24 to 70 millimetres in length and 5·5 to 14 millimetres in breadth. The oral sucker and acetabulum are in the proportion of 0·5 : 2·0. The pharynx is globular, and there is a prepharynx, with a sphincter. The œsophagus is short, and the intestinal cæca are not branched, and extend to the posterior border. The genital pore is situated anteriorly to the acetabulum, but the most remarkable feature is the very long cirrus, about one-fourth the length of the body. The testes lie posteriorly, with the ovary and the uterus in front. The yolk glands are extensive, like those in *F. hepatica*.

Life-History. The eggs are 0·12 to 0·13 millimetre in length and 0·077 to 0·08 in breadth, and the larval stages are said to occur in shrimps.

Habitat.—The intestine of the pig and man.

Pathogenicity.—It is believed to cause dysenteric diarrhœa, wasting, and jaundice at times.

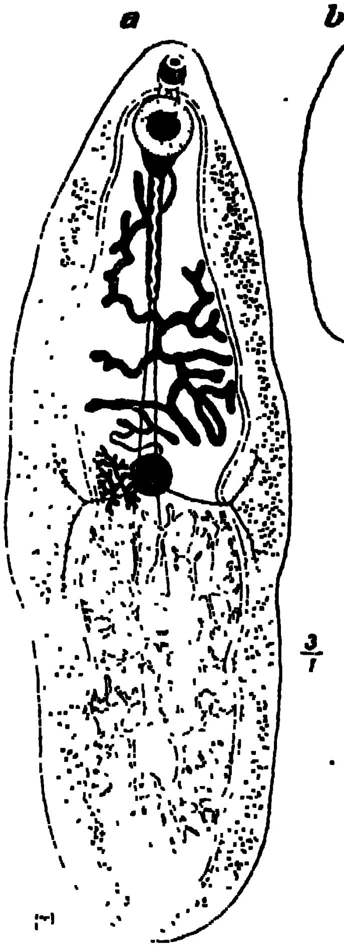

Fig. 220.—*Fasciolopsis buski.*
(After Odhner, from the *Centralblatt für Bakteriologie.*)
a, Schematic ; *b*, natural size.

Fasciolopsis fülleborni Rodenwaldt. 1909.

History.—This worm was discovered and described by Rodenwaldt in 1909, being found in the motions of an Indian in Hamburg.

Morphology.—The parasite is very large, measuring from 30 to 50 millimetres in length and from 14 to 16 millimetres in breadth. The oral sucker and acetabulum are in the proportion of 0·75 to 0·9. There is a prepharynx and pharynx, but no œsophagus.

The intestinal cæca are long and wavy, and extend to the posterior end. The genital apertures lie in front of the acetabulum.

The cirrus sac is very long and well developed, and the testes lie behind the ovary and the oötype. The latter is much larger than in *F. buski*, and is oval instead of being round. The yolk glands extend from the acetabulum to the posterior end of the body, being situated laterally. The excretory vesicle is well developed.

The eggs measure 0·1 millimetre in length by 0·073 millimetre in breadth.

Habitat.—Intestine of man.

Pathogenicity.—The patient harbouring it was suffering from fever, which had been diagnosed as typhoid.

Kwan's Fluke (= F. goddardi ?).

Under this term Heanley has described a trematode found by Dr. Kwan King Hung in a child in the island of Hong Kong.

Morphology.—In length it is 2 inches, in breadth ½ inch. The cuticle possessed spines. The intestine was not clearly seen, but the cæca were unbranched. The testes were large and placed one behind the other. The

ovary was branched, and it—the shell gland and the yolk glands (which met each other posteriorly)—resembled those of *F. buski*.

Pathogenicity.—The patient suffered from vomiting, which resulted in the expulsion of the flat-worms.

Fasciolopsis goddardi Ward, 1910.

Definition.—Fasciolopsis with spines and very large vitellaria.

Remarks.—This fluke, which is imperfectly known, was found in Shanghai, China and measures 22 × 9 mm.

FAMILY HETEROPHYIDÆ ODHNER, 1914.

Definition.—*Fascioloidea*, hermaphroditic, with the ovary in front of the testes, genital pore behind the ventral sucker, and surrounded by a pseudo-sucker, which is behind or on a level with the acetabulum, and has its muscles blended with the body musculature and not sharply differentiated therefrom.

Type Genus. *Heterophyes* Cobbold, 1866.

Classification.—The two genera which concern us can be differentiated as follows:—

A. Acetabulum and genital suckers ventrally situate and separate—*Heterophyes*.

B. Acetabulum and genital suckers dextro-laterally situate and surrounded by a complex musculature—*Metagonimus*.

GENUS: HETEROPHYES Cobbold, 1866.

Synonyms.—*Cotylogonimus* Luhe, 1899; *Cœnogonimus* Looss, 1899.

Definition.—Heterophyiidæ with suckers ventrally situate, with a narrow, movable, anterior portion, and a broader, less movable, posterior portion, which contains the genitalia. Cuticle with scale-like spines; suckers widely separated; œsophagus long. Genital pore placed laterally, behind the ventral sucker, and surrounded by a genital prominence with chitinous rodlets. No cirrus pouch. The testes are at the posterior end, and the ovary in a median position between them. Yolk glands are small, and situated at the sides posteriorly.

Type Species.—*Heterophyes heterophyes* v. Siebold, 1852.

Heterophyes heterophyes v. Siebold, 1852.

Synonyms.—*Distomum heterophyes* v. Siebold, 1852; *Mesogonimus heterophyes* Railliet, 1890; *Cœnogonimus heterophyes* Looss, 1900; *Cotylogonimus heterophyes*, Braun, 1901.

Definition.—Heterophyes with ventrally situate and separate acetabular and genital suckers.

History.—This minute parasite was discovered by Bilharz in the intestine of a boy in Cairo in 1851, and again a little later, but the third observation was not till 1891 by R. Blanchard; since then Looss has found it in Alexandria and Cairo, where he says it is not uncommon. Leiper has recorded several cases in Chinese seamen.

It is also found in dogs and cats in Egypt, Japan, and Formosa; in man in Khartoum (eggs 0·026 × 0·013 mm.), also adults; and in dogs in the same town.

Morphology.—*Heterophyes heterophyes* is pear-shaped, very narrow in front, broad behind; 2 millimetres in length by 1 millimetre in breadth, but can stretch to quite double this length. Cuticle with rectangular scales, and with numerous glands on the anterior ventral surface. Oral sucker 0·1 millimetre and ventral 0·35 millimetre in diameter. Œsophagus relatively long. Intestinal cæca end posteriorly near each other. Testes situated posteriorly, not quite on the same level on each side of the excretory vesicle; ducts join in a large vesicula seminalis, from which a canal unites with the metatrema, and then discharges into the genital cavity, the pore of which is placed laterally, surrounded by an annular muscular elevation, provided with seventy-five to eighty branched chitinous spines, probably intended to help in sexual intercourse.

The ovary lies medianly, and its duct passes backwards to join the receptaculum seminis, which is just in front of the testes.

Here also joins the vitellarian duct of the yolk glands, which also lie laterally in the posterior third of the body. The uterus is coiled throughout the posterior part of the body. The canal of Laurer is present. The eggs have thick shells, and are 0·03 millimetre in length and 0·017 millimetre in breadth, containing a miracidium.

Habitat.—Small intestine.

Life-History.—Unknown.

Pathogenicity.—Perhaps nil, but the parasite is very small, and may therefore be overlooked.

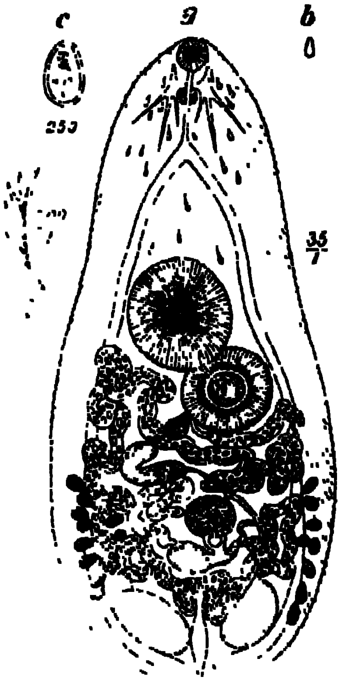

FIG. 221.—*Heterophyes heterophyes.*

(After Looss, from Braun's 'Animal Parasites of Man,' English edition.)

a, Schematic × 35; *b*, natural size; *c*, eggs × 250; *d*, spine × 700.

GENUS METAGONIMUS Katsurada, 1913.

Synonym.—*Yokogawa* Leiper, 1913.

Definition.—Heterophyiidæ with suckers dextro-laterally situate.

Type Species.—*Metagonimus yokogawai* Katsurada, 1913.

Metagonimus yokogawai Katsurada, 1913.

Synonym.—*Yokogawa yokogawai* Leiper, 1913. Leiper now believes that this fluke is the same as one previously described by Kobayashi as *Loxotrema ovatum*, n.g., n.sp.

Definition.—Metagonimus 1·5-2·5 × 0·4-0·7 mm., with body covered with nail-shaped spines about 10 microns in length, with a characteristic sac-like acetabulum placed deeply in the body and not opening on the ventral surface, but dextro laterally.

History.—It was found in Japan in the upper or middle part of the jejunum, rarely the cæcum, of man and mammals. They enter and destroy the solitary glands.

Morphology.—*Metagonimus yokogawai* is a small fluke possessing the characters given above. The oral sucker is 77-85 microns in diameter. The testes are elliptical and situate posteriorly. The ejaculatory ducts open with the uterus into a genital sinus, which opens into a pit at the front of the ventral sucker.

The ovary is spherical, and lies in the middle of the posterior part of the body. A receptaculum seminis and a Laurer's canal are present. The vitellarian acini lie on each side in the posterior part of the body. The uterus forms three to four transverse coils.

Life-History.—The eggs are elliptical, 28 × 16 microns, double contoured and yellowish brown, with an operculum, but no shoulder, and a knob at the narrower end.

Muto found cercaria in the liver of *Melania libertina*, in Kaishu, Korea, where metagonimiasis is common. On breaking up the liver in water, it was found that the cercaria became encysted under the scales of uninfected goldfish kept in the water. Kittens fed with these fish became infected in twelve to fifteen days.

The cercariæ also live in a trout, *Plecoglossus altivelis*, rarely in other fish. Infection takes place by eating raw fish, and the period, judging by dogs, is seven to sixteen days for the eggs to appear in the fæces.

Pathogenicity. It causes chronic diarrhœa in man.

FAMILY TROGLOTREMIDÆ ODHNER, 1914.

Definition. Fascioloidea hermaphroditic, with ovary in front of testes, genital pore just in front or just behind rim of acetabulum, but not surrounded by a pseudo-sucker, and with the cuticle completely covered with pointed spines. Vitellaria well developed and for the most part dorsally situate. More or less flattened worms 2-3 mm in length, with extreme posterior end prolonged into a small appendage, with ventral surface flat or somewhat hollowed, and dorsal surface vaulted. Musculature in forms living in cysts poorly developed. Pharynx present. Gut diverticula terminate a short distance from the posterior end. Genital pore immediately in front or immediately behind the rim of the acetabulum in the middle line or slightly to the left. Cirrus usually absent. Pars prostatica and seminal vesicle present. Testes symmetrical. Ovary in front of the testes. Vitellaria well developed. Uterus long and much coiled, with small eggs, or short and kinked with large eggs

Remarks.—Odhner formulated this family in Zoologiska Bidrag fran Uppsala in 1914 for *Distomum acutum*, in the frontal sinuses of *Mustela putorii*; *D. gastrophilum* from cysts in the pylorus of *Phocæna communis*, for *Collyriclum faba* from *Sylvia hortensis* and for *Paragonimus ringeri*, etc.

Type Species.—*Troglotrema* Odhner, 1914.

GENUS PARAGONIMUS Braun, 1899

Definition.—Troglotremidæ with thick, oval, or broad, fusiform bodies, almost circular on transverse section. Cuticle, with sac-like spines. Suckers separated by half the length of the body

The intestinal cæca are wavy, and run to the posterior end of the body, but are unbranched. The excretory vesicle runs from the pharynx backwards to its aperture on the posterior margin of the body. The genital pore is just behind the ventral sucker. There is no cirrus pouch, and no receptaculum seminis.

Type Species.—*Paragonimus westermanii* Kerbert, 1878.

Classification.—There are five species, but *P. rudis* Diesing, 1850, from a Brazilian otter, and *P. compactus* Cobbold, from an Indian ichneumon, are not well known. According to Ward the other three may be distinguished as follows, but Japanese workers do not accept these characters as of specific value:—

A. Chisel-shaped spines:—
  I. Arranged in circular rows in groups—*Ringeri*.
  II. Arranged in circular rows singly—*Kellicotti*.
B. Lancet-shaped spines:—
  Arranged in circular rows in groups—*Westermani*.

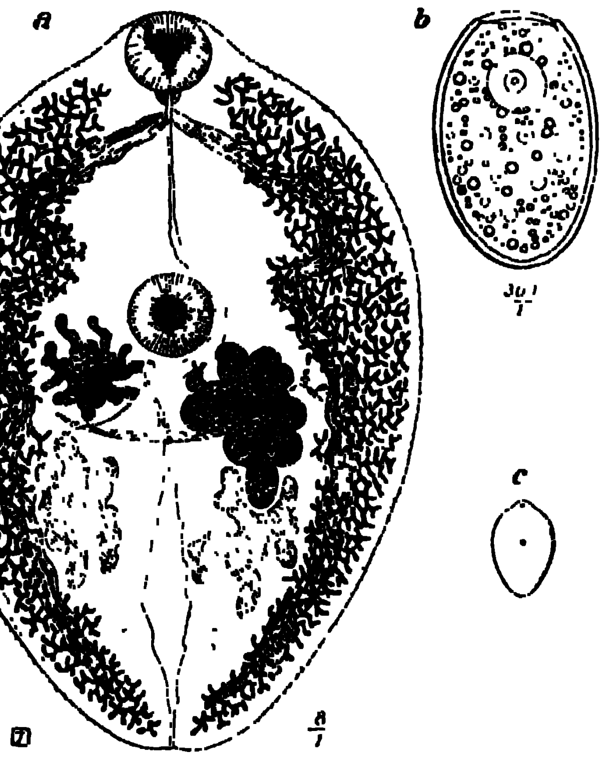

FIG. 222. *Paragonimus ringeri*.
(After Looss, from Mense's 'Tropenkrankheiten.
a, Schematic × 8; *b*, eggs × 300; *c*, natural size.

Paragonimus ringeri Cobbold, 1880.

Synonyms.—*Distoma ringeri* Cobbold, 1880; *D. hepaticum* Miura, *D. pulmonale* Baelz, 1883; *D. pulmonis* Suga, 1883; *D. cerebrale* 1889; Yamagiwa, 1890; *Mesogonimus westermani* Railliet, 1890; *M. pulmonale* Stossich, 1892.

History.—*Paragonimus westermani* was discovered by Kerbert in 1878 in the lungs of two Bengal tigers, which died respectively in the Zoological Gardens of Amsterdam and Hamburg.

In 1880 Baelz found in the sputum of cases of hæmoptysis bodies which he took to be psorosperms, and therefore called the disease gregarinosis pulmonum, but when these were referred to Leuckart he said that they were eggs of a *Distomum*. In the same year Manson found what he took to be eggs of some parasite in a case of hæmoptysis, in a Chinaman from Northern Formosa, and later he saw a Portuguese with hæmoptysis and obscure thoracic symptoms, who lived in Tamsui in North Formosa.

This man died in Formosa, and Dr. Ringer, who performed the post-mortem, discovered in the lungs a minute, fleshy, slightly flattened, oval body, grey in colour, and about a quarter of an inch in length, which expelled some brownish material from a minute orifice near one end.

This specimen was sent to Manson, who noted the same eggs as he had found in the Chinaman already mentioned, and then forwarded the parasite to Cobbold, who, rightly thinking it new to science, named it *Distomum ringeri*, the name now in use. In 1883 Baelz, having found specimens in the lungs, named it *D. pulmonale*. In 1890 Otani and Yamagiwa proved that it could occur in other parts of the body besides the lungs by finding it in the brain, where it produced symptoms of Jacksonian epilepsy. Stiles and Looss defined its zoological position; Ward found it in cats, Railliet in dogs, and Stiles in hogs; while the best description of the lesions caused by it is that by Musgrave in 1907, who found it in the Philippine Islands.

It is very common in Japan, and is found in China, Korea, and North America, a human case being reported from Mexico by Naunyn.

In 1908 Ward found *P. kellicotti* in pigs, dogs, and cats in North America.

Morphology.—The parasite varies from a reddish-brown to a light slate colour when first removed from the body, but soon becomes greyish on exposure to the air. In shape it is oval, with a somewhat flattened ventral surface, and is capable of slight alterations of its appearance by protruding and retracting its head, and by altering its ventral sucker so that it may appear terminal. The cuticle is covered with scale-like spines, which may be capable of being moved. The oral sucker is spherical and terminal, 0·63 to 0·97 millimetre in diameter. The ventral sucker is situated in the anterior half of the body, and is 0·76 to 1·31 millimetres in diameter. The œsophagus is short, and divides into the two wavy cæca. The genital pore may be indistinct, and is always small, lying close to and behind the ventral sucker. The testes lie about, but not quite on, the same level on each side of the median line just behind the uterus. There is neither a cirrus nor a cirrus pouch. The ovary is opposite and slightly posterior to the uterus, which is visible just posterior to the ventral sucker. The yolk glands lie at the sides, and their branches almost meet dorsally, while ventrally they only extend to the intestinal cæca. Laurer's canal is present. The eggs are oval in shape, of a reddish-brown to a light yellow in colour, with a length from 0·08 to 0·1 millimetre, and a breadth from 0·052 to 0·075 millimetre. They possess an operculum, and contain the ovum and yolk cells.

The excretory vesicle is well developed, and extends from the pharynx backwards.

Life-History.—According to Nakagawa, the miracidia infect the snails *Melania libertina* and *Melania obliquegranosa*.

Nagakawa in Formosa found encysted larvæ in fresh-water crabs:—1. *Geothelphusa obtusipes*. **Synonyms.**—*Potamon obtusipes, Thelphusa rubra*. 2. *Geothelphusa dehaanii*. **Synonyms.**—*Potamon dehaanii, Thelphusa berardi*, and perhaps—3. *Eriocheir japonicus*. **Synonym.**—*E. formosa*.

According to Sadao Yoshida, in the first two, the larvæ are found in the liver, rarely in the gills or muscles, and in the last chiefly in the gills, muscles, and hypoderm, and rarely in the liver.

Dogs and cats have been infected by these observers from the crabs, when the larva, escaping from the cyst in the intestine, penetrates the wall near the jejunum and enters the abdominal cavity, perforates the diaphragm, and, entering the subpleural tissue, may pierce its way into the lung and encyst or pass into the neck (and perhaps so to the brain, etc.). The lungs are their favourite seat, and the only one in which they attain maturity.

Kakami, on the other hand, says that cercariæ may be found in *Melania libertina*, and that they get into drinking-water and so infect people directly.

Pathogenicity.—It causes paragonimiasis in man.

FAMILY OPISTHORCHIIDÆ BRAUN, 1901, *emendavit* STEPHENS, 1916.

Definition.—Fascioloidea, hermaphroditic, with oral sucker without collar of spines. Ovary in front of testes. Genital pore behind ventral sucker. Cuticle without pointed spines. Small to medium flukes tapering anteriorly. Cirrus absent, but receptaculum seminis and Laurer's canal present. Eggs small.

Classification.—The family is divided into subfamilies as follows:—

A. Excretory pore terminal; bladder long, dorsal to testes.
   Uterine coils not overlapping intestinal cæca—*Opisthorchiinæ*.

B. Excretory pore ventral; bladder short, ventral to testes.
   Uterine coils overlapping intestinal cæca—*Metorchiinæ*.

SUBFAMILY OPISTHORCHIINÆ LOOSS, 1899, *emendavit* Stephens, 1916.

Definition.—As above.

Classification.—The genera important to us can be distinguished as follows:—

A. Testes lobed:—

I. With long retractile process projecting from ventral surface and carrying out its apex the acetabulum and the genital pore—*Paropisthorchis*.

II. Without such process:—

Vitellaria from acetabulum to ovary in one mass—*Opisthorchis*.

Vitellaria divided into one mass in front of and another behind the ovary—*Amphimerus*.

B. Testes branched:—

Branches cover intestinal cæca ventrally—*Clonorchis*.

Type genus.—*Opisthorchis* R. Blanchard, 184

Opisthorchis R. Blanchard, 1845.

Definition.—Opisthorchiinæ with long flattened body and somewhat pointed anterior extremity, suckers small, intestinal cæca unbranched, yolk glands situate laterally and not extending beyond the ventral sucker in front, testes in the posterior part of the body, one behind the other.

Type Species. *Opisthorchis felineus* Rivolta, 1885.

Classification. The species of this genus are separated from one another with great difficulty.

The following are found in man: *Opisthorchis felineus* Rivolta, 1885; *Opisthorchis viverrini* Poirier, 1866.

These two species are distinguished as follows:—

A. Cuticle without spines—*Felineus*.

B. Cuticle with minute spines—*Viverrini*.

Opisthorchis felineus Rivolta, 1885.

Synonyms.—*Distoma conus* Gurlt, 1831, *nec* Creplin, 1825; *D. lanceolatum* v. Siebold, 1836, *nec* Mehlis, 1825; *D. sibiricum* Winogradoff, 1892; *D. tenuicolle* Mühl, 1896, p.p.

Definition.—Opisthorchis with cuticle without spines.

Remarks.—*Opisthorchis felineus* lives in the gall-bladder and bile-ducts of the domestic cat, and is also found in dogs in Europe. The North American species is different (*O. pseudo-felineus*).

In human beings it is apparently a common parasite in Siberia, where it was first found by Winogradoff in Tomsk.

Morphology.—It is reddish-yellow in colour, with a conical neck at the level of the ventral sucker, marked by a shallow constriction.

The length is from 8 to 11 millimetres and the breadth 1·5 to 2 millimetres. The testes lie in the posterior part of the body, one behind the other. The yolk glands are situate on either side of the middle third of the body, beginning behind the ventral sucker and terminating about the level of the ovary.

The genital pore is close in front of the ventral sucker.

The eggs are oval, with a well-defined operculum (30 μ by 11 μ).

Life-History.—The parasites live in the bile-duct, and the eggs, containing a ciliated miracidium, escape in the fæces. Complete development is not known, but cercaria have been found in fish which infect men and cats.

Pathogenicity.—It causes inflammation, dilatation of the bile-ducts in man, with atrophy of the liver substance, ascites, and icterus.

Opisthorchis viverrini Poirier, 1886.

Definition.—Opisthorchis with cuticle covered with minute acicular spines. Ovary multilocular. Branches of intestine almost reach the hinder end of the body, and the ovary and testes are deeply lobed.

Remarks.—This trematode, which belongs to the Indian civet-cat, was obtained by Kerr from prisoners at Chiengmai, and recognized by Leiper.

Infection.—Infection is probably by eating raw or partially cooked fresh-water fish.

Paropisthorchis Stephens, 1912.

Definition.—Opisthorchiinæ with lobed testes and with ventral process on which are situate the ventral sucker and the genital pore.

Type Species.—*Paropisthorchis caninus* Barker, 1912.

Paropisthorchis caninus Barker, 1912.

Definition.—Paropisthorchis with the generic characters.

Remarks.—Cobbold in 1858 found a little fluke, *Distomum conjunctum*, in the bile-ducts of *Canis fulvus* Lewis, the American fox.

Fourteen years later Lewis and Cunningham found the same fluke in Indian pariah dogs, and in 1874 McConnell found what was thought to be the same fluke in human beings in Calcutta. In 1903 Braun pointed out that the American and Indian flukes were different, and named the latter *Opisthorchis noverca* (*vide infra*, Amphimerus).

In 1912 Barker separated the parasite of the Indian pariah dog from the human, calling the former *O. caninus*; and in the same year Stephens created a separate genus for it. Leiper still maintains, however, that these two forms, in man and dog, are identical.

It is not known to occur in man.

Amphimerus Barker, 1912.

Definition.—Opisthorchiinæ without ventral process, but with lobed testes and vitellaria divided by the position of the ovary into anterior and posterior lobes.

Type Species.—*Amphimerus noverca* Braun, 1903.

Remarks.—This genus was created for Braun's *Opisthorchis noverca*, which, as explained above according to Stephens, only applies to McConnell's flukes, found in two Mohammedans in Calcutta.

Amphimerus noverca (Braun, 1903).

Definition.—Amphimerus with the characters of the genus.

Morphology.—It is lancet-shaped, with anterior and posterior extremities, pointed body, covered with spines; 9·5 to 12·7 millimetres in length and 2·5 millimetres in breadth, with two suckers very close together, the anterior being larger than the posterior. The genital pore opens just in front of the ventral sucker. The pharynx is sphæroidal, and the intestinal cæca extend far back. The two testes are very distinct, the anterior rounded and the posterior lobate. The ovary is slightly lobate, and it and the uterus are situated medianly. The yolk glands lie laterally in the middle third, extending from behind the ventral sucker to the back of the testes. There is no cirrus pouch. The eggs are oval (0·034 by 0·021 millimetre).

Habitat.—The dog and man.

Pathogenicity.—Not known.

Clonorchis Looss, 1907.

Definition.—Opisthorchiinæ characterized by the fact that the testes are not notched or lobate, but distinctly ramified, the branches crossing the intestinal cæca on their ventral side and extending very near the body margin. The excretory vesicle is simply an unpaired tube, which becomes somewhat widened at its anterior end, assuming sometimes the shape of an irregular triangle.

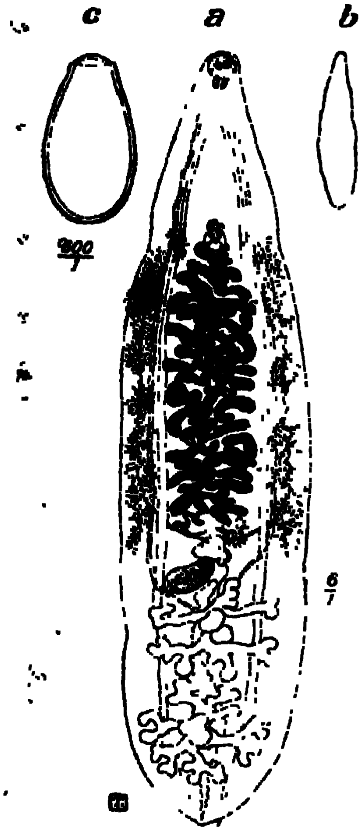

Fig. 223.—*Clonorchis sinensis.*

(After Looss, from the *Annals of Tropical Medicine and Parasitology.*)

a, Schematic; *b*, natural size; *c*, egg × 500.

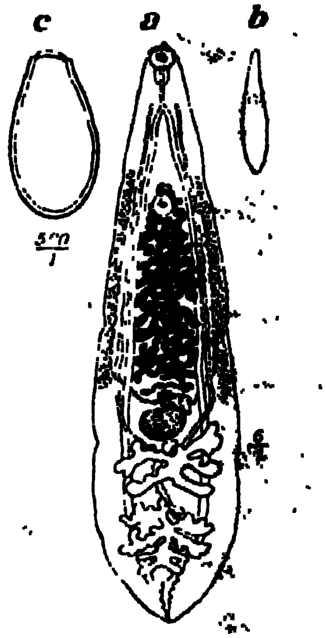

Fig. 224.—*Clonorchis endemicus.*

(After Looss, from the *Annals of Tropical Medicine and Parasitology.*)

a, Schematic; *b*, natural size; *c*, egg × 500.

Species.—*Clonorchis sinensis* Cobbold, 1875; *Clonorchis endemicus* Baelz, 1883; but the work of Kobayashi in 1917 tends to show that they are one and the same species.

Clonorchis sinensis Cobbold, 1875.

Synonyms.—*Distoma sinense* Cobbold, 1875; *D. spathulatum* Leuckart, 1876; *Distomum hepatis innocuum* Baelz, 1883.

Definition.—Clonorchis with the generic characters.

History.—*Clonorchis sinensis* was first discovered by McConnell in 1874 in the liver of a Chinaman. It was believed to be an *Opisthorchis*, but in 1907 Looss gave reasons why it should be placed in the new genus *Clonorchis*. As far as is known it occurs principally in China and Japan, and has not yet been found in animals.

Remarks.—It may be the same as *Clonorchis endemicus* Baelz, 1883; *Distoma hepatis endemicum sive perniciosum* Baelz, 1883; *Distoma japonicum* R. Blanchard, 1886. In 1883 flukes were first described in the liver of human beings in Japan by Kiyono, Nakahama, Suga, and Yamagata, and a little later in the same year Baelz reported the occurrence of two hepatic distoma in Japan.

1. *Distoma hepatis innocuum*, up to 20 millimetres in length, with a lighter-coloured uterus of larger volume, with slightly larger ova, 21 to 36 μ in length by 18 to 20 μ in breadth, and with a black granular pigment in its excretory apparatus and body parenchyma. It caused little or no symptoms in human beings, and was found accidentally in post-mortems.

2. *Distoma hepatis endemicum sive perniciosum*, which was smaller, 8 to 11 millimetres in length, and did not possess the above characters, while its eggs were only 20 to 30 μ in length by 15 to 17 μ in breadth.

Kobayashi finds that Looss's differences between *C. sinensis* and *C. endemicus* do not hold good. They were (1) size; (2) discontinuity of the vitellaria; (3) pigmentation; (4) size and shape of the egg. In the experimentally reared forms there are no such constant differences.

It is found in Japan, where it is common, and in Annam and Tonkin, in man, cats, dogs, and pigs.

Morphology.—*Clonorchis sinensis* is a white, or yellowish-red, or brownish, narrow trematode, 13 to 19 millimetres in length and 3 to 4 millimetres in breadth. The pigmentation is due to the deposit of fine yellowish or brown granules in the body parenchyma. The ramifications of the testes are long, the anterior arising from four and the posterior from five main stems, with sometimes ventral bulgings. The ovary is trilobate, but may show three to six smaller lobules. The yolk glands reach from the ventral sucker to the level of the ovary, and are peculiar in that certain groups of follicles remain undeveloped. In perfectly mature specimens the seminal vesicle extends back as far as the middle of the uterus. The eggs are generally narrowed towards the anterior end, and have a rather high lid, with a sharply projecting brim (these peculiarities may be absent.) The egg is 29 μ in length and 16 μ in breadth.

Life-History.—Kobayashi has found the cysts in the muscles of fish—*Pseudorasbora parva*, *Leucogobio güntheri*, *Leucogobio mayedæ*, and *Carassius auratus*—and was able to infect cats by feeding with the infected flesh. He also found cysts in other fish—*Acheilognathus lanceolatus*, *A. limbatus*, *A. cyanostigmus*, *Paracheilognathus rhombeus*, *Pseudoperclampus typus*, *Abbottina psegma*, *Biwia zezera*, and *Sarcocherlichthys variegatus*. These fish are the second intermediate host. The first intermediate host and the method of infection of the fish are unknown, but *Melania libertina* is suspected.

Habitat.—It is found in cats, dogs, hogs, and men.

Pathogenicity.—Enlargement of the liver, and diarrhœa.

A Possible Feline Clonorchis (or Opisthorchis).

Looss draws attention to the fact that Ijima, in 1886, describes a *Distomum* from the liver of a cat in Japan, with fine spines, and smaller than *C. endemicus*, which is to be looked upon as a normal parasite of the cat. It is only 1·5 millimetres in length by 0·9 millimetre in breadth. It may be a *Clonorchis* or an *Opisthorchis*.

Katsurada, in 1900, published a paper based upon seventy-six post mortems with an enormous number of parasites, among which he mentioned three found in a man from the province of Saga, with an average length of 5·10 millimetres and breadth of 0·96 millimetre, which Looss considers can only be explained as an infection with a feline species.

Habitat. Cats and man (?).

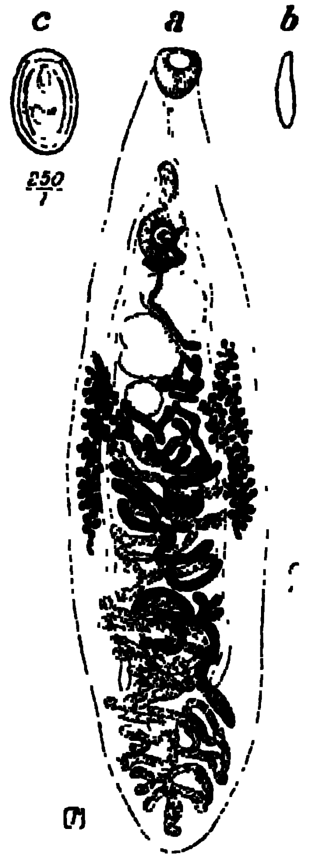

FIG. 225.—*Dicrocœlium dendriticum* Rudolphi.

(After Looss, from Mense's 'Tropenkrankheiten.')

a, Schematic × 6; *b*, natural size; *c*, eggs × 250.

FAMILY DICROCŒLIIDÆ

ODHNER, 1910.

Definition.—Fascioloidea, hermaphroditic, without spiny collar around the oral sucker, and with the ovary behind the testes.

Type Genus.—*Dicrocœlium* Dujardin, 1845.

Dicrocœlium Dujardin, 1845.

Definition. Dicrocœliidæ with lancet-shaped bodies, without spines, and with suckers placed close together. Intestine does not reach the posterior end. Genital pore close behind the pharynx, with a cirrus pouch in front of the ventral sucker, just behind which the testes lie with the ovary in the median line behind them. The uterus lies behind the ovary and testes, extending as far back as the posterior border. The yolk glands are small, and situated in the middle quarter of the lateral areas of the body. The excretory vesicle is tubular. Ova dark brown. Worms live in the liver and gall-bladder, rarely in the intestine.

Type Species. *Dicrocœlium dendriticum* Rudolphi, 1819.

Dicrocœlium dendriticum Rudolphi, 1819.

Synonyms.—*Fasciola lanceolata* Rudolphi, 1803, *nec* Schrank, 1790; *Distomum lanceolatum* Mehlis, 1825; *Dicrocœlium lanceolatum* Dujardin, 1845; *Dicrocœlium lanceatum* Stiles and Hassall, 1896.

History.—Bucholz appears to have been the first to discover these worms in the gall-bladder in Weimar, and, later, Chabert in the intestines of a girl in France, and Kirchner in Weimar. Since then they have been noted in Italy and Egypt. They are found in the bile-ducts of herbivorous and omnivorous animals in Europe, North Africa, Asia, and North and South America.

Morphology.—*Dicrocœlium dendriticum* is a small trematode, measuring 8 to 10 millimetres in length by 1·5 to 2·5 millimetres in breadth. It is pointed in front and narrow behind, so that the widest point is just behind the yolk glands. Cuticle is smooth; the oral sucker is terminal, and about the same size as the ventral (0·5 to 0·6 millimetre). The intestine bifurcates just in front of the genital pore, which is situate in the median line in front of the ventral sucker, behind which the two testes lie, from which the vasa deferentia run forwards to form a cirrus lying in a cirrus sac

The ovary lies behind the posterior testis; there is a receptaculum seminis and a Laurer's canal. The yolk glands lie in the lateral portion of the middle fifth of the body, the posterior portion of which is filled up by the large coiled uterus. The eggs are thick-shelled, and yellowish to brown in colour, with a length of 38 to 45 μ and a breadth of 22 to 30 μ

Life-History.—Not known, but suspicion rests on *Planorbis marginatus* and land-snails.

Pathogenicity.—No special symptoms.

FAMILY ECHINOSTOMIDÆ Looss, 1902.

Definition.—Fascioloidea, hermaphroditic, with a fold or collar bearing a row or rows of pointed spines on the dorsal and lateral aspects of the oral sucker. The rows of spines are continued laterally on to the ventral corners, and the number of spines is constant for each species. The corner spines are large or specialized.

Classification.—The family is divided into two subfamilies as follows:—

A. Cirrus sac does not reach beyond acetabulum. Without strong rosethorn hooks—*Echinostominæ*.

B. Cirrus sac reaches beyond acetabulum. With strong rosethorn hooks *Himasthlinæ*

SUBFAMILY ECHINOSTOMINÆ Looss, 1899.

Definition.—As above.

Type Genus.—*Echinostoma* Rudolphi, 1809.

Classification.—*E. malayanum* Leiper, 1911, has been placed by Odhner in the genus *Euparyphium* Odhner, so that it now becomes *Euparyphium malayanum*, as, according to Leiper, it is probably the same as *Artyfechinostomum sufrartyfex* Lane, 1915, which Lane found in a girl of eight years of age on the Ragnik Tea Estate in Assam. In 1916 Stephens pointed out that Lane's genus did not possess the strong rosethorn hooks of the Himasthlinæ. In 1917 Lane pointed out that as Odhner's principal character of the Echinostominæ was that the cirrus sac usually reaches to the centre of the acetabulum, but not beyond it, while that of *A. sufrartyfex* reaches 0·75 mm., therefore it is not a member of the Echinostominæ.

GENUS ECHINOSTOMA Rudolphi 1809.

Synonym.—*Fascioletta* Garrison, 1908.

Definition.—Echinostominæ, with small elongated bodies, broader anteriorly than posteriorly, with characteristic circumoral ring of spines and with other spines on the body, and with large prominent acetabulum. Œsophagus short, intestinal cæca unbranched. Excretory vesicle tubular. Genital pores anterior to the acetabulum. Testes compact, situate in the median line one behind the other. Cirrus and pouch well developed. Ovary compact; no receptaculum seminis; Laurer's canal present. Yolk glands well developed in the posterior fifth of the body; well developed shell gland and uterus, which lies between the ovary behind and the acetabulum in front. Ova large and operculated.

Remarks.—With regard to the position of *Echinostoma*, it should be observed that some authorities do not classify it under the Fasciolidæ, but in a special family Echinostomidæ which we adopt.

Type Species. The type species is *Echinostoma revolutum* (Froelich, 1802), of which the synonym is *Distoma echinatum* Zeder, 1803. Another species of importance in tropical medicine is *E. ilocanum* (Garrison, 1908).

Echinostoma ilocanum Garrison, 1908.

Synonym.—*Fascioletta ilocana* Garrison, 1908.

History.—*Echinostoma ilocana* was discovered and described by Garrison, who in 1907 noticed peculiar eggs in the fæces of Philippino prisoners in Bilibid Prison in Manila and subsequently, after treatment with male-fern, obtained a small number of trematodes. Quite recently Odhner has shown that it belongs to the genus *Echinostoma*, family Echinostomidæ.

Morphology. *Echinostoma ilocana* is a very small trematode, measuring 4 to 6 millimetres in length by 0·75 to 1·35 millimetres in breadth and 0·5 to 1 millimetre in thickness. Posteriorly it is attenuated. The acetabulum is about three times the size of the oral sucker, which is either terminal or slightly ventro-subterminal. The prepharynx is long, the pharynx globular; the œsophagus short, bifurcating just anterior to the genital pore into the intestinal cæca. The genital pores open separately a little behind the halfway point between the pharynx and the acetabulum.

The cirrus pouch is well developed, and contains posteriorly the vesicula seminalis, into which open the vasa deferentia, and which gives rise to the long coiled cirrus. Each testis shows an anterior and a posterior lobe. The ovary is globular, the yolk glands well developed, and the uterus fairly developed. Ova 88·8 to 114·7 μ long by 53·5 to 81·0 μ broad.

Life-History.—Nothing is known of the life-history beyond the fact that a miracidium hatches in about ten days after the eggs have left the host.

Habitat.—The intestine of man in Luzon, in the Philippine Islands.

Pathogenicity.—It is probable that the worm is non-pathogenic.

GENUS EUPARYPHIUM Odhner.

Euparyphium malayanum Leiper, 1911.

Synonym.—*Echinostoma malayanum* Leiper, 1911.

History.—In 1911 Leiper received two consignments of flukes from Dr. Macaulay of Singapore and from Dr. Stanton of Kuala Lumpur which had been collected from the intestine of a Tamil in the Malay States.

Morphology.—It is a thick, fleshy trematode, light brown in colour, 12 millimetres in length, 3 millimetres in breadth, and 1·3 millimetres in thickness. The oral sucker is situated on a kidney-shaped anterior portion, which is somewhat detached from the rest of the parasite by a furrow on either side. This circumoral disc is surrounded by a row of forty-two stout spines. The cuticle of the body is unevenly furnished with spines. The acetabulum is several times larger than the oral sucker. The oral sucker lies in the middle third of the circumoral disc, and leads into a spheroid muscular pharynx, and so into the œsophagus, which bifurcates immediately behind the pharynx into two branches, which are simple and end blindly at the posterior end of the body.

The deeply lobed testes lie one behind the other behind the acetabulum; there is a well-developed cirrus pouch and a long, thick cirrus The ovary is smooth, and lies immediately in front of the anterior testis and just behind the acetabulum. The yolk glands are numerous, extending from the acetabulum to the posterior end of the body. The brown eggs are few in number and large in size.

Habitat.—Leiper does not think that this worm is a normal parasite of man, and considers that domesticated animals, especially cats and dogs, should be investigated for it.

Pathogenicity.—Not stated.

SUBFAMILY HIMASTHLINÆ Odhner, 1910.

Definition.—Echinostomidæ in which the cirrus sac extends caudad to the acetabulum.

Remarks.—The only genus with which we are concerned is:—

GENUS ARTYFECHINOSTOMUM Clayton-Lane, 1915.

Definition.—Himasthlinæ without strong rosethorn hooks.

Remarks.—There has been much disput [illegible] to whether this is a good genus or not.

Type Species.—*Artyfechinostomum sufrartyfex* Clayton-Lane, 1915.

Artyfechinostomum sufrartyfex Clayton-Lane, 1915.

Nomenclature.—Leiper has pointed out that this name clashes with the recommendations of the International Rules: 'The use of proper names in the formation of compound generic names is objectionable.' However, the name cannot now be changed.

History.—The worm was found in a girl, aged eight years, on the Ragnik Tea Estate in Assam, and was thought by Leiper to be probably the same as *Euparyphium malayanum*; but in 1917 Clayton-Lane showed that the cirrus sac extended 0·75 mm. caudad to the acetabulum, a fact agreeing with the definition of the subfamily.

FAMILY SCHISTOSOMIDÆ Looss, 1899.

Definition.—Fascioloidea with separate sexes, and with genital pore posterior to the elevated acetabulum. No pharynx. Intestinal caecare unite to form a single intestine.

Type Genus.—*Schistosoma* Weinland, 1858.

Schistosoma Weinland, 1858.

Synonyms.—*Gynæcophorus* Diesing, 1858; *Bilharzia* Cobbold, 1859; *Thecosoma* Moquin-Tandon, 1860

Definition.—Schistosomidæ with long filiform *females* and shorter *males*, with body considerably widened behind the acetabulum. In this part the lateral walls can curve ventrally to form an almost closed *canalis gynæcophorus*, within which the female is enclosed. No cirrus pouch. No pharynx No Laurer's canal. Eggs with spines and no lids. Miracidia ciliated with large glandular cells discharging anteriorly beside gastric sac. Development in various snails. Cercariæ with forked tails and no eye spots. Enter vertebrate hosts through skin or mucosa, and pass into blood-vessels.

Classification.—The species known to occur in man may be recognized as follows (*S. magna* Cobbold, 1852, found in a monkey *Cercocebus fuliginosus* is represented to-day by only a piece of a male, which Leiper says cannot be recognized as belonging to a human species):—

A. Cutiele with spines:
  I. *Male*, four to five large testes; *femdle*, ovary posteriorly situate. *Eggs*, terminal spined. *Development* in subgenera and species of *Bullinus*—*Hæmatobium*.
  II. *Male*, eight small testes; *female*, ovary anteriorly situate. *Eggs*, lateral spined. *Development* in species of *Planorbis*—*Mansoni*.

B. Cuticle nearly smooth, only a few spines seen in fresh condition along margin of canal
  Male, six to eight testes, *female*, ovary almost in middle of body. *Eggs* with small lateral spines or thickenings. *Development* in species of *Blanfordia*—*Japonicum*.

Schistosoma hæmatobium Bilharz, 1852.

Synonyms.—*Distomum hæmatobium* Bilharz, 1852; *D. capense* Harley, 1864; *Bilharzia hæmatobia* Cobbold, 1859

Definition.—Schistosoma with spiny cuticle. *Males* with four to five large testes and with intestinal caeca uniting late to form a short single intestine. *Females* with ovary in the posterior half of the body. Uterus very long, with many terminal spined eggs. Vitellaria in posterior fourth of the body. Development of cercariæ in subgenera and species of *Bullinus*.

History.—*Schistosoma hæmatobium* was discovered in the portal vein of a man in 1851 by Bilharz in Cairo, and later by Harley in

1864 in a patient from the Cape of Good Hope. Since then it has been found widely distributed through Africa (Egypt, Sudan, Tunis, Algiers, West Coast, including the Gold Coast, East Coast, and South and Central Africa), which is its endemic centre, and in Asia, in Syria, Arabia, Mauritius, Persia, India. Only imported cases occur in Ceylon.

Other species are known in sheep, horses, oxen, etc.

In 1915 Leiper discovered its complete life-history in the snail and its method of entry into the vertebrate.

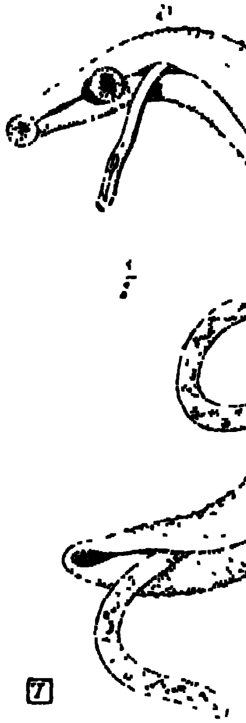

Fig. 226. *Schistosoma hæmatobium.* (After Looss, from Mense's 'Tropen krankheiten').

This drawing shows the female worm enclosed in the gynæcophoric canal of the male.

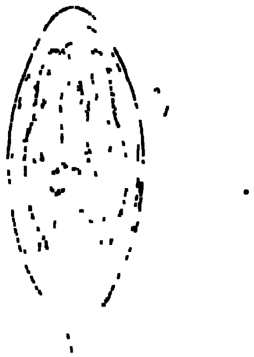

Fig. 227. Egg of *Schistosoma hæmatobium* (× 250). (After Looss, from Mense's 'Tropenkrankheiten.')

Morphology.—**Male.**—The male is whitish in colour, and from 12 to 14 millimetres in length, with a greatest width behind the ventral sucker of 1 millimetre. It is really thin and flat though it may look cylindrical, because the lateral margins are turned ventrally inwards, enclosing a canal called the 'gynæcophoric canal,' in which the female lies. The whole body is covered with projections tipped with short spines, which enable it to cling to the wall of the bloodvessel. The oral sucker looks ventrally. The ventral sucker is situate near to it. There is no pharynx, but the œsophagus is long and covered with numerous glands, and bifurcates just in front of the ventral sucker into the intestinal cæca, which unite behind the testes into a median trunk. The excretory pore is at the posterior end, situated a little dorsally. There are four to five testes, from which the vas deferens runs to a vesicula seminalis, from which an ejaculatory duct proceeds to the genital pore situated behind the ventral sucker at the beginning of the gynæcophoric canal.

Female.—The female worm is long, thin, being 20 millimetres in length (*i.e.*, longer than the male) and 0·25 millimetre in breadth (much thinner than the male). Posteriorly it is coloured dark brown, because of the colour of the contents of the intestine. The cuticle is smooth, except in the sucker and at the tail end, where there are large spines. The alimentary canal is much the same as in the male. The ovary is median, and the ovarian duct,

taking origin at the posterior end, runs forward to join with the vitellarian duct from the single yolk gland, which lies about the middle of the body. The junction of the two ducts is at first narrow and surrounded by the shell gland, but it soon dilates into the uterus, which runs forwards to end in the genital pore, just behind the ventral sucker. The eggs are bluntly spindle-shaped, yellowish in colour, slightly transparent, and provided with a thin shell, without a lid, but possessing a terminal spine, which may be absent at the posterior end. They measure from 0·12 to 0·19 millimetre in length [illegible] millimetre in breadth, but vary considerably.

Life-History.—The young immature and mature males and females are found in the portal system.

Looss notes that it is not uncommon to find males alone in the portal vein, and, further that they are all of the same age. Eventually they pair, and now the male carries the female along that vein down the inferior mesenteric vein to the bladder, which is a fairly direct route, but Looss considers that they may be chemically attracted to the bladder, for their journey is against the blood stream, and they are enabled to perform it by means of the bristles on the male cuticle.

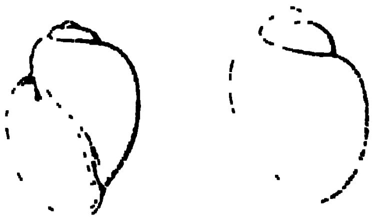

FIG. 228.—*Bullinus contortus* MICHAUD, 1829.

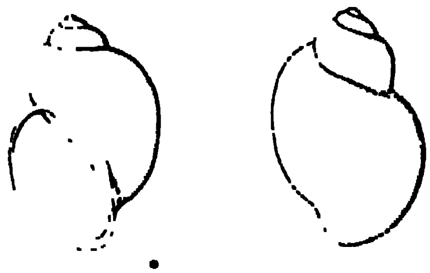

FIG. 229. *Bullinus dybowskii* FISCHER, 1891.

The length of time occupied by the journey is not known, and probably varies considerably. Arrived in the veins of the bladder, the real oviposition begins, and Looss is inclined to think that the female can push the head (close to which is the genital opening) into the capillaries, and thus lay the eggs directly into these channels, where they are held in position by contraction of the capillary upon them. Looss thinks that it is probable that the worms may live three years in these vessels, producing during that period large numbers of eggs, which work their way like any other foreign body into the lumen of the bladder, probably by means of the contractions of that organ.

Leiper finds that in experimentally infected monkeys eggs begin to appear about ten weeks after infection.

Egg.—During their journey through the tissues the eggs increase in size from 0·08 to 0·09 μ in length and 0·03 to 0·04 μ in breadth in the oötype to 0·13 to 0·15 μ in length and 0·04 to 0·06 μ in breadth in the urine, while the embryo develops, so that when they are voided in the urine they contain a well-developed miracidium; but during this journey many die and become calcified. It is not known how long an egg must take before it escapes in the urine, but Looss points out that even the presence of an egg with a true miracidium is no evidence that the parent worms are alive.

Miracidium.—These eggs will simply die, unless they gain access to water, in which they hatch, and the ciliated miracidium escapes and swims about. In the so-called body cavity of this miracidium there are germinal cells.

Intermediate Hosts.—When miracidia are allowed to hatch out in water containing suitable and unsuitable snails, they crowd round and enter the former, while they neglect the others. In a short time all the miracidia have disappeared from the water containing suitable snails.

The snails which are suitable are those in which Leiper found the development to proceed viz., *Bullinus contortus* Michaud, 1829; *B. dybowskii* Fischer, 1891, and *B. innesi* Bourguignat. In South Africa Becker has experimentally implicated *Bullinus* (*Physopsis*) *africanus* as an intermediary.

Within these molluscs the miracidium makes its way into the liver and becomes changed into a smooth-walled sac the sporocyst —from which are formed daughter sporocysts, and from these cercariæ. In any case the cercaria is the end of this stage, and is alone the infective organism.

In some of our experiments we so heavily infected our snails that they died, but in nature this does not take place.

Cercariæ.—If an infected snail is allowed to remain in clear water it is amazing the quantities of cercariæ which may escape therefrom into the water and swim about.

Infection.—Leiper has shown that these cercariæ may penetrate the skin and infect animals. They may also penetrate the mucosa of the mouth and throat, and then by gradual growth and differentiation of the organs become male or female adult worms.

Pathogenicity.—It is usually the cause of urinary schistosomiasis, or, as it is better known, vesical Bilharziosis, but occasionally it may give rise to Bilharzial Dysentery.

Schistosoma mansoni Sambon, 1907.

Definition.—Schistosomum with spiny cuticle. *Male* with eight small testes. The gut forks unite early, and hence the straight intestine is long. *Female* with ovary in the anterior half of the body. Uterus very short, with only one lateral spined egg present at a time. Vitellaria in posterior two-thirds of body. *Development of cercaria* in *Planorbis boissyi* in Egypt and the Sudan, and *P olivaceus* Spix in Brazil, and *P. guadelupensis* in Venezuela.

Historical.—In 1851 Bilharz in Egypt noted that certain female worms possessed uteri containing lateral-spined eggs, and later Sonsino considered that these worms should be made into a species separate from those with terminal-spined eggs, but nothing came of it. In 1902 Castellani in Uganda noted that some patients had only lateral-spined eggs in the fæces and no ova in the urine. In

1903 Manson observed the same fact in a patient from the West Indies. In 1907 Sambon created a new species, *Schistosoma mansoni*, for the following reasons:—

1. Lateral-spined eggs are never found in the urine, but only in the fæces, and never occur in the bladder, only in the rectum and liver.
2. The egg is oval in shape, with a lateral spine, while that of *S. hæmatobium* is oblong and lanceolar in shape, with a terminal spine, and that of *S. japonicum* oval or roundish, with a lateral very small spine in about 75 per cent. of those examined by Looss.

The lengths and breadths are different. *S. mansoni*, 112 to 162 μ by 60 to 70 μ, *S. hæmatobium*, 110 to 120 μ by 46 to 50 μ; *S. japonicum*, 75 to 90 μ by 53 to 75 μ.

3. The males are apparently similar, but the females have a difference in the genital tract, which has been described by Fritsch and when mature contain lateral-spined ova in the uterus.
4. The geographical distribution of *S. mansoni* and *S hæmatobium* is different. *S. hæmatobium* is alone found in the Cape; *S. mansoni* is the only species in the West Indies and in South America.

Looss in Egypt immediately challenged Sambon's statements, but the history of this polemic will be found in the earlier editions of this book. We have all through felt that Bilharz, Sonsino, Manson, and Sambon, were right, and Ward always supported Sambon, and now this has been proved experimentally by Leiper to be correct.

In 1909 Da Silva described the adult worms as follows:—

Males The male measures 12 millimetres in length by 0·448 millimetre in breadth in the middle The ventral sucker is 0·540 millimetre behind he oral sucker.

The anterior end shows six sexual masses composed of testes and seminal vesicles The posterior end is tapering The spinous papillæ are not so marked as in *S hæmatobium*

Females The female worms measure 11·5 to 15 millimetres in length by 0·168 millimetre in breadth in the middle The distance between the two suckers is 0·224 to 0·252 millimetre. It is thickest in the middle, and tapers to each extremity. The anus opens 0·336 millimetre in front of the tip of the tail The oviduct is much shorter than in *S hæmatobium*, and enters the vitelline ducts after only a short turn. The uterus contains laterally spined eggs The eggs measure 140 μ by 62 μ, with 18 μ as the length of the spiculum The miracidium escapes by a transverse rupture of the shell, and measures 153 μ by 72 μ.

In 1911 Flu, in studying the Bilharziosis in Surinam, concluded that *S. mansoni* is distinct from *S. hæmatobium* because (1) *S hæmatobium* has eggs differently shaped from those of *S mansoni* ; (2) the anterior border of the lateral folds in the male *S hæmatobium* forms almost a right angle with the anterior portion of the body, while in *S mansoni* the transition is more gradual; (3) the ovaries of *S mansoni* have always a more or less winding course, a character not described for any other species of *Schistosoma* ; (4) the oötype is asymmetrical in relation to the long axis of the worm; the oviduct opens laterally on the ventral side where the shell gland is situate; (5) *S. mansoni* lives in the region of the mesenteric veins, and *S. hæmatobium* predominates in the pelvic veins; (6) *S. mansoni* gives rise to an illness like katayama disease, and never to the bladder symptoms produced by *S. hæmatobium*: (7) the morbid anatomy of cases invaded by *S. mansoni* agrees with those invaded by *S. japonicum*, and differs considerably from those caused by *S. hæmatobium*; (8) the geographical distribution is in opposition to Looss's view that the lateral-spined eggs are unfertilized because they are the only eggs found in Brazil, the Antilles, and Surinam.

He also found a single type of egg with lateral spine in the uterus and oötype of sixty females.

In 1915 Leiper's work in Egypt proved that the miracidium developed in a special snail, *Planorbis boissyi*, and that the vertebrate could be infected by the skin or oral mucosa.

In 1917 Chalmers and Pekkola in the Anglo-Egyptian Sudan have experimentally infected the same snail with the miracidia, and obtained cercariæ, and in the same year Lutz carried out similar experiments in Brazil with *P. olivaceus*.

In 1917 Iturbe, working in Caracas, Venezuela, found that the miracidia could infect *Planorbis cultratus* and *P. guadelupensis*, but the latter was more easily infected, and showed typical cercariæ by the end of the sixth week. He considers it to be the true carrier of the infection there. He noted that it was easier to infect animals *per os* than by the skin. He found no less than 120 out of 400 specimens of *P. guadelupensis* to be naturally infected around Caracas. The 'rediae' described by him have since been recognized as immature stages of a new species of Tetracotyle.

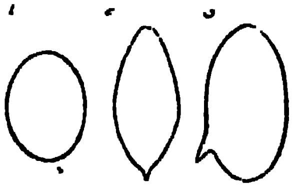

FIG. 230.—OUTLINES OF TH OF (1) *S. japonicum* (WITHOUT SPINE); (2) *S. hæmatobium*, (3) *S. mansoni*. (After Sambon)

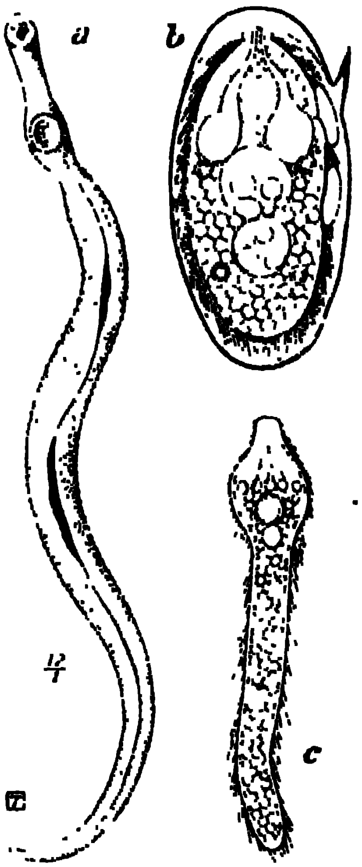

FIG. 231.—*Schistosoma mansoni* (After Holcomb) *a*, Male; *b*, egg; *c*, larva.

Morphology.—Sufficiently described above.

Life-History.—The adults live chiefly in the mesenteric veins, and the ova pass into the submucosa of the large bowel and through this into the fæces, and so escape from the body. The egg is oval, 112-162 × 60-70 microns, and possesses a well defined lateral spine.

The miracidia quickly hatch when placed in water in the tropics, and swarm around *Planorbis boissyi*, into which they disappear so rapidly that in twenty minutes none will be visible in the water.

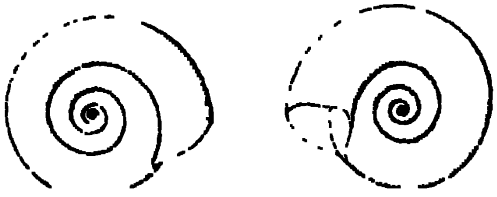

FIG. 232. *Planorbis boissyi* POTIEZ AND MICHAUD, 1838.

They pass to the liver of the mollusc and form sporocysts, rediæ, and cercariæ and finally end in cercariæ, which, leaving the snail and swimming about the water, enter the skin or mucosa of the mouth or throat and so infect man.

Pathogenicity. -*S. mansoni* is the cause of intestinal schistosomiasis (Chapter LXXIX.)

FIG. 233. SPOROCYSTS OF *Schistosoma mansoni* SAMBON, 1907, STILL PARTIALLY EMBEDDED IN TISSUE FROM THE LIVER OF THE PLANORBIS.

(After Leiper, from 'Researches on Egyptian Bilharziosis.')

FIG. 234. CERCARIA OF *Schistosoma mansoni* SAMBON, 1907.

(After Leiper.)

Schistosoma japonicum Katsurada, 1904.

Synonym. *Schistosomum cattoi* Blanchard, 1905.

Definition. -Schistosoma with a nearly smooth cuticle. *Male* with a few spines or protuberances along the margins of the gynæcophoric canal in the fresh condition. Testes six to eight, irregularly elliptical. Intestinal cæca unite very late and form a very short intestine. *Female* with ovary almost in the middle of the body. Vitellaria do not reach the posterior extremity. Uterus long, with many eggs, showing small lateral spines or thickenings. *Development of cercariæ* in species of *Blanfordia*.

History.- -For several years an endemic disease, characterized by enlargement of the liver and spleen, fever, diarrhœa with mucus and blood in the motions, associated with ascites and cachexia and extreme weakness, had been observed in the provinces of Yamanashi and Hiroshima of Central Japan and Saga of Kiushu. Eggs containing a miracidium were to be found in the liver and other organs.

Katsurada then examined cats in the neighbourhood, and found numerous *Schistosoma* in the portal veins of two cats in the province of Yamanashi, in which there were eggs exactly similar to those found in the above-mentioned disease. Catto a little later found the same parasite in a Chinaman from the province of Fukien. Logan and others have found it in Chinamen in the province of Hunan, Nicols in a case from the Philippines, and Manson and Sambon in cases from China.

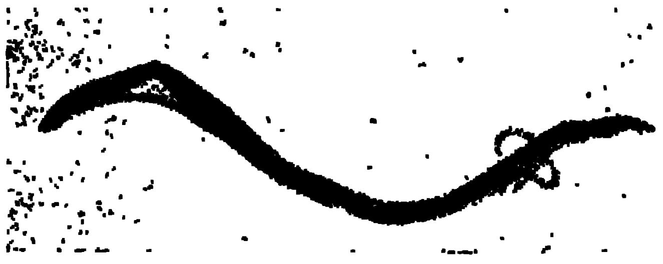

FIG. 235.—*Schistosoma japonicum* KATSURADA, 1904. MALE AND FEMALE. (From a photograph by J. J. Bell.)

With regard to the life-history, in 1908 Fujinami and Nakamura immersed cattle, cats, and dogs in water containing many miracidia from *S. japonicum*, but no infections followed. They then immersed a second series in rice-fields, ditches, and streams, reputed to be sources of infection, and heavy infections with *S. japonicum* resulted, the young parasites, 0·15 mm. in length, being found in the portal system on the third day after immersion.

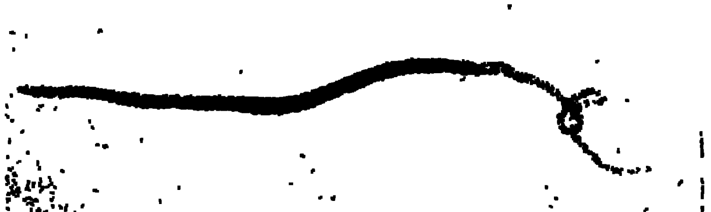

FIG. 236.—*Schistosoma japonicum* KATSURADA, 1904. FEMALE. (From a photograph by J. J. Bell.)

In 1911 Miyagawa described smaller forms as seen in the cutaneous tissues and peripheral vessels in two to twenty-four hours after immersion.

In 1913 Miyairi, experimenting with local snails, found a sporocyst in an unidentified snail.

In 1914 Miyairi and Sudzuki found a snail with a dark shell with seven spirals to be heavily and naturally infected with cercariæ, and, taking non-infected young samples, were able to find that the miracidia penetrated the cuticle of the snail, and found their way to the gills and the wall of the alimentary canal, where in twelve days the first rediæ appeared and gradually concentrated in the bile-ducts, where they grew and formed second rediæ. Mice were immersed in the water in which the full-grown snails were kept, and after three weeks many *S. japonicum* specimens were found in their livers.

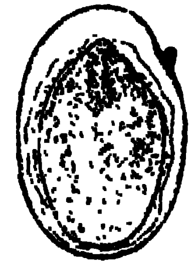

FIG. 237.—Egg of *Schistosoma japonicum*. (After Leiper.)

In 1914 Leiper confirmed this work in Japan, having recognized morphologically the cercariæ originating in sporocysts, mistermed rediæ by the Japanese authorities. The mollusc in question was named *Katayama nosophora*. *Katayama* is a synonym of *Blanfordia*.

In 1916 Narabayashi showed that man, cattle, horses, goats, pigs, cats, and dogs, are naturally infected by *S. japonicum*, which contains ferments which can digest albumen in an alkaline medium. He also found that in dogs and guinea pigs, after penetrating the skin, most of the parasites enter the venous blood stream, though some few enter arteries or lymphatics. Eventually they all enter the right side of the heart and are scattered all over the lungs, at the bases of which they collect and then migrate through the mediastinum, diaphragm, and liver into the portal system, while a few re-enter the circulation and reach the rectum.

Morphology. In general it resembles *S. hæmatobium*, but the cuticle of the female is smooth and that of the male has only the few spines mentioned above. There are no 'bosses.'

Male.—8-10 millimetres in length, 0·53 millimetre in breadth, with acetabulum larger than oral sucker. Œsophagus with two bulbs. Junction of intestinal cæca far back, and united intestine only one-fifth to one sixth of body length. The lateral excretory canals open into a dorsal pore. Testes six to eight in anterior part of hind body, from which the vasa efferentia unite into a common vas deferens, which opens just behind the acetabulum. Seminal vessels present.

Female.—8-26 millimetres in length and about 0·4 millimetre in breadth. Suckers armed with fine spines. Body thicker behind ovary, behind which gut forks unite. Ovary elliptical, dilated behind where the oviduct arises, and running forwards joins the vitellarian duct. Vitellaria well developed, lying behind the ovary, but not quite reaching the posterior end of the body. Shell gland at the junction of the oviduct with the vitellarian duct. Canal forms an oötype, and then becomes the uterus, which opens just behind the acetabulum.

Life-History.—The eggs vary from 50 to 300, and *in utero* are soft, and so can form various shapes. *Ex utero* they are oval, faintly yellow, and double contoured, 83·5 × 62·5 microns, and have small lateral spines or thickenings, and at the opposite side cap-like thickenings.

The miracidia hatch out quickly and develop into cercariæ in

Blanfordia nosophora. The cercaria is barrel-shaped, tapering towards the anterior end, mouth with two short lancet-shaped bristles. Small ventral sucker at posterior one-sixth of body. Hinder end with three pairs of poison glands, from each of which a duct runs forwards to open into the mouth. Two pairs of laterally placed flame cells with vessels. In the middle of this body there is an oval light brown body with a small anterior canal. The cercariæ penetrate the skin, pass via the veins to the heart, and so to the lungs, from the bases of which they penetrate the mediastinum, diaphragm, liver, and so enter the portal vein, from which the eggs pass to the submucosa and mucosa of the colon and cause growths. The adult worms can live at least two years in the vertebrate.

Pathogenicity.—The cercariæ, while entering the skin, cause the disease *kabure*, and in the body *katayama disease*.

Christophers and Stephens' Schistosoma.

Christophers and Stephens in 1903 described a *Schistosoma* egg which differs from the usual descriptions, and may belong to a new and as yet unknown species or genus, but it was found with ordinary *S. hæmatobium* eggs, and may therefore be an abnormality. The egg was found in Madras; it was of an elongated, spindle shape, with a long snout-like process extending from the broader end (205·2 μ by 53·2 μ).

New Schistosoma.

In 1904 Salomone and Bello found portions of a worm which they think may be a new *Schistosoma* in a patient suffering from hæmaturia contracted in Brazil. It may, however, have been a *S. mansoni* which very occasionally occurs in the bladder wall and is a common infection in Brazil.

CHAPTER XXV

CESTOIDEA

Cestoidea—History—Morphology—Life History—Habitat—Classification—Cestodes in man—References.

CESTOIDEA Rudolphi, 1808

Definition. Platyhelmia without alimentary canal in any stage of the life cycle, with segmented body, in which the epidermis, which has sunk into the parenchyma, secretes a thick cuticle. Lime-secreting cells are developed in greater or less number, and form calcareous concretions. Organs of fixation of a variable character are developed. The habitat of the adult worm is typically the intestine, and that of the larval form some other part of the body, normally that of another host.

History. It is believed that cestodes were known to the ancients, and that the reason why Moses, who figures largely in the history of Tropical Medicine, forbade the Israelites to eat pigs and such animals, was because of the parasites known to exist in their flesh.

Aristotle knew the proglottides of tapeworms, and as early as 1502 *Taenia* was distinguished from *Bothriocephalus*. Tyson (1683) discovered the head of the tapeworm of a dog. Redi (1687-1705) came to the conclusion that *Cysticerci* were animals, and Zeder (1800) formed them into a separate group, *Cystici*; but Kuchenmeister in 1851 proved by feeding experiments that these were only the larvæ of tapeworms, and that, as a rule, two different kinds of animals were required as hosts in order that the life-cycle might take place.

Leuckart, Braun, Fuhrmann, Looss, Sonsino, Grassi, Blanchard, von Linstow, Luhe, Stiles, Leiper, and Sambon may be mentioned as investigators who have greatly improved our knowledge of these parasites.

Morphology. There are two groups of cestodes, one called the Cestodaria containing genera with only a single segment, and another Cestoda, in the restricted sense of the word, which includes all forms possessing a scolex and segments. It is with this latter group that we are now concerned.

The true cestodes are easily recognized by their band-like segmented body, which is usually of a white colour. They are broad and large posteriorly, becoming narrower and narrower till the place is reached where they are attached to the intestinal wall. This anterior end is called the 'scolex,' while the segments are called 'proglottides.' The scolex is divisible into a broader anterior portion called the head, and a narrower posterior portion, the neck.

The head is provided with muscular suckers, which keep it attached to the mucous membrane of the bowel. Often there are also hooks present on some part of the head, not infrequently on an anterior projection called the rostrum. The neck is constricted, and shows posteriorly faint rings indicating the commencement of new segments, which are always formed from the neck.

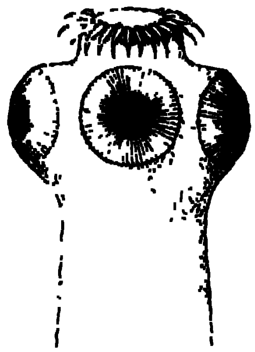

FIG. 238.—HEAD OF *Taenia solium*. (After Leuckart.)

Behind the head come the proglottides, the youngest being those situated anteriorly, and the most fully developed posteriorly. Their number is very variable, and their size increases from before backwards. They contain the male and female sexual organs.

The whole surface of the worm is covered by a thick, non-chitinous cuticle, said to contain a quantity of lime salts, under which lies a basal membrane; beneath this come the cuticular muscles, and then the cortical parenchyma, in which lie the sunken epithelial cells, nerve cells, sense organs, excretory cells, etc. Among these cells are peculiar calcareous corpuscles, varying from 3 to 30 μ in diameter, and having essentially the structure of a fat cell, that is to say they are composed of concentrically deposited calcareous material enclosed in a cell with a nucleus at one side. These corpuscles are highly characteristic of a Cestode. The calcareous matter is composed of 79 per cent. organic matter and 21 per cent. of lime salts in the form principally of the carbonate, but also of an albuminate and a urate. Their function is not understood; perhaps it is skeletal, perhaps protective.

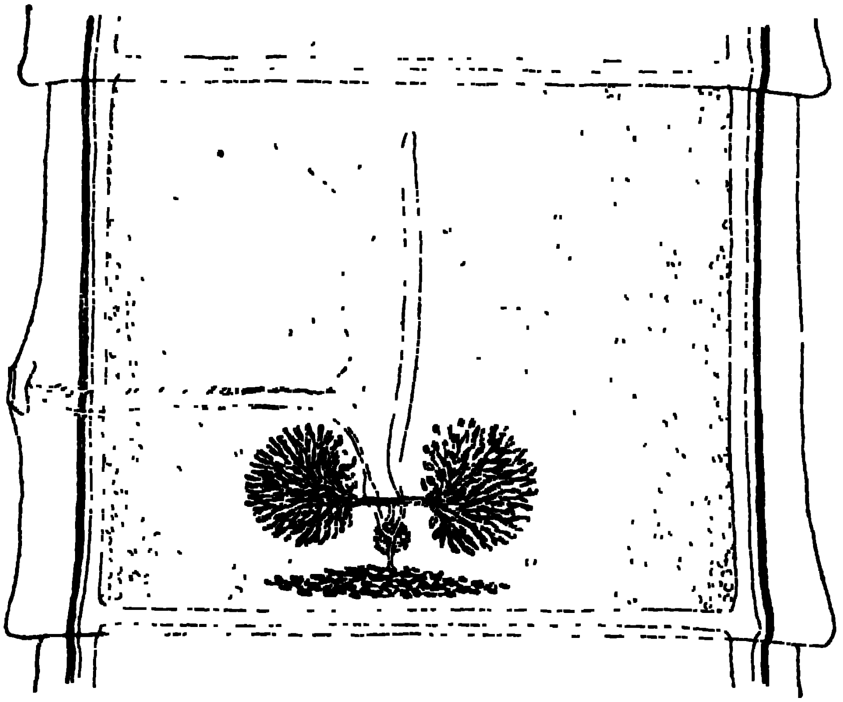

FIG. 239.—MATURE SEGMENT OF *Taenia saginata* GOEZE, 1782. (After Leuckart.)

In the cortex come the longitudinal muscles, beneath which are the transverse muscles, which enclose a central area of the parenchyma called the medullary layer, and therefore separate cortical from medullary layers.

There is no alimentary canal, and the excretory system with its flame cell terminations consists of anastomosing capillaries emptying into a dorsal and ventral collecting tube on each side of the body, which run from the scolex to the last proglottis, where they open to the exterior. In the originally posterior proglottis there is a pear-shaped excretory vesicle in the middle of the posterior edge, but this arrangement is lost when this proglottis drops off, and then the tubes open as a rule separately on the last proglottis. The nervous system consists of one ganglion in the scolex and two nerve cords. The generative organs gradually develop in the proglottides as they grow older, the youngest having no trace of them. With the exception of the end portions, these organs lie in the medullary layer of the body.

The male organs, which are the first to reach maturity, usually consist of numerous follicular testes scattered over the dorsal portion of the medullary layer, but may be consolidated into one to three glands. The efferent ducts from these unite about the middle of the proglottis into a vas deferens, which, after a wavy convoluted course, enters a cirrus pouch and terminates in the genital atrium near the vaginal orifice.

The female reproductive organs consist usually of two ovaries, which lie near the ventral surface of the medullary layer, from which a common oviduct runs to join with the spermatic duct, which, after travelling a certain distance, is dilated to form a receptaculum seminis, and continued as the vagina to the female opening in the genital atrium. After the junction with the spermatic duct, the oviduct is joined by the common duct of the yolk or vitellogene gland or glands, and then, forming the ootype, receives the ducts of the shell gland, and passes on to enter the uterus. This is usually a blind tube, but may open by a special aperture on the same or the opposite surface to that on which the genital atrium is found.

When the uterus becomes laden with eggs, it is apt to alter its appearance and become branched, and grows, filling up the proglottis, while the male generative organs atrophy and disappear (*vide* Fig. 253, p. 614).

Life-History.—The proglottis can fertilize itself with or without the use of the cirrus, or different proglottides may fertilize one another. In any case, the receptaculum seminis receives the spermatozoa, which travel down the spermatic duct, and, meeting the ovum, fertilize it. The fertilized ovum now obtains its yolk (vitellus) and its shell, and then passes into the uterus, from which it may escape by the uterine orifice when there is one, or not until the proglottis is destroyed.

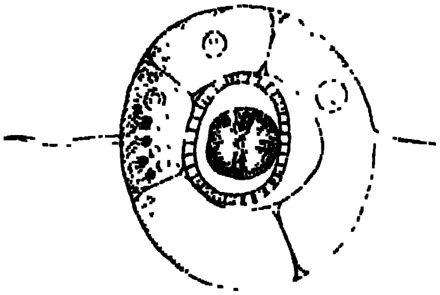

FIG. 240.—UTERINE EGG OF *Tænia saginata*. (× 375.) (After Leuckart.)

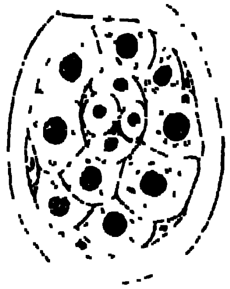

FIG. 241.—OVUM OF *Dibothriocephalus latus*. (After Leuckart.)

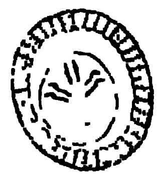

FIG. 242.—FÆCAL EGG OF *Tænia solium*. (× 300). (After Leuckart.)

Development usually begins in the uterus. An egg is as a rule oval in form, enclosed in a brown or yellow shell with or without an operculum. This shell contains food yolk and the developing embryo, whose cells form two membranes—an outer in contact with the shell, and an inner in contact with the embryo.

The outer envelope and the shell are soon lost, and when the embryo appears in the fæces it is surrounded by its inner envelope, the embryophore, and has developed six hooks. In this stage of development it is called an onchosphere.

It will therefore be evident that the so-called egg as seen in the fæces is not an egg at all, but the onchosphere with its embryonic envelope, which in certain species may be ciliated.

When the onchosphere enters the alimentary canal of a new host, generally of a different class from the original host it throws off its envelope, and works its way into the tissues by its hooks until it arrives in some suitable organ, when it throws off its hooks, encysts, and forms either a little bladder-like cyst, from the wall of which the scolex develops (the whole being called a '*Cysticercus*'; if the cyst is small, it is called a 'cysticercoid'; and if in addition it has a caudal appendix, a 'cercocystis'), or it develops directly into the scolex without the intervention of a cyst, forming a plerocercoid (πλήρης, full; κέρκος, a tail). These wanderings of the onchosphere in search of a suitable resting-place may produce unpleasant symptoms if there are a number of parasites. The time occupied in the transformation of an onchosphere into a *Cysticercus* varies, being from two to six months, or longer.

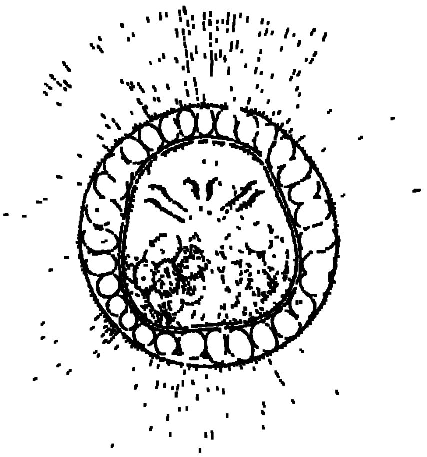

FIG. 243.—FREE CILIATED EMBRYO OF *Dibothriocephalus latus*.
(After Leuckart.)

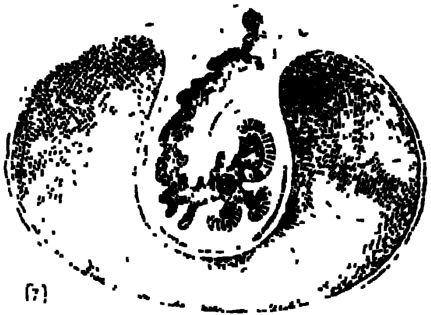

FIG. 244. CYSTICERCUS OF *Tænia saginata* GOEZE, 1782.
(After Leuckart.)

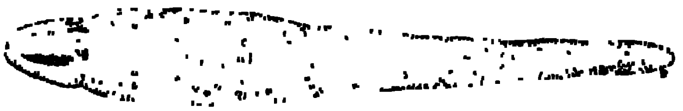

FIG. 245. PLEROCERCOID OF *Dibothriocephalus latus*.
(After Leuckart.)

With but rare exceptions the *Cysticercus* does not develop further until it enters another and different host, though some, like *Hymenolepis murina*, which is said to have its larvæ in the villi and its adults in the intestine of the rat, infest only one host.

Often the *Cysticercus* is found in a herbivorous animal, while the tapeworm occurs in a carnivorous or omnivorous animal. Infection is direct by feeding, for in the alimentary canal the cyst dies off, and leaves the scolex, which develops in the course of a few weeks into an adult tapeworm, whose span of life appears to be about a year, but may be much more or much less. An example is *Cysticercus fasciolaris* of the mouse, which becomes *Tænia crassicollis* in the cat. Abnormalities are often met with in the segments.

Habitat. As a rule the adult lives in the alimentary canal usually of a vertebrate, but they may be found in the liver and pancreas. They are capable of active movements during life. Food is obtained by osmosis from the contents of the alimentary canal.

Classification.—The classification followed is that of Monticelli, given by Braun in Bronn's 'Klassen und Ordnung des Thierreichs.'

The *Cestoidea* Rudolphi, 1808, are divided into *Cestoidaria* Monticelli, 1892, which are Cestodes consisting of a single segment containing a single set of reproductive organs, and *Cestoda sensu stricto* Monticelli, 1892, which are the typical cestodes with a scolex and segments. The subclass Cestoda are divided into orders as follows:—

Cestoda Sensû Stricto Monticelli, 1892.

Synonyms.—*Pollaplasiogonei* E. Blanchard, *Cestodes digeneses* van Beneden, *C. polyzoa* Lang.

Definition.—Cestodes in which the adult worm consists of a scolex and proglottides.

ORDER I. PSEUDOPHYLLIDEA *Carus*, 1863.—**Synonyms.**—*Bothriocephaloidea*. Scolex armed or unarmed, with two usually slightly developed, groove-like suckers, with three genital orifices. Vitellaria situated laterally. Eggs with or without a lid.

ORDER II. TETRAPHYLLIDEA *Carus*.—Scolex armed or unarmed, with four very motile pedunculated or sessile bothridia, or with four round suckers, no uterine orifice; cirrus and vagina open at the sides. Vitellaria situated laterally.

ORDER III. CYCLOPHYLLIDEA *van Beneden*.—Scolex with four suckers, between which there is an apical rostellum with or without hooks; segmentation distinct; no uterine orifice; vitellogene gland single, placed behind the ovary. Eggs without lids.

ORDER IV. DIPHYLLIDEA *Carus*.—Head stalk armed with hooklets, with solex, rostellum, and two bothridia.

ORDER V. TRYPANORHYNCHA *Diesing*.—Scolex with two or four bothridia, and four retractile armed rostella.

The only orders which contain parasites found in man are I. and III.

CESTODES IN MAN.

The cestodes which are found in man may be classified as follows:—

Order	Family	Subfamily.	Genus	Subgenus.	Species.
Pseudophyllidea	Dibothriocephalidæ	Dibothriocephalinæ	Dibothriocephalus		1. D. latus.
					2. D. cordatus.
					3. D. parvus.
					4. D. grandis.
					5. D. braunii.
			Diplogonoporus		
			Sparganum		6. S. mansoni.
					7. S. prolifer.
					8. S. baxteri.
		Ligulinæ	Braunia		9. B. jassyensis.
Cyclophyllidea	Tæniidæ	Dipylidiinæ	Dipylidium		10. D. caninum.
			Hymenolepis	Hymenolepis	11. H. nana.
					12. H. diminuta.
				Drepanidotænia (?)	13. H. lanceolata (?).
		Davaineinæ	Davainea		14. D. madagascariensis.
					15. D. asiatica.
		Tæniinæ	Tænia	Tænia	16. T. solium.
				Tæniarhynchus	17. T. saginata.
					18. T. africana.
					19. T. hominis.
					20. T. philippina.
					21. T. confusa.
					22. T. bremneri.
			Echinococcus		23. E. granulosus.
					24. E. multilocularis.

Two tapeworms are not included in this list: *Tænia (Tænia) tæniæformis* Bloch, 1750, a tapeworm found in cats, and *T. (Tænia) pisiformis* Bloch, 1780, a tapeworm found in rabbits, because no definite evidence exists that man has ever been infected by them.

At the time of writing, man alone is known to be the host of the adults of the following worms: *Tænia solium*, *T. saginata* (there is probably no doubt about this), *T. africana*, *T. hominis*, *T. philippina*, *T. confusa*, *T. bremneri*, *Dibothriocephalus parvus*, *Hymenolepis nana* (?), *Davainea madagascariensis*, *D. asiatica*. Other hosts may yet be found.

The following are only occasional parasites in man: *Dibothriocephalus latus* (true host may perhaps be the dog?), *D. cordatus* (true host, the seal and walrus), *Hymenolepis diminuta* (true host, the rat and mouse), *Drepanidotænia lanceolata* (true host, ducks and geese).

Therefore in man there is the question of intestinal tæniases to be considered. But cysts may also develop in man from *T. solium* and *Echinococcus granulosus* and *multilocularis*. From the species of *Sparganum* larval forms give rise to somatic tæniiases. These affections, with their treatment, will be considered later, as will the treatment.

It must be noted that the cysticercus of *T. saginata* is not included, as it is very doubtful whether it has ever been found in man.

Cysticercus acanthotrias Weinland, 1858, is the same as *C. cellulosæ* —*i.e.*, the larva of *T. solium*.

The following tables, modified from Stiles, may be of help, as they give the names of recognition of the genera, and the species of *Tænia*, as determined by the head or the segment, and also a scheme for recognizing the eggs.

Table of Genera.

A. Head with two elongated or slit-like suckers; uterus forms a rosette; genital pores ventral—*Dibothriocephalidæ*.

I. *Tapeworms*.—Single set of genital and uterine pores present in medium ventral line—*Dibothriocephalus*.

Double set of uterine and genital pores present in ventro submedium line—*Diplogonoporus*.

II. *Plerocercoids* (*Sparganum*). Probably larval forms of this group.

B. Head with four cup-shaped suckers, uterus does not form a rosette, genital pores lateral—*Tæniidæ*.

I. Large forms, ripe segments 9 to 35 millimetres long. Uterus median, with lateral branches—*Tænia*.

II. Smaller forms, ripe segments up to 7 millimetres long.
 (a) Genital pores single, rostellum with no more than two hooks.
  (1) Suckers not armed. Three testes in each segment—*Hymenolepis*.
  (2) Suckers armed with hooks. 15 to 50 testes in each segment—*Davainea*.
 (b) Genital pores double, rostellum with several rows of hooks—*Dipylidium*.

Table of the Species of Tænia found in Man.

A. SPECIMEN IS A TAPEWORM.

Head Characters.

I. Head armed with hooks. Subgenus: *Tænia*. Species: *T. solium*.

II. Head unarmed. Subgenus: *Tæniarhynchus*.
 (1) Circular ring around head behind the suckers, which are directed postero-anteriorly—*T. hominis*.
 (2) Without circular ring.
  (a) Head cuboid, 1·5 to 2 millimetres in diameter; suckers 0·7 to 0·8 millimetre in transverse diameter—*T. saginata*.
  (b) Head small, 1·38 millimetres broad, 1·03 millimetres thick, 0·17 millimetre long; suckers 0·63 millimetre in transverse diameter—*T. africana*.
  (c) Head small cuboid, 1 to 1·5 millimetres in diameter, 0·75 millimetre thick, and 1 millimetre long; suckers 0·34 to 0·37 millimetre in transverse diameter—*T. philippina*.

III. Head not known—*T. confusa*, *T. bremneri*.

Segment Characters.

I. *Segment Longer than Broad.*

(a) Only in the last 100 segments—*T. saginata*.
(b) In the last half of the worm—*T. solium*.
(c) In nearly the entire worm—*T. confusa*.
(d) In the entire worm—*T. africana*.
(e) Known segments very large, 28·6 by 8·5 millimetres on an average—*T. bremneri*.
(f) Unknown.—*T. hominis*.

II. *Segment Broader than Long.*

Except in the terminal segments, which are equilateral or slightly longer than broad --*T. philippina.*

B. Specimen is a Cysticercus.

I Small bladder-worm with one scolex - *Tænia.*
  (*a*) Head armed—*T. solium*
  (*b*) Head unarmed (very rare, if ever present)- -*T. saginata.*
II. Large bladder-worm with brood capsules, inside which are the scolices - *Echinococcus.*

C. Specimen is an Egg

I With an operculum - -*Dibothriocephalidæ.*
68 to 71 μ × 45 to 50 μ *D. latus.*
75 to 80 μ × 50 μ *D. cordatus*
63 48 μ to 50 μ brownish *D. grandis.*

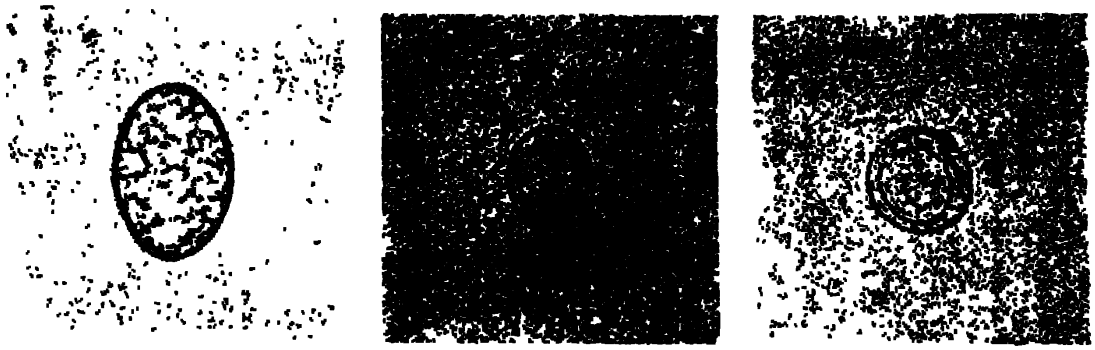

Fig. 246. *Dibothrio-cephalus latus*
Fig. 247. *Tænia solium*
Fig. 248.- -*Dipylidium caninum.*

Figs. 246-248. Eggs of Cestode Worms from Human Fæces.
(From photographs by J. J. Bell.)

II Without an operculum and with a six hooked embryo -*Tæniidæ.*
  (*a*) Egg with a thick, radially-striated, inner shell or embryophore *Tæniinæ.*
    (A) Embryophore round or oval, 39×33 μ. Africa—*T. africana*
    (B) Embryophore oval, whitish to yellow, 39 × 30 μ. America *T. confusa.*
    (C) Embryophore, 38 × 30·4 μ. Africa- -*T. bremneri.*
    (D) Embryophore oval, 35 to 41, μ × 26 to 35 μ. Philippines *T. philippina.*
    (E) Embryophore, ovoid, rusty brown, 35 to 40 μ × 20 to 30 μ Cosmopolitan and common -*T. saginata*
    (F) Embryophore almost round; brown, 31 to 30 μ. Not uncommon in the tropics---*T. solium.*
    (G) Egg and embryophore unknown. Asiatic Russia- - *T. hominis.*
  (*b*) Egg with a thin, membranous inner shell.
    (1) *Not in Capsules- -Hymenolepis.*
      (*a*) Egg oval or globular, with two distinct membranes—outer 30 to 60 μ, inner 16 to 34 μ- -mammillate projection at each pole- *H. nana.*

(b) Egg round or oval; outer membrane, 54 to 86 μ; yellowish, may be radially striated; inner membrane, 24 to 40 μ × 20 to 35 μ, with not very evident mammillate projection at each pole. *H. diminuta.*

(c) Egg oval or spherical, outer membrane, 50 to 100 μ × 35 to 100 μ, inner membrane 30 to 40 μ × 25 μ, occasionally polar papillae, very rare in man. *H. lanceolata.*

In Capsules.

Eight to twenty [illegible] in a capsule, egg spherical, 43 to 50 μ. *D. caninum.*

One to three eggs in a capsule, with calcareous corpuscles. Eggs with two shells and two mammillate projections, onchosphere, 8 μ. *D. madagascariensis.*

Egg capsules without calcareous corpuscles, mature eggs not observed. *D. asiatica.*

ORDER I. PSEUDOPHYLLIDEA Carus

This order has three families [illegible] P[illegible] Amphitretidae. The first [illegible] contains human parasites.

Family Dibothriocephalidae [illegible] Pseudophyllidea with variously developed suckers, and a uterus which forms a rosette. Eggs with opercula. There are two subfamilies with species found in man: (1) Dibothriocephalinae, (2) Ligulinae.

Subfamily 1. Dibothriocephalinae. The suckers or bothria are more or less definite slit-like furrows. Proglottides distinct, and drop off in groups. Genus 1. *Dibothriocephalus*, Genus 2. *Diplogonoporus*, Genus 3. *Sparganum.*

Dibothriocephalus Lühe, 18[illegible]

Synonyms. *Diphyllobothrium* Cobbold, 1858 (con[illegible] o be correct name by some authors); *Bothriocephalus pro parte* Rud[illegible] o, *Dibothrius pro parte* Rudolphi, 1819, *Dibothrium pro parte* Diesing.

Dibothriocephalinae with a more or [illegible] longated, unarmed scolex with flat suckers cutting deeply into the head [illegible] ngle genitalia in each proglottis. [illegible] (3) *D. cristatus*, (4) *D. parvus.*

Dibothriocephalus latus Linnaeus, 1758.

Synonyms. *Taenia lata* L., 1748, *T. vulgaris* L., 1758, *T. membranacea* Pallas, 1781, *T. tenella* Pallas, 1781, *T. dentata* Batsch, 1786, *T. grisea* Pallas, 1796, *Bothriocephalus latus* Bremser, 1819, *Dibothrium latus* Diesing, 1850, *B. balticus* Küchenmeister, 1855, *B. cristatus* Davaine, 1874, *B. latissimus* Bugn., 1886.

History. This tapeworm has long been known in Europe, especially in French Switzerland and the Baltic provinces, Germany, and in many other parts. It is however well known in Asia, Turkestan, and Japan; in Africa about the Lake Ngami, in Madagascar, and in North America.

It occurs in man, and dogs, and cats.

Morphology. It is about 9 metres in length, with some 3,000 to 4,200 segments; colour yellowish grey. Scolex elongated, almond-shaped, 2·5 millimetres in length, with two deep laterally placed suckers. Neck very narrow, and of variable length.

Proglottides very broad (10 to 20 millimetres), breadth being greater than the length; postero-lateral angles project. Testes situated dorsally; vas deferens has a vesicula seminalis and a cirrus sac which opens dorsally. Vaginal opening directly behind this, leading into a receptaculum seminis. Yolk glands in pairs, shell gland behind, ovaries on each side of the median line behind. Uterus is arranged in a rosette, with four to six convolutions.

and possesses its own separate opening. The genital orifices are two in number: a transverse slit for the cirrus pouch and the vagina, and a posterior roundish opening for the uterus. Calcareous bodies present. The brown eggs are oval, 68 to 71 μ in length, and 45 μ in breadth, with an operculum.

Life-History.—The egg remains undeveloped for a longer or shorter time, and eventually a six-hooked onchosphere enclosed in a ciliated embryophore, escapes through the lid opening, after undergoing a preliminary development in a species of *Cyclops*, then gets into certain fish, particularly *Esox lucius* (pike), *Lota vulgaris* (Miller's thumb), *Perca fluviatilis*, *Salmo umbla*, *Trutta vulgaris*, *T. lacustris*, *Thymallus vulgaris*, *Coregonus lavaretus*, *C. albula*, and *Onchorhynchus perryi* in the muscles of which it becomes a plerocercoid.

When these fish are eaten, the plerocercoids quickly develop into the tapeworm, eggs appearing in the fæces in some twenty-one to twenty-four days.

Habitat.—Man, dog, cat and fox.

Pathogenicity.—It produces a severe form of anæmia, together with fever (99° to 104° F.) in some cases, and a quick pulse, which is supposed to be due to the action of a toxin.

Dibothriocephalus cordatus R. Leuckart, 1863.

Synonym.—*Bothriocephalus cordatus* R. Leuckart, 1863.

This parasite is commonly found in the seal, the walrus, and the dog in Greenland and Iceland. It may infest man.

Morphology.—The principal features are the short, broad, heart-shaped head with the grooves on the flat surface, the absence of the neck, and the length only 1 to 1¼ metres. Uterine rosette with six to eight loops. Eggs with lids 75 μ in length by 50 μ in breadth.

Dibothriocephalus parvus Stephens, 1908.

This parasite was found by Elkington in Tasmania in 1906 in a Syrian aged thirty-seven, who had not long arrived from his native country.

Morphology.—Scolex not known. Proglottides with darkly coloured central, uterine rosette with four to five loops on each side of the median line; largest segment, 5 by 2 millimetres. Genital atrium 0·4 to 0·5 millimetre behind the anterior margin, uterine opening some distance behind the genital atrium. Calcareous bodies were not seen. Eggs 59 by 40 μ.

Diplogonoporus Lönnberg, 1892.

Synonym.—*Krabbea* R. Blanchard, 1894.

Bothriocephalinæ with short scolex, powerful suckers, no neck, and two sets of genitalia side by side in each proglottis.

Type Species.—*Diplogonoporus balænopteræ* Lönnberg, 1892.

Diplogonoporus grandis R. Blanchard, 1894.

Synonym.—*Krabbea grandis* R. Blanchard.

So far this parasite has only been observed twice in Japanese in Hiogo, Japan.

Morphology.—Scolex unknown. Proglottides 1·5 millimetres broad in front and 2·5 millimetres broad behind, very short, only 0·45 millimetre. Two ventral grooves on either side of the median line with the genital pores. Uterus with few loops. Eggs brown; thick shell, 63 to 68 μ in length and 50 μ in breadth, with opercula.

Diplogonoporus brauni Léon, 1907.

Two specimens of this worm have been found in Roumania.

Morphology.—The worm presents the appearance of a thick, opaque, greyish ribbon 12 centimetres in length, marked by slight transverse rings and with a dorsal and ventral sucker which mark a division of the head into two unequal parts. There is no neck. The genital orifices are double, with a double genital apparatus in each ring. The vitellogene glands are situate peripherally. No genital sinus, no calcareous corpuscles.

Sparganum Diesing, 1850.

A collective group of larval stages of Dibothriocephalidæ which have not reached a stage in their development at which they can be determined generically: *Sparganum mansoni*, *S. prolifer*, *S. baxteri*.

Sparganum mansoni Cobbold, 1883.

Synonyms.—*Ligula mansoni* Cobbold, 1883; *Bothriocephalus liguloides* R. Leuckart, 1886; *Dibothrium mansoni* Ariola, 1900.

This larva was found by Manson while making a post-mortem on a Chinaman in Amoy, lying under the peritoneum near the kidneys and over the iliac fossæ; he also found one free in the pleural cavity. Scheube discovered another specimen in the urethra of a Japanese, and Sonsino a third in an Egyptian jackal.

Morphology.—Long, white ribbon-shaped parasites, with feeble movements. No head or definite structure visible. Length, 30 to 35 centimetres; breadth, 3 to 12 millimetres. At the broader end there is a sort of papilla. There is no reproduction by fission.

Sparganum prolifer Ijima, 1905.

Synonym.—*Plerocercus prolifer* Ijima, 1905.

In 1905 Ijima found this worm in a woman living near Tokio, and in 1907 Gates found the same or a similar worm in a man in Manatee, U.S.A.

Morphology.—The larva which lies enclosed in a cyst, may attain 1 to 12 millimetres in length by 2·5 millimetres in breadth. The head at the narrow end is motile, and capable of evagination and invagination. It shows an apical depression, which perhaps serves as a sucker, but there are no true suckers or other organs of attachment.

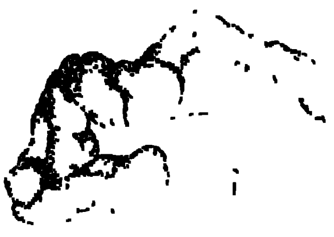

FIG. 249.—*Sparganum prolifer* IJIMA. (After Stiles.)

Calcareous spherical corpuscles can be found anywhere, except in the head. No genitalia are to be seen, but there is a good muscular and excretory system and food-reserve bodies. It can multiply by transverse division, and supernumerary heads may become independent, and may assume bizarre and irregular shapes. The adult is unknown.

Habitat.—It lives in the subcutaneous tissue and elsewhere in man.

Pathogenicity.—It produces nodules in the skin and fascia between the muscles and in the abdominal cavity. Associated with these nodules there may be considerable swelling of the integument, and, in fact, a condition not unlike elephantiasis may arise. Also there may be acne-like spots all over the body causing itching, which may lead to the escape of a worm from the spot. When a nodule is cut open, a cyst is found containing one or two worms, either filled with a watery fluid, or with a jelly or slime-like substance. Apparently after weeks or months the cyst-wall may become firm and thick, and encapsulate the worms. This condition may last for years, and apparently can kill the victim, who may be literally ' eaten up of worms.'

Sparganum baxteri Sambon, 1907.

This Dibothriocephalid larva was found by Baxter in an abscess in the thigh of a Masai in late German East Africa.

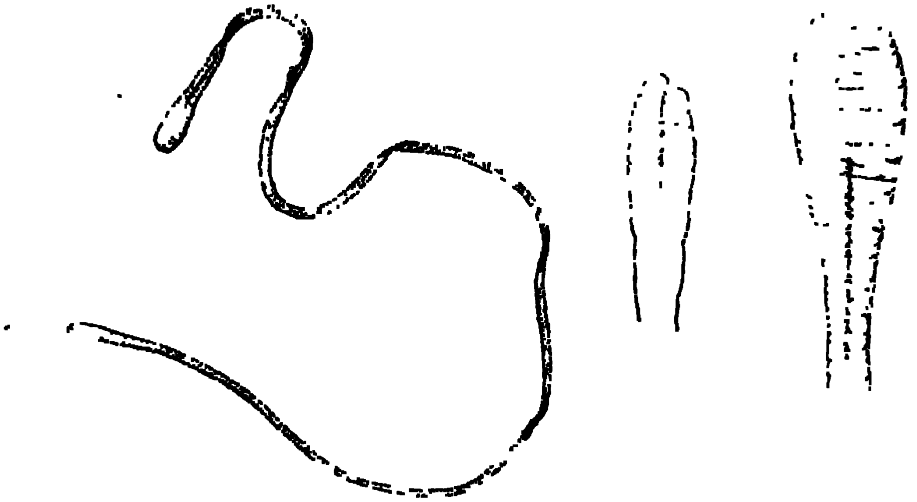

FIG. 250. *Sparganum baxteri* SAMBON.
(After Sambon.)

Morphology.—It has a long unsegmented body, 15 centimetres in length and 1 millimetre in breadth, with numerous irregular transverse folds, and a distinct longitudinal groove on the ventral surface. Anterior extremity is 2 millimetres broad, with a completely invaginated head; posterior extremity, 1·2 millimetres broad, with a shallow medium slit.

Leon has described a new tapeworm in man which he has referred to the Ligulinæ, in which it requires a new genus called *Braunia jassyensis* Leon 1908.

ORDER III. CYCLOPHYLLIDEA van Beneden.

There is only one family with human parasites.

FAMILY TÆNIIDÆ Ludwig, 1886.

Scolex globular or pyriform, with unarmed suckers, and an armed or unarmed rostellum. Vagina posterior to the cirrus. Mostly parasitic in mammals. Larval stage a cysticercus or cysticercoid. Subfamily 1. Dipylidiinæ; Subfamily 2. Davaineiinæ; Subfamily 3. Tæniinæ.

SUBFAMILY 1. DIPYLIDIINÆ Stiles, 1896.

Definition.—Tæniidæ, with armed rostellum and unarmed suckers. Genital pores marginal. Genitalia simple or double.

Uterus becomes divided into ovarium follicles, or entirely atrophied, and the eggs are set free into the parenchyma. Eggs with thin transparent shells, with or without appendages.

Genera.- (1) *Dipylidium*; (2) *Hymenolepis*.

Dipylidium R. Leuckart, 1863.

Definition. Dipylidiinæ of medium or small size, with retractile rostellum armed with several rings of alternating hooks, which have a broad basis. Genitalia duplicated, with pores on each side of a proglottis. Eggs with a double shell.

Dipylidium caninum Linnaeus, 1758.

Synonyms. *Tænia canina* Leuckart 1758, *Moniliformis* Pallas, 1781; *T. cucumerina* Blochmann, 1782; *T. elliptica* Batsch, 1786; *Dipylidium cucumerinum* Leuckart, 1863.

Dipylidium is frequently found in the dog and the cat, which are its proper hosts; in man it is only an accidental and rare parasite, having been first found by Dubois, a pupil of Linnaeus, in 1751. Melnikow showed that the scolex was to be found in the dog-louse (*Trichodectes canis*) and in that of the cat (*T. subrostratus*), as well as in the dog flea (*Ctenocephalus canis* Curtis), the cat flea (*C. felinis* Bouché), and in that of man (*P. irritans*), but how the infection reaches man is not definitely proved. Recently Blanchard has summarized sixty cases in man up to the year 1907, most of which occur among young children.

FIG. 251.—*Dipylidium caninum*. Nest of Eggs × 25. (After a photograph by J. J. [illegible])

Morphology.—It measures 15 to 35 and even to 40 centimetres in length, and the segments are from 1·5 to 3 millimetres in breadth.

The scolex has the typical rostellum, with three to four rings of hooks, diminishing in size from the first circle, where they are 12 to 15 μ, to the last, where they are only 5 to 6 μ in length, and four suckers, which are unarmed.

The genitalia are double, with pores on each side. The eggs are round, from 43 to 50 μ in diameter, with a thin shell.

Life-History.- The ripe proglottides by their own movement pass through the host's anus, and get into the fur, where the eggs infect the dog and cat louse, or flea, in which they develop into cysticercoids (*Cryptocystis trichodectis* Villot, 1882).

The dog bites the louse or flea and infects itself, and may pass on the cysticercoids to man by licking. The cat licks its fur, and gets infected in that manner.

Blanchard thinks that the cat spreads the parasite by infecting milk with the cysticercoids when it steals a drink from a bowl, the contents of which are afterwards given to children.

Hymenolepis Weinland, 1858.

Synonym.—*Diplacanthus* Weinland, 1858, *nec* L. Agassiz, 1842.

Definition.—*Dipylidiinæ* with small head, with armed, well-developed, or unarmed, rudimentary rostellum. Neck long. Proglottides serrated, longer than broad. Genital pores always on the left. Three testes. Eggs with three shells.

Type.—*H. diminuta.* The genus possesses two subgenera, *Hymenolepis* and *Drepanidotænia.*

Subgenus 1. Hymenolepis Sensu Stricto.

With the characters of the genus, but the hooks have the dorsal root much longer than the ventral, and number twenty-four to thirty.

Proglottis narrow, female genitalia ventral to or between testes.

Hymenolepis (Hymenolepis) diminuta Rudolphi, 1819.

Synonyms.—*Tænia diminuta* Rudolphi, 1819; *T. leptocephala* Creptlin, 1825; *T. flavopunctata* Weinland, 1858; *T. varesina* Parona, 1884; *T. minima* Grassi, 1886.

It is a parasite of *Epimys norvegicus*, *E. musculus*, and *E. rattus alexandrinus*, being not uncommon in rats in Ceylon.

The first human specimen was discharged by a child aged nineteen months, and was presented to the Boston Medical Improvement Society by Dr. Ezra Palmer in 1842. Since then a number of cases have been recorded in Philadelphia, Sicily, Italy, France, South America, and the West Indies.

Morphology.—The worm measures 20 to 60 centimetres in length, and up to 3·5 millimetres in breadth. The head is very small, only 0·2 to 0·5 millimetre in diameter, club shaped, and has a rudimentary, unarmed rostellum and four elliptical suckers. The segments measure 0·66 millimetre in length by 3·5 millimetres in breadth. The anterior proglottides show a yellow spot (hence the name *T. flavopunctata*), caused by the distended receptaculum seminis. The posterior proglottides show a brownish-grey colour, due to the mature uterus. The genital pore is situated laterally. The eggs are oval, with a diameter of about 60 μ.

Life-History.—It is a common parasite in rats and mice, while the cysticercus is said to live in the larva and imago of the meal-moth (*Asopia farinalis*), in an earwig (*Anisolabis annulipes*), and in the beetles *Acis spinosa* and *Scaurus striatus*, it is not likely that rat fleas are important, as the cysticercus has been found in *Ceratophyllus fasciatus* by Nicoll and Minchin, and Johnston in Australia has found it in *Xenopsylla cheopis*.

The infection in man is mostly among infants and children.

Hymenolepis (Hymenolepis) nana von Siebold, 1852.

Synonyms.—*Tænia murina* Dujardin, 1845, *nec* Gmelin, 1790; *T. nana* von Siebold, 1852, *nec* van Beneden, 1867; *T. ægyptiaca* Bilharz, 1852; *Diplacanthus nanus* Weinland, 1858.

This is the dwarf tapeworm of man, and was discovered by Bilharz in the ileum of a boy who died of meningitis in Cairo. It is found in Egypt, Europe, North and South America, Siam, and Japan, and is by no means a rare parasite in man. Calandruccio estimates that 10 per cent of the children in Sicily are affected. Stiles reports 4·8 per cent. for 125 children in Washington. The number found varies from one or two to several thousands in one individual.

There is doubt as to whether this worm is or is not identical with *Hymenolepis nana var. fraterna* Stiles, 1906, which is common in rats and mice. Probably it is distinct from this parasite, because Grassi and Looss were unable to transmit it to mice.

Morphology.—It is the smallest tapeworm in man, measuring only 10 to 15 millimetres in length, and from 0·5 to 0·7 millimetre in breadth.

The head is globular, and provided with a rostellum with one ring of twenty-four to thirty hooks, which are very small, 14 to 18 μ in length. The neck is relatively long.

There are about 150 proglottides 0·4 to 0·9 millimetre in breadth and 0·014 to 0·030 millimetre in length. The genital pore is marginal. The mature uterus contains about thirty or more eggs, which are oval and measure 30 to 48 μ, and contain onchospheres measuring 16 to 19 μ in diameter.

Life-History.—It is believed that the cysticercus will be found in some insect.

The nearly related *T. nana var. fraterna* completes its development entirely in the rat, for the cysticercus develops in the villus, while the adult lies in the lumen of the intestine.

Pathogenicity.—Owing to its small size it is apt to be overlooked, but there is no doubt that it spreads in crowded institutions and poorer families. Apparently, when the parasite occurs in small numbers no symptoms result but in considerable numbers disturbance may occur, which has been assigned by Mingazzini to the effects of toxins.

Treatment.—Male-fern is the best treatment (*vide* Chapter LXXV.).

Prophylaxis. While it is doubtful whether *T. nana* and *T. nana var. fraterna* are the same or different species, it will be necessary to guard against the contamination of food by rats and mice. Moreover, it must be remembered that the infection spreads in crowded dwellings, and therefore isolation of the infected child should be insisted upon.

Subgenus 2. Drepanidotænia Railliet, 1892.

With the characters of the genus but the hooks have a dorsal root much larger than the ventral, and are only eight to twenty in number. Proglottis broad, testes three, alongside which lies female genitalia.

Hymenolepis (Drepanidotænia) lanceolata Blochmann, 1782.

Synonyms.—*Tænia lanceolata* Blochmann, 1782; *T. anserum* Frisch, 1727; *T. acutissima* Pallas, 1781; *T. anseris* Blochmann, 1779; *T. lanceola* Batsch, 1786; *Halysis lanceolata* Blochmann, 1803.

It is common in ducks, geese, and other birds, including the flamingo, and has been found in man in Europe, but the record is considered to be very doubtful; probably the worm should not be included among human parasites.

Morphology.—It is about 30 to 130 millimetres in length and 5 to 18 millimetres in breadth, with a very small globular head. Eggs, with three envelopes, oval (50 by 35 μ).

Life-History.—The cysticercoid lives in a cyclops, which is eaten by ducks and geese.

SUBFAMILY 2. DAVAINEINÆ Braun, 1900.

Definition.—*Tæniidæ.* Rostellum and suckers armed. Eggs mostly encapsuled.

Genus.—*Davainea* R. Blanchard.

Davainea R. Blanchard, 1891.

Definition.—Davaineinæ, with a globular head, armed with two rings of hammer-like hooks and four suckers, surrounded by several rings of hooks.

Species.—*D. madagascariensis*; *D. asiatica*.

Davainea madagascariensis Davaine, 1869

Synonyms.—*Tænia madagascariensis* Davaine, 1869; *T. demarariensis* Daniels, 1895.

This worm was first discovered by Grenet in children at Mayotte (Comores). Over ten infections have been recorded: by Davaine from the Comoro Islands, Leuckart from Siam, Daniels from British Guiana, Blanchard from Nossi-Bé, four by Cherreau from Mauritius, and two by Garrison from the Philippines.

Morphology.—The worm is 25 to 30 centimetres in length, with a maximum breadth of 1·4 millimetres. The scolex has four large suckers and a rostellum, with ninety hooks (18 μ long). The proglottides number from 500 to 700, being 2 millimetres long by 1·4 millimetres broad. Genital pores are unilateral, and near the proximal corner. Testes number about fifty, with a long vas deferens and a fusiform cirrus pouch. The receptaculum seminis is long and broad. The uterus is composed of a number of tubes, rolled up on each side into an almost spherical coil. When mature, these windings uncoil and fill the proglottides; then they lose their walls, and the eggs, lying free in the parenchyma, become surrounded by proliferating cells, which form capsules for them.

As many as 300 to 400 of these capsules may exist in one proglottis, arranged in transverse rows.

The egg consists of the usual two membranes and an onchosphere, which is 8 by 15 μ.

Life-History.—The life-history is unknown, but it is suggested that the cysticercus may be found in the cockroach (*Periplaneta orientalis* or *P. americana*).

Allied genera are common in rats, hares, fowls, pigeons, turkeys, pheasants, partridges, grouse, and other birds.

Davainea asiatica von Linstow, 1901.

Synonym.- *Tænia asiatica* von Linstow, 1901.

This worm was found in a person in Aschabad, near the northern frontier of Persia, and consists of 750 proglottides without a head. The genital pores all lie on the same lateral border. The testes are globular, the cirrus pouch pyriform. The female organs lie anteriorly, with a large ovary and a small vitellogene gland. There is a large receptaculum seminis The uterus breaks into sixty to seventy large egg follicles. Nothing is known about the appearance of the mature egg, or about the life-history

SUBFAMILY 3. TÆNIINÆ Stiles, 1896.

Definition. - *Tæniidæ*, usually of considerable length, with segments longer than they are broad. Scolex with either a rostellum armed or unarmed, or an apical sucker. Genital pores irregularly arranged on the lateral borders. Genitalia single. Testes numerous, placed laterally. Ovary shell and vitellogene gland situated posteriorly. Uterus, a single median trunk, from which lateral branches develop later. Eggshell thin; embryonic envelope (embryophore) thick, with radial stripes. Cysticercus generally in herbivora, adults in carnivora.

Tænia Linnæus, 1758.

Definition.– Tæniina with the characters of the subfamily. The genus *Tænia* is subdivided into three subgenera:

Subgenus 1. *Tænia* Linnæus, 1758. Type: *T.* (*Tænia*) *solium.*

Subgenus 2. *Tæniarhynchus* Weinland, 1858. Type: *T.* (*Tæniarhynchus*) *saginata*

Subgenus 3. *Multiceps* Goeze, 1782. Type: *T.* (*Multiceps*) *cœnurus*. This, however, is not a human parasite.

Tænia (Tænia) solium Linnæus, 1758.

Synonyms. *T. cucurbitina* Pallas, 1766; *T. pellucida* Goeze, 1782; *T. vulgaris* Werner, 1782, *T. dentata* Batsch, 1786; *Halysis solium* Zeder, 1803; *T. armata humana* Brera, 1808

The name ' solium ' is derived from a Syrian term *schuschl*, meaning a chain, which has arrived at its present form by being first turned into Arabic and finally into Latin. It is often called the armed tapeworm.

This worm is cosmopolitan in its distribution, for it can be found wherever a pig and a man can live, for the cysticercus lives in the pig, man, and rarely in sheep and dogs, while the tapeworm only lives in man. Even monkeys appear not to be capable of infection.

It seems to be more widespread in the tropics than in the Temperate Zone. It is not uncommon in Ceylon, and it is apparently common in Panama.

Morphology.—Length usually 2 to 3 metres, but may reach 8 metres. Mature segments measure 5 to 6 millimetres in breadth. Scolex provided with a rostellum, which may be pigmented and is armed with a double row of alternately large and small hooks, which number from twenty-two to thirty-two, and with four hemispherical suckers. The neck is long. Proglottides number from 800 to 900, with a length of 10 to 12 millimetres in mature segments. Genital pore lateral and irregularly alternate. The mature uterus has seven to ten ramified lateral branches, and contains three ovaries, the third being formed by subdivision of the one on the side of the genital pore. Eggs globular, pale yellow in colour, from 31 to 38 µ in diameter.

Life-History. — The adult worms live solely in the human intestines, from which the onchospheres with their envelopes escape in the fæces, and are apt to be eaten by pigs, or these may be infected by contaminated food or water. The cysticercus, often called *Cysticercus cellulosæ* (synonym, *C. acanthotrias*), develop in the flesh of the pig. If this flesh is eaten in an undercooked condition, the cysticercus infects the human being and forms the tapeworm. Occasionally man becomes infected with *Cysticercus cellulosæ*, most commonly in the brain, then the eye, the muscles, liver, lungs, etc., where they are sometimes few, sometimes numerous. This infection must be due to contaminated food or water.

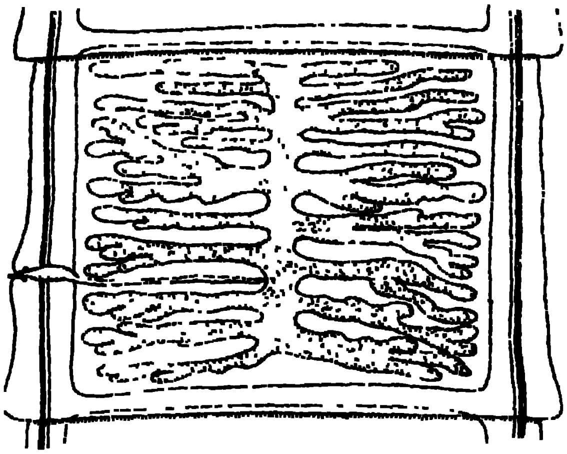

FIG. 252.—PROGLOTTIS OF *Tænia solium* LINNÆUS. (After Stiles.)

The tapeworm can live for years in the intestine of man. A variety called *T. solium, var. abietina* Weinland, originally found in a Chippewa Indian belongs probably to this species.

Pathogenicity.—The intestinal symptoms are not severe, but colicky pains and diarrhœa alternate with constipation. The patient may slowly emaciate. The danger of this infection is the entry of eggs into the human being and the formation of cysticerci in the organs.

Treatment.—Warn the person affected to be very careful to keep his hands clean, and to avoid infecting himself and other people with the eggs. Kill the tapeworm with extract of male-fern given in capsules (four to eight of 10 minims each), or in emulsion on an empty stomach, and followed after four to six hours by a saline purgative.

Prophylaxis.—Fæces should be so treated as not to infect pigs, and the flesh of these animals should be carefully cooked.

Tænia (Tæniarhynchus) saginata Goeze, 1782.

Synonyms.—*T. solium* Linnæus, 1707, *pro parte*; *T. cucurbitina* Pallas, 1781, *pro parte*; *T. inermis* Brera, 1802, *T. dentata* Nicolai, 1830; *T. lata* Pruner, 1847, *Bothriocephalus tropicus* Schmidtmuller, 1847, *T. mediocanellata* Kuchenmeister, 1855; *T. zittavensis* Küchenmeister, 1855; *T. tropica* Moquin-Tandon, 1860.

This is the unarmed beef-worm or the fat tapeworm, which has a cosmopolitan distribution, the adult being known only in man and the cysticercus in cattle, though it can be produced experimentally in a number of animals. It is very common in the tropics, especially in Africa, and particularly Abyssinia, the Sudan, and Asia.

Morphology.—It measures 4 to 8 to 10 metres in length, and has been said to attain much greater length. A mature segment is 4·7 millimetres in breadth. The head possesses four hemispherical, often pigmented, suckers, and a sucker in place of a rostellum. The neck is long. The proglottides number about 1,000 segments, with a length of about 16 to 20 millimetres when mature, The genital spores are arranged irregularly at the sides, and the median uterus produces twenty to thirty-five ramified lateral branches. Malformations of the segments are not uncommon. Eggs globular, often with the original shell, to which may be attached one to two filaments and the two embryonic envelopes, as well as the onchosphere. The inner embryonic envelope is oval, striated, measures 30 to 40 μ in length by 20 to 30 μ in breadth. Segments can escape *per anum* by their own action.

Life-History.—The adult worm lives in man, the cysticercus requiring some fifty-four days (Perroncito quoted Leuckart) to develop, so that proglottides are seen, and the embryophore, escaping in the faeces, enters cattle by means of contaminated food or water, and develops in their muscles into the *Cysticercus*

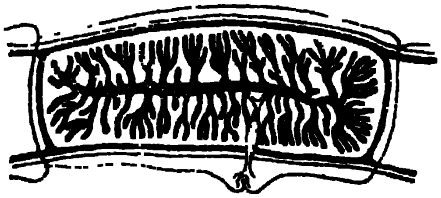

FIG. 253.—PROGLOTTIS OF *Tænia saginata* GOEZE.
(After Stiles.)

bovis, which is rather small—only 7·5 to 9 millimetres in length and 5·5 millimetres in breadth. The tongue and the muscles of mastication, especialy the pterygoids, are chiefly affected.

Man becomes infected by eating under-cooked meat. It can live in him for a number of years. The cysticercus very rarely occurs in man.

Pathogenicity.—It is believed to be more difficult to kill medicinally than *T. solium*, and to produce more severe anaemia.

Treatment.—As for *T. solium*.

Prophylaxis.—Prevent human faeces contaminating the food of cattle, and have the meat, especially the tongue and the pterygoid muscles, inspected in the slaughter-house. In African beef animals also common in the muscles of the shoulder, foreleg, back, rump, and hindquarters. Only in extensive infections and exceptionally in slight invasions, it is found in the lymph glands, lungs, liver, brain and œsophagus which, therefore, ought also to be inspected.

Tænia (Tæniarhynchus) africana von Linstow, 1900.

Two specimens of this worm were found in a negro in late German East Africa, at Langenburg, near Lake Nyassa.

Morphology.—It is about 1·4 metres in length. The scolex is provided with an apical sucker in place of a rostellum, and also with four ordinary suckers. The neck is very short. The proglottides vary in length and breadth, according to position, but always broader than long, in the portion discovered. This species is as yet not clearly defined from *T. saginata*.

The ripe segments are 9 millimetres broad by 1·20 millimetres thick. Their number is about 600. The genital pore is irregularly alternate on the lateral border. The testes are very numerous, and the vas deferens much convoluted, with a thick, pear-shaped cirrus pouch. The cirrus is beset with bristles, as is the vagina. The receptaculum seminis is large. The ovary is large and double, and the vitellogene gland is situated at the posterior border. The mature uterus consists of a median portion with fifteen to twenty-four non-ramified lateral branches.

The embryophore is thick, with radial markings, round or oval (39 by 33 μ).

Life-History.—The life-history is not known, but it is suggested that the cysticercus may live in *Bos indicus*, the hump-backed cow, the flesh of which the natives of East Africa eat raw.

Tænia (Tæniarhynchus) hominis von Linstow, 1902.

This worm was found by Anger in a man in Aschabad in Siberia.

The length was 70 millimetres. The scolex had a rudimentary rostellum without hooks. There were four unpigmented suckers, behind which there was a ring-shaped swelling. Nothing further is known about this parasite.

Tænia (Tæniarhynchus) philippina Garrison, 1907.

This specimen was found by Hare in a prisoner in Bilibid Prison, in the Philippine Islands, in 1905.

Morphology.—The length is 80 to 100 centimetres; maximum breadth 1 centimetre. Head cuboid, with an unarmed retractile rostellum and four suckers. Neck segmental. Proglottides number about 800, being sexually mature about the 470th. Mature proglottides 4 to 5 millimetres in width and 0·8 to 1 millimetre in length. Surfaces and margins extend posteriorly in an elongated cuff-like projection over the succeeding segment. Testes 130 to 160 μ in length, and from 60 to 80 μ in breadth. Vas deferens without vesicula seminalis; cirrus and pouch present. Genital pore situated irregularly on the lateral borders. Ovaries, with two unequal transversely elongated lobes, close against the vitellogene gland. Vagina without setæ and with two coils. Uterus stem with a V-shaped course posteriorly, and with four to six distinct coils anteriorly. Mature uterus very compact, with a median stem and numerous long, slender dichotomous branches.

Embryophore oval, 35 to 41 μ long, and 26 to 35 μ broad.

Life-Cycle.—Life-history not known.

Tænia (?) **confusa** Ward, 1896.

This worm has so far only been found in Lincoln, Nebraska, U.S.A.

Morphology.—Length about 8½ metres, breadth 5 millimetres, scolex unknown. Segments much longer than they are broad, 27 to 35 millimetres long by 3·5 to 5 millimetres broad. Genital pore irregularly placed behind the middle of the lateral border. Testes numerous, vas deferens not much coiled, cirrus pouch thick-walled. Cirrus beset with little hairs. Receptaculum seminis globular; ovary small and double, bean-shaped. Vitellogene gland narrow and triangular; shell gland globular. Uterus, when mature, consists of a median trunk, and fourteen to eighteen short dichotomous branches on each side. Embryophores are oval, thick, and striated (39 by 30 μ).

Life-Cycle.—Nothing is known.

Tænia (?) **bremneri** Stephens, 1907.

This worm was found by Dr. Bremner in a Fullani woman in Northern Nigeria.

Morphology.—The head is not known. The segments examined measured, on an average, 28·6 by 8·5 millimetres, but ranged from 21 by 6 millimetres to 32 by 29 millimetres in size. The central uterine axis has twenty-two to twenty-four ramified lateral branches, and one terminal branch with four to five ramifications. The genital pore is prominent, and lies behind the middle of the segment. Eggs measure on an average 38 by 30·4 μ.

Leiper considers that these large segments are relaxed *Tænia saginata*.

Life-Cycle.—Nothing is known at present about the life-history.

Echinococcus Rudolphi, 1801.

Synonym. *Acephalocystis* Laennec, 1804.

Species. *Echinococcus granulosus* Batsch, 1786; *E. multilocularis* Huber 1896.

Echinococcus granulosus Batsch, 1786.

Synonyms.—*Tænia echinococcus* Zeder, 1803, Siebold, 1853; *T. nana* van Beneden 1861, *nec* Siebold 1853, *Echinococcifer echinococcus* Weinland, 1861.

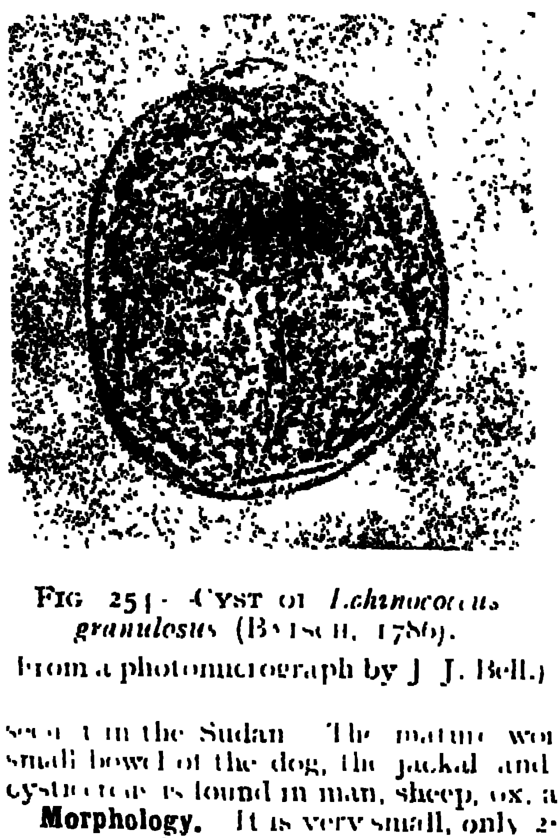

FIG. 254.—Cyst of *Echinococcus granulosus* (Batsch, 1786).
(From a photomicrograph by J. J. Bell.)

Hydatid disease appears to have been known since the days of Hippocrates. In 1684 Redi suggested that the cysts were animal in origin, and in 1766-67 Pallas clearly showed their relationship to tapeworms (*Tænia hydatigena*).

It appears doubtful whether there are two species of worms associated with hydatid disease, but the appearance of the larvæ and the geographical distribution tend to separate the genus into two species. *Echinococcus granulosus* causes the cystic form of hydatid disease. It is found most markedly in Iceland and Australia, but also exists all over Europe, and is known in New Zealand. It is rare in India, and the only case we have seen in Ceylon came from South Africa, where it occurs, but Begbie has recently described another case in Ceylon. It is known in the Philippine Islands, and is not uncommon in Egypt and Algeria, and we have seen it in the Sudan. The mature worm, which is very small, lives in the small bowel of the dog, the jackal and the wolf in large numbers, while the cysticercus is found in man, sheep, ox, and pig.

Morphology. It is very small, only 2·5 to 5 to 6 millimetres in length, and is composed only of a scolex and three to four segments. The scolex has four suckers and a rostellum armed with a double row of twenty-eight to fifty hooks, which vary in size, the larger being 40 to 45 μ in length, and the smaller 30 to 38 μ in length. The genital pores alternate.

The testes are numerous, the vas deferens spirally coiled, the vitellogene gland double, the shell round. The mature uterus has only lateral protuberances, no true branches, and the eggs may form heaps.

The egg is globular, 30 to 36 μ in diameter.

Life-Cycle.—The dog infects man with the onchospheres, usually directly when being petted. Infection may, however, be brought about by contaminated food.

On arrival in the stomach, the onchosphere escapes from its embryophore and bores its way into the liver or some other organ. Here it grows, and forms a cyst with a thick outer cuticle, inside which is fluid enclosed by a layer of parenchyma, the endocyst, composed of two layers of cells. The irritation caused by the growth of this cyst produces a connective-tissue coat, formed by the organ in which the cyst is growing. The cyst in this condition is called an acephalocyst (*Echinococcus cysticus sterilis*), and is often found in cattle.

The next stage is the formation of the brood capsule. The inner layer of the endocyst grows inwards, forming large numbers of small hollow capsules (brood capsules), which have the endocyst externally and the cuticle internally. On these capsules heads develop. The cyst now forms the *Echinococcus cysticus fertilis*, found in domestic animals.

In man, however, daughter-cysts appear between the strata of the cuticle, into which cells belonging to the endocyst have found their way and formed cysts, with an external cuticular and an internal parenchymal layer. These cysts may, of course, bulge, and escape externally or internally. If externally, they then lie between the capsule and the mother-cyst and form *Echinococcus hydatidosus var. exogenus*, or if internally, they fall into the interior of the mother-cyst and form *Echinococcus hydatidosus var. endogenus* These daughter-cysts may remain sterile or produce brood capsules and heads. Granddaughter-cysts may be formed in the same way. The wall of the mother-cyst may disappear, leaving the daughter-cysts free.

Of all these varieties, the endogenous cyst is the most common. It may reach several pounds in weight, with hundreds of daughter-cysts.

In Khartoum cysts fed into dog developed in fourteen days into worms, but not quite sexually mature

It is believed that the usual cycle of life-history takes place in the dog and the sheep. Manson suspects the jackal in India as a spreader of the disease to man. Stirling and Verco lay down the following factors as necessary for the spread of the disease:

1. Sufficiency of infected dogs
2. Domestic herbivora, especially sheep as intermediary hosts.
3. Conditions favourable for the transmission of the parasite from the dog to man.
4. Facility of access to dogs of infected carcasses

Perhaps, however, the egg gains access to the human body through contaminated food and dust

Pathogenicity. -The cysts grow but slowly, consequently organs adapt themselves to the pressure, so that the symptoms may be wanting and depend entirely upon whether the organ can or cannot expand

If, however, fluid escapes from a cyst urticarial eruptions, or even rigors, with local pain and tenderness, may result

Prophylaxis. --Prophylaxis must be on the lines indicated by the factors above mentioned -viz., registration of dogs, destruction of pariah dogs, non-feeding of dogs with raw meat, clean kennels, non-handling of dogs.

Echinococcus multilocularis Leuckart, 1863.

Synonym.—*Echinococcus osteokluster* Huber, 1896.

This is the parasite which causes the alveolar or multilocular form of hydatid disease, which is very different from the ordinary form The disease was first observed by Ruysch in 1721, and was generally looked upon as a colloid cancer, until Virchow in 1856 showed that it had its origin in a worm Mangold and Muller consider that by feeding experiments they obtained from it a *Tænia* different from *E. granulosus* in the hooks and the distribution of the ova.

Melnikow-Raswedenkow gives quite a different life-history for this parasite, which, if correct, will make it a new species. Further, there is the support of Stiles, Stirling, Verco, and others for the differentiation of the parasites from one another.

This form of hydatids occurs in man, sheep, and pigs, but principally in large cattle.

The geographical distribution is interesting, it being mostly found in South Germany, Switzerland, the Austrian Alpine region, Russia, and East Siberia, in which districts it occurs in large cattle and man, whereas it is absent from Iceland and Australia and European districts where sheep are common and where the other form is frequently met with

Morphology.– Melnikow-Raswedenkow says that the cysts are composed of parenchyma internally and externally, the latter being in direct contact with the tissue of the host, and producing, it is said, not merely scolices, but immature amœboid embryos, which spread the cyst by continuity, or may enter the blood-stream and form metastases

An amœboid embryo develops into a much-folded chitinous vesicle, having parenchyma both internally and externally This parenchyma produces poisons which act upon the host The cyst is looked upon as the homologue of a ripe proglottis because it can produce living embryos, for the parenchyma can form scolices, immature embryos without a capsule, and mature ovoid embryos enclosed in a chitinous capsule.

The scolices, however, are frequently destroyed by phagocytosis, because they are situated in direct contact with the host's tissue Hence the failure of feeding experiments, as the scolices arrive in the intestine damaged.

The result of this development is to produce a collection of cysts, measuring from 0·1 to 5 millimetres in diameter, embedded in connective tissue. Disintegration may begin in the centre of the masses of the cysts. Whether the *Tænia* obtained by feeding experiments are the same as *T. echinococcus* or not is uncertain.

Pathogenicity. - It produces a primary tumour in the liver, brain, spleen, kidney, or adrenals, with metastases in different parts of the body The symptoms produced vary with the region affected, but eventually, perhaps after years, lead to anæmia, emaciation, and weakness, which cause death.

CHAPTER XXVI

NEMATHELMINTHES

Nemathelminthes — Nematoda — Anguillulidæ — Angiostomidæ — Gnathostomidæ — Physalopteridæ — Filariidæ — Dracunculidæ — Mermithidæ — Ascaridæ — Oxyuridæ — Strongylidæ — Metastrongylidæ — Trichostrongylidæ — Ankylostomidæ — Eustrongylidæ — Trichinellidæ — Trichurineæ — Gordiacea — Acanthocephala — References

PHYLUM II. NEMATHELMINTHES.

METAZOA, worm-like in form, tubular, or filiform unsegmented, but covered with a cuticle which may be ringed. Without appendages or limbs, but usually with bristles, hooks, papillæ, or, rarely, suckers. Usually with an alimentary canal, but without any closed vascular system, and without respiratory organs. With a complete absence of cilia. Sexes are separate. Usually parasitic through some part of the life-cycle, in which the larvæ develop in a different host or organ from that occupied by the adult. The larvæ may be free and the adult parasitic, or *vice versa*

Remarks.—The Nemathelminthes are extremely important to the student of tropical medicine, for they include some of the most potent agents of disease—*e.g.*, *Ankylostoma duodenale* and the *Filariidæ*. Recent researches have shown that, no matter how common the worm may appear to be, it is advisable to carefully study it, as it has been found that several species and genera have been included in an old species which was thought to be so well known, that nothing new could be discovered concerning it—*e.g.*, *Ascaris*, in examining specimens of which Leiper has separated two new genera.

Classification.—The Nemathelminthes can be divided into two classes:—

CLASS I.—Anterior end not provided with an armed proboscis; intestine present either complete or in part rudimentary.

This class includes two orders:—

Order I. Nematoda.
Order II. Gordiacea.

CLASS II.—Anterior end provided with an armed proboscis; intestine absent.

Order III. Acanthocephala.

CLASS I.

ORDER I. NEMATODA.

Definition.—Nemathelminthes with white filiform bodies, with usually a complete alimentary canal in the adults, but sometimes this may be represented by only an œsophagus and a rudimentary intestine; with papillæ on the head. The male with one testis, a strongly recurved posterior extremity, and usually spicules. The female with a vulvar opening always distinct from the anus. Egg contains ovum only.

Morphology.—The Nematoda are parasitic, as a rule, but minute sexually mature forms can be met with in moist soil all over the world. The body is enclosed in a thick, transparent, smooth, or ringed cuticle, which may form hooks, spines, or lateral fins.

Under the cuticle comes a syncytium called the epidermis, under which is the peculiar muscular layer cut into four quadrants by thickenings of the epidermis, which project inwards, surrounding dorsally and ventrally a nerve cord, and laterally excretory canals. Under the skin comes the large undivided body cavity, which is not of the nature of a true cœlom, as it is not between the two layers of the mesoblast, but between mesoblast externally and hypoblast internally, and contains a fluid which may represent the hæmolymph fluids of higher animals.

The digestive system consists of a mouth situated at the anterior end, and surrounded by two to six lips, which opens into a thick suctorial œsophagus lined with chitin.

The œsophagus opens into the intestine, which is a thin-walled tube lined by a simple layer of endothelial cells, and leads to the short chitinous rectum, which ends in the anus.

The excretory system consists of two longitudinal tubes lying in the lateral line, and uniting anteriorly by a transverse 'bridge' to open in a pore situated in the mid-ventral line just behind the mouth in the region of the nerve ring.

The nervous system consists of a circumœsophageal ring, with six anterior and six posterior nerve trunks.

The sexes are separate. The male reproductive organs consist of one tube divisible into testis, vas deferens, vesicula seminalis, and ductus ejaculatorius, which opens on the ventral surface of the rectum close to the anus, while the posterior end of the body is modified for sexual purpose with alæ and papillæ. The female reproductive organs consist of two much-coiled tubes divisible into ovary, oviduct, and uterus, which join together to form the simple vagina, which opens about the middle of the body in the mid-ventral line; in some instances just in front of the anus, in others, as in the filaria worms, quite near the head

Biology.—They appear to live upon the juices of the part of the body in which they are found. Generally this is the intestine, the contents of which supply them with ample food. But some of them are capable of entering the villi of the intestine.

Life-History.—Sometimes the life-history is fairly simple, or is supposed to be so, for it is possible that we are not well acquainted with details.

Other life-histories are most complicated, and must be dealt with in detail.

Pathogenicity.—Some of the worms are markedly pathogenic, while others usually produce but slight effects.

Classification.—The Nematoda are classified into—The Non-Bursata, comprising the families: (1) Enoplidæ, (2) Anguillulidæ, (3) Angiostomidæ, (4) Gnathostomidæ, (5) Physalopteridæ, (6) Filariidæ, (7) Dracunculidæ, (8) Mermithidæ, (9) Ascaridæ, and (10) Oxyuridæ; and the Bursata, which are subdivided into the Strongyles, comprising the families (11) Strongylidæ, (12) Metastrongylidæ, (13) Trichostrongylidæ, (14) Ancylostomidæ, and the Pseudostrongyles, comprising the families (15) Eustrongylidæ (16) Trichinellidæ, and (17) Trichosomidæ

The Enoplidæ are free-living, and do not concern us.

The following table gives the parasites known in man, excluding a number of doubtful Filariidæ

Division.	Family.	Genus.	Species.
Non-Bursata.	Anguillulidæ .	Anguillula .	1. A. aceti.
		Anguillulina ..	2. A. putrefaciens
		Rhabditis .	3. R. niellyi.
		Leptodera ..	4. L. pellio.
	Angiostomidæ ..	Strongyloides ..	5. S. intestinalis.
	Gnathostomidæ	Gnathostoma ..	6. G. spinigerum.
	Physalopteridæ	Physaloptera	7. P. caucasica. 8. P. mordens.
	Filariidæ . .	Filaria .. .	9. F. bancrofti. 10. F. ozzardi. 11. (F. inermis ?)
		(Microfilaria) .	12. (M.) powelli 13. (M.) philippinensis.
		(Agamofilaria) .	14. (Agm.) conjunctiva 15. (Agm.) labialis. 16. (Agm.) oculi. 17. (Agm.) georgiana.

	Oxyuridæ ..	Oxyuris	30. O. vermicularis.
	Eustrongylididæ	Dioctophyme .	31. D. renale.
	Trichosomidæ ..	Trichinella .	32. T. spiralis.
		Trichuris ..	33. T. trichiura.

Division.	Family.	Genus.	Species.
Bursata.	Strongylidæ	Triodontophorus	34. T. deminutus.
		Œsophagostomum	35. Œ. brumpti.
			36. Œ. stephanostomum var. thomasi.
	Metastrongylidæ	Metastrongylus	37. M. apri.
	Trichostrongylidæ	Nematodirus	38 N. gibsoni.
		Hæmonchus	39. H. contortus.
		Trichostrongylus	40. T. colubriformis.
			41. T. probolurus.
			42. T. vitrinus.
			43. T. orientalis.
	Ancylostomidæ	Ancylostoma	44 A. duodenale.
			45. A. ceylanicum.
		Necator	46. N. americanus.

It is not possible at the present moment to give a scientific and easily workable classification of the Nematoda, because the type genera require revision. We group the various families under the following divisions :--

A. *Nematoda* in which the bursa copulatrix is merely a cuticular expansion not supported by true fleshy rays in the males—*Non-Bursata*.

B *Nematoda* with true bursa copulatrix--*i.e*, supported by fleshy rays in the male-*Bursata*

DIVISION NON-BURSATA.

Leiper gives the following table for differentiation of the non-bursate families which are represented in the parasitic nematodes of man:-

A. Œsophagus a simple cellular tube- *Trichosomidæ*

B. Œsophagus a simple muscular bulb:-

(*a*). Mouth surrounded by several protuberances. Male with one spicule; female with one uterus--*Eustrongylidinæ*.

(*b*) Mouth guarded by large fleshy jaws. Male with two spicules: female with two uteri:-

(1) Jaws two in number: skin smooth--*Physalopteridæ*

Jaws two in number; skin spinous--*Gnathostomidæ*.

(2) Jaws three in number. skin striated- *Ascaridæ*.

(*c*) Mouth a simple pore without buccal capsule:--

(1) Female without vagina: embryos striated. Male with two equal spicules- *Dracunculidæ*.

NEMATODE EGGS.

(From preparations and photographs by J. J. Bell.)

FIGS. 263 AND 265.—ABNORMAL EGGS PROBABLY OF *Ascaris lumbricoides*.

NON-BURSATA.

FAMILY 2. ANGUILLULIDÆ.

Very small Nematoda, mostly free-living, rarely parasitic, with an oral cavity armed with a tooth or spine, and an œsophagus with a double dilatation. Male with two spicules, and sometimes a bursa copulatrix. Female with a pointed tail, and a vulva situated in the middle of the body.

Genera.—(1) *Anguillula*, (2) *Anguillulina*, (3) *Rhabditis*, (4) *Leptodera*.

Anguillula Ehrenberg, 1820.

Anguillulidæ with small mouth, œsophagus with two dilatations of which the posterior has valves. Male without bursa, spicules with accessory pieces feather-shaped. Female with the vulva in the hinder portion of the body; uterus asymmetrical.

Anguillula aceti Muller, 1783.

Anguillula aceti is the common vinegar eel, which has several times been reported as occurring in the human bladder, but the method of infection is unknown.

Morphology.—Cuticle not striated, body cylindrical, tapering a little to the anterior, but considerably to the posterior end. Male 1 to 2 millimetres long and 24 to 40 μ broad, with two pre-anal and one post-anal papillæ. Two equal spicules 38 μ long. Female, 2·4 millimetres long and 50 to 72 μ broad. Vulva near the equator. Embryos 222 by 12 μ.

Pathogenicity. Nil.

Anguillulina Gervais and van Beneden, 1859.

Synonym. *Tylenchus* Bastian, 1864.

Anguillulidæ possessing a spine on the oral cavity. Male bursa without papillæ; uterus asymmetrical.

Species.—*Anguillulina putrefaciens* Kuhn, 1879.

Anguillulina putrefaciens Kuhn, 1879.

Synonyms.—*Tylenchus putrefaciens* Kuhn, 1879; *Trichina contorta* Botkin, 1883.

This small nematode lives in onions and it or other varieties may at times find access to the stomach with the food, and be rejected by vomiting as reported by Botkin in 1883.

Rhabditis Dujardin, 1845.

Small Anguillulidæ with no teeth in the oral cavity, with accessory pieces to the two male spicules, and without lateral ridges.

Rhabditis niellyi Blanchard, 1885.

Synonym.—*Leptodera niellyi* Blanchard, 1885.

This parasite was described by Nielly in 1882 in a boy who suffered from an itching papular eruption in Brest, which he had never left.

Morphology.—The parasites measured 0·33 by 0·013 millimetre in width, and possessed a cuticle with delicate transverse striation, a double-bulbed œsophagus, and an intestine, but no genital organs.

Pathogenicity.—The specimens were found in the papules, and also in the blood at the beginning of the illness, but not in the fæces, urine, or sputum.

Life-History. Unknown.

Leptodera Dujardin, 1845.

Anguillulidæ with mouth guarded by two, three, or six lips. Male with or without bursa, which when present, never surrounds the point of the tail. Two equal spicules, and three pre-anal papillæ. Female with the tail prolonged into a long unsymmetrical point.

Leptodera pellio Schneider, 1866.

Synonyms.—*Pelodera pellio* Schneider, 1866; *Rhabditis genitalis* Scheiber, 1880.

Leptodera pellio is merely an occasional parasite in man. Infection arises in rather a peculiar manner. The larva lives in the earthworm (*Lumbricus terrestris*) while the adults exist in decomposing matter in the soil.

The Hungarian peasants use soil for making poultices, from which the little worms apparently make their way into the vaginæ of women and live there. Oerley has shown experimentally that they will live in the vagina of a mouse.

Morphology.—Male, 0·8 to 1·05 millimetres in length, with a bursa supported by seven to ten ribs on each side. Spicules, which are not quite alike measuring 27 to 33 μ in length. Female, 0·9 to 1·3 millimetres in length, with a vulva slightly posterior to the middle of the body.

Pathogenicity. Nil.

FAMILY ANGIOSTOMIDÆ.

Nematoda characterized by heterogony, each species having a free living bisexual rhabdite form and a parasitic hermaphrodite filarial form.

Strongyloides Grassi, 1879.

Synonyms.—*Pseudorhabditis* Perroncito, 1881; *Rhabdonema* Leuckart, 1882.

The parasitic form has an unarmed mouth, long cylindrical œsophagus, which reaches nearly to the middle of the body. The free-living stage has a small mouth, short œsophagus with a double dilatation, in the hinder part of which are small teeth. The male spicules are of equal size.

Strongyloides stercoralis Bavay, 1877.

Synonyms.—*Anguillula intestinalis et stercoralis* Bavay, 1877; *Leptodera intestinalis et stercoralis* Cobbold; *Pseudorhabditis stercoralis* Perroncito, 1881; *Rhabdonema strongyloides* Leuckart, 1883; *R. intestinale* Blanchard, 1886.

History.—This little worm, which is not uncommonly met with in fæces, was first described in 1876 by Normand in the fæces and the intestine of French soldiers just returned to Toulon from Cochin China.

At first it was thought that there were two species—one in the fæces (*Anguillula stercoralis*) and the other in the bowel (*A. intes-*

tinalis)—but Leuckart showed that they were but succeeding stages of one life-cycle. It is found in Europe, Africa, India, Ceylon, Indo-China, China, the Philippines, Oceania, the United States, the West Indies, and Brazil.

The fully-developed worm is found in the duodenum and jejunum, into the mucosa of which it has bored its way deeply.

Morphology.—The parasitic adult worm is very small—2·2 millimetres long and 34 μ broad – with a finely striated cuticle, and a mouth surrounded by four lips, leading into a cylindrical œsophagus, equal in length to one-quarter of the whole body. The anus is just in front of the tip of the tail. Inside this parasite can be seen ellipsoidal eggs. The sex of this parasite is doubtful. Is it a hermaphrodite, in which the male organs, after serving their purpose, have degenerated, or is it a parthenogenetic female? At present these questions cannot be answered definitely. Most probably it is a hermaphrodite. The eggs measure 50 to 58 μ in length by 30 to 34 μ in breadth, and are arranged in strings surrounded by a delicate tubular structure. They occur in the fæces only during attacks of diarrhœa.

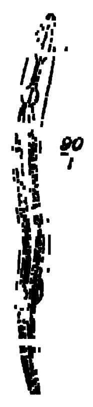

FIG. 267.—RHABDITIFORM EMBRYO OF *Strongyloides intestinalis* BAVAY AS FOUND IN HUMAN FÆCES. (After Looss.)

Life-History.—The eggs are oviposited into the mucosa of the host's intestine, and the embryos hatch and find their way into the lumen, and are evacuated with the fæces. On reaching water or moist earth these embryos grow into adult male and female forms, which conjugate, and then the female lays eggs. The eggs produce free-living rhabditiform embryos, which moult and turn into filariform embryos, which have been shown by Mozocchi and van Durne to penetrate the skin, not through the hair-follicles, but through the horny layer into the rete Malpighii, and so into the corium. The experiments of Fülleborn and V. Schilling-Torgau in infecting tracheotomized dogs or dogs with the œsophagus cut and fixed to the skin with larvæ of *Strongyloides stercoralis* Bavay, 1877, have shown that the more important route is from the skin to the lungs and so via the trachea and œsophagus to the bowels, while a less important route from the skin via the blood-stream directly to the bowel can also take place (*vide* the life-history of *Ancylostoma duodenale*, p. 663). On arrival in the intestine they burrow into Lieberkühn's follicles, and begin to lay their eggs.

Pathogenicity.—The parasite is generally believed to cause a catarrh of the small intestine, though many believe it to be non-pathogenic.

FAMILY 4. GNATHOSTOMIDÆ.

Nematoda, with two large lips and the whole or only the anterior part of the body covered with minute ramified spines. They live often in the tumours in the gut wall of vertebrates, especially mammals.

Two genera: *Gnathostoma* Owen, 1836, and *Tanqua*.

Gnathostoma Owen, 1837.

Synonyms.—*Cheiracanthus* Diesing, 1839; *Liorhynchus* Rudolphi.

Definition.—With the characters of the family.

Remarks.—The genus comprises only intestinal parasites, of which nine species are known in man, alligators, cats, tigers, pigs, etc.

Gnathostoma spinigerum Owen, 1837.

Synonyms.—*Cheiracanthus siamensis* Levinsen, 1889; *Gnathostoma siamense* Levinsen, 1889; *Cheiracanthus robustum* Diesing, 1839.

Remarks.—Only two specimens are known, one a female, which was obtained by Deuntzer from a young Siamese woman in whose breast a hard painful swelling had formed, accompanied with slight fever, and another a male described by Leiper. Nodules the size of beans appeared in the skin, from one of which the worms were extracted. Two other similar cases have recently been reported. Leiper has recently compared a male specimen from man with typical specimens of *G. spinigerum* of the tiger, and declares them to be identical.

Morphology.—*Male.*—10·55 millimetres long by 0·6 millimetre broad, with the anterior half of the body quite straight and terminating in a globular swelling, which carries two large fleshy lips which guard the mouth. Neck only 0·3 millimetre in diameter. In front of the neck the cuticle is provided with eight transversed rows of chitinous hooks, with their points directed backwards. Behind the neck the cuticle has many cuticular laminæ, but the posterior half of the body is without armature.

The mouth is simple, without a vestibule. The paired labial glands open on the lips already mentioned. The œsophagus is 2·4 millimetres long and very muscular, and opens into the chyle intestine, which, being uniformly 0·25 millimetre broad, is with difficulty separated from the rectum, which leads to the cloaca.

There are two pre-anal and two post-anal large nipple-like genital papillæ around the cloaca, and though the cuticle is folded there is no bursal formation; but there are two unequal spicules, 1·1 millimetres and 0·4 millimetre long. There is a distinct muscular ejaculatory duct, 1·5 millimetres long.

Female.—Nine millimetres long by 1 millimetre broad, with eight rows of bristles around the head and spines covering the anterior third of the body. Each spine ramifies into three points, of which the middle is the longest. The anterior end was narrow and the mouth appeared to be bordered by two lips. The posterior end had a three-lobed prominence, at the base of which the anus opened.

Habitat.—Subcutaneous tumours in man in Siam. Allied species live in the stomach of pigs and oxen. The species is said to occur in the pariah dogs of Calcutta.

Pathogenicity.—Man is apparently an aberrant host, for in man only do the worms wander into the connective tissue and form subcutaneous tumours. The species normally lives in the stomach of animals, causing fibrous thickenings.

FAMILY 5. PHYSALOPTERIDÆ.

Physaloptera Rudolphi, 1819.

Physalopteridæ possessing mouth with usually two lips, each with papillæ and teeth. Posterior end of the male lancet-shaped, owing to a widening of the cuticle. The ventral aspect is here covered with cuticular plates, and there are four pairs of pedunculated external papillæ and a number of sessile internal papillæ and unequal spicules. Female; vulva situated anteriorly. Eggs thick-shelled and smooth.

Physaloptera caucasica von Linstow, 1902.

This has only been found once by Ménétries in the alimentary canal of man in the Caucasus.

Male 1·42 millimetres long by 0·71 millimetre broad. Female 27 millimetres long by 1·14 millimetres broad. Eggs 57 by 30 μ.

Physaloptera mordens Leiper, 1907.

Leiper has recently described a large number of cases of infection with *Physaloptera* in natives of tropical Africa, which differed from *P. caucasica* not only in size, but in the length of the spicules in the male.

FAMILY 6. FILARIIDÆ Claus, 1885.

Synonyms.—*Filaridea* Carus, 1863; *Filariadea* Leuckart, 1876; *Filaridæ* Cobbold; *Filarides* Assenova, 1896.

Definition.—Long filiform nematodes with uniform diameter, and a straight head provided with two latero median and four submedian papillæ. Mouth terminal, with two lips, and occasionally a more or less distinct buccal capsule. Œsophagus slender, elongated, and may be divided into two portions, but has no posterior bulb. Mid-gut present, rectum present, anus subterminal.

Males with one or two unequal spicules and a spirally recurved tail, provided with papillæ, and in some cases with lateral alæ. Females larger than the males, with or without a vulva in the gravid worms, which, when present, is situate anteriorly. Uterus usually double. All species parasitic and ovoviviparous, with a change of host in at least certain species.

Type Genus.—*Filaria* Muller, 1787.

The genus *Filaria* was created by Muller in 1787, unfortunately without naming a particular type, which Stiles suggests should be *Filaria martis* Gmelin, 1790 (*F. perforans*). This is found in *Mustela martes* L., the pine marten of Europe, and was one of the parasites originally described by Müller. This parasite requires to be restudied before definite characters can be given for the genus.

Classification.—The subfamilies are *Filariinæ* and *Onchocercinæ*.

SUBFAMILY FILARIINÆ Stiles, 1907.

Filaria Müller, 1787.

Definition.—This is doubtful. Filariidæ with long slender filiform bodies; anterior extremity attenuated, obtuse; posterior very attenuated, more so than the head. Cuticle without transverse striation, and without bosses. Male shorter than the female, with spirally bent tail provided with lateral cuticular alæ, pre- and post-anal papillæ, and unequal spicules. Females longer than males, with vulva situate anteriorly near the mouth.

Synonyms.—*Fileraria* Rudolphi, 1809; *Filaire* Lee, 1840; and some misprints.

Type.—*F. martis* Gmelin, 1790.

Species.—*F. bancrofti* Cobbold, 1877; (?) *F. demarquayi* Manson, 1895.

Some years ago the genus *Filaria* contained a large number of species parasitic in man, but the following genera have definitely been separated from *Filaria*: *Acanthocheilonema*, *Dirofilaria*, *Dracunculus*, *Onchocerca*, and *Hamularia*. At the present time there are only three species known to be human parasites, which are referred to the genus *Filaria*—viz., *F. bancrofti* Cobbold, 1877; *F. ozzardi* Manson, 1897; and *F. inermis* Grassi, 1888; in addition to the embryonic forms included in the collective group (*Microfilaria*) and the immature forms in the collective group (*Agamofilaria*). There are, however, a number of spurious or doubtful forms scattered throughout medical literature and described as human parasites which must be eliminated from the genus, and these are:—

1. *Filaria* (?) *hominis oris* Leidy, 1850.—This probably belongs to the Mermithidæ and may have been a mermis accidentally taken into the child's mouth while eating, say, an apple, because it had an obtuse posterior extremity with a recurved hook.

2. *Filaria* (?) *gigas* Prout, 1902.—Two embryonic *filarial* structures 220 to 340 μ by 8 to 12 μ, found with rounded head and tapering tail ending bluntly, no sheath; stained readily with fuchsin. Low thinks that these might be contaminations—*i.e.*, insect hairs; Looss thinks that they may be cast skins, and as Stiles has also adopted this view the parasite may perhaps be eliminated. Recently Leiper has considered it to be a stained fungoid growth.

3. *Nematoideum tracheale* Cobbold, 1864.

The following can certainly be eliminated:

4. *Filaria* (?) *restiformis* Leidy, 1880, as this is *Agamomeris restiformis*, and belongs to the Mermithidæ.

5. *Filaria* (?) [illegible]. Stiles believes this to be merely *Oxyuris vermicularis*, it may be the embryo of a *Filaria*.

6. *Filaria* (?) *niellyi* is *Rhabditis niellyi*.

7. *Filaria* (?) *zebra* Mon Grand, 1852, is said to be a fibrinous clot, and therefore a species *fictitia*.

The following may have to be eliminated:—

8. *Filaria* (?) *kilimaræ* Kolb, 1898.—These consist of several female specimens once found free in the abdominal cavity of a fallen Kitu warrior. Oral papillæ are said to have been like *Dracunculus medinensis*.

They were 10 to 20 centimetres in length, and 0·5 to 1 millimetre in diameter, white, and resembled *Gordius aquaticus* in general appearance.

With these Kolb classified free-living worms, and therefore doubts are held as to the exact zoological determinations of the species recorded.

9. *Filaria* (?) *romanorum orientalis* Sarcani, 1888.—Observed in the blood of a Roumanian woman; 1 millimetre long by 0·3 millimetre broad, with intestine and generative apparatus developed; believed by some to be an adult threadworm.

The uncertain species are:—

1. *Filaria Species* (?) Cholodkowsky, 1896.—Found in whitlow-like tumours on the fingers of peasants in the Twer Government.

2. *Filaria Species* (?) Prout, 1902.

3. There was a parasite called *Spiroptera hominis* Rudolphi, 1819, which appears to have been spurious, being really *Filaria communis*, of which *Filaria piscium* is a synonym.

Filaria bancrofti Cobbold, 1877.

Synonyms.—*Trichina cystica* Salisbury, 1868, *nec* Rudolphi, 1819; *F. sanguinis hominis* Lewis, 1872; *F sanguinis hominis ægyptiaca* Sonsino, 1874; *F. dermatemica* da Silva Araiyo, 1875; *F. wuchereri da* Silva Lima, 1877; *F. sanguinis hominum* Hall, 1885; *F. sanguinis hominum nocturna* Manson, 1891; *F. nocturna* Manson, 1891.

History.—The *Microfilaria* was discovered in Paris by Demarquay in August, 1863, in the chylocele fluid of a patient from Havana. In 1866 Wucherer found it in Brazil in the urine of patients suffering from chyluria. In 1872 Lewis made the important observation that its true anatomical habitat is the blood. Bancroft, in 1876, discovered the adult female form; Bome, in 1888, discovered the adult male. In 1899 Manson discovered that the *Microfilaria*, on disappearing from the peripheral circulation, resorted to the lungs during the day-time. The parasite is spread by mosquitoes, as discovered by Manson in 1878, who thought that the *Filariæ* escaped from their insect hosts into water, and reached man by this means. Later Bancroft conjectured that *Filariæ* might be inoculated directly into man, and about this time sent infected mosquitoes to Manson in London. Bancroft's material was investigated, at Manson's request, by Low, who discovered that the *Filariæ* migrate to the mouth-parts of their insect hosts after a period of growth within the musculature. A little later, independently, James made the same discovery in India. In the meantime Grassi and Noè investigated the life-history of a corresponding *Filaria* of the dog (*D. immitis*), and demonstrated that it undergoes a similar development also in mosquitoes, choosing, however, the Malpighian tubes instead of the thoracic muscles as the seat of their development. Moreover, Grassi and Noè were successful in inoculating normal dogs by means of mosquitoes fed on infected dogs. Fülleborn and Bahr have most carefully re-studied the subject.

Morphology- *General Characters* The worms are whitish in colour, long, and filiform, with a smooth cuticle, and a globular head terminating in a simple, circular, unarmed, lipless mouth. The tail is rounded.

Sexual Characters.- The male is smaller than the female, and a complete specimen measures on the average 38 millimetres in length and 0·12 millimetre in thickness. In the dead worm the tail is spiral or much incurved, but may be straight during life, according to Maitland. The anus, which is 0·13 millimetre from the posterior extremity, is guarded by two projecting lips. The anal papillæ are not easily defined, but are said to consist of three pairs of pre-anal and three of post-anal papillæ. Leiper has recently figured fourteen pairs.

There are two unequal curved retractile spicules. The larger measures 0·6 millimetre and the smaller 0·2 millimetre in length. They consist of a basal portion, which is broad, rigid, and chitinous, measuring 0·17 millimetre in the larger and 0·12 millimetre in the smaller spicule, and a long, thin, colourless, cylindrical, slightly undulating terminal portion.

The female, while more or less transparent, is longer and thicker than the male, and measuring 76 to 100 millimetres in length, with a thickness of 0·185 millimetre.

The mouth is situated at the anterior extremity, being 8 μ in diameter, and leading into an œsophagus which passes insensibly into the intestine. This terminates in the anus, situated 0·28 millimetre from the incurved posterior end.

The vulva, situate 1·2 millimetres from the anterior extremity, opens into a single vagina, from which two uterine tubules run along most of the length of the body. These tubules contain the eggs and embryos in various stages of development.

Cobb's formula is:-

$$\frac{0\cdot36,\ 3\cdot04\ (?),\ 1\cdot22,\ 99\cdot5}{0\cdot145,\ 0\cdot377\ (?),\ 0\cdot254,\ 0\cdot147}.$$

The numerator indicates lengths from the anterior extremity to (1) base of œsophagus; (2) nerve ring, (3) posterior pharyngeal construction; (4) vulva in females or middle in males, (5) anus. The denominator represents transverse measurements at the same levels. All measurements are expressed as percentages of the total length. At the present time Cobb's formula is not accepted as a reliable guide to the parasitic species.

Life-History.- The males and females may be found coiled together in the lymphatics of the scrotum, the arm, the leg, hydroceles of the cord, epididymis, or testicle, and more rarely in those of the pelvis and abdomen. The males are less numerous than the females.

When placed in saline solutions, they show active movements, coiling and uncoiling themselves for several hours.

In the uterus of the female, as has already been stated, eggs may be noted in all stages of development.

At first nearly round, measuring 50 by 34 μ, and containing a coiled up embryo, the eggs become more and more elongated by the movements of the embryo, until in the anterior part of the uterus they are much longer than broad. Finally, they escape through the genital pore, and enter the lymph-stream, along which they travel through lymphatic vessels and glands, the thoracic duct, the right side of the heart, and the lungs, to reach the peripheral circulation, where they are best seen at night; hence the name *Microfilaria nocturna*. In the blood they appear as little wriggling filiform bodies, knocking the corpuscles about, but not moving from the position in which they are lying. The *Microfilaria* in the blood are said to be a little larger than those in the uterus, which is thought by Penel to be due, not to growth, but to inhibition of fluid by osmosis.

They measure from 290 to 320 μ in length and from 7·5 to 8·4 μ in breadth (Low), and are seen to be long, slender, cylindrical organisms with a rounded anterior and a tapering posterior end, enclosed in a sheath—the vitelline or egg membrane—inside which they are capable of darting backwards and forwards, because it is longer than they are, the empty portion being noted either in front of the anterior or behind the posterior end of the *Microfilaria*. Manson considers that this sheath is of vital importance to the little parasite, as it prevents its using its anterior spine to escape out of the blood-vessel, and so losing the chance of its invading a mosquito.

The anterior rounded extremity is said to possess a thick hemispherical proboscis, carrying a minute apical spine, which is capable of being covered by a retractile and protractile six-lipped prepuce, but this observation requires confirmation.

Behind the anterior end, the body can be seen to be composed of a transversely striated dermo-muscular layer, inside which are a number of closely packed cells whose nuclei show up clearly on staining. Unstained, the central mass appears granular, but the granules are, however, wanting at certain spots, which, following Annett, Dutton, and Elliot may be defined as: (1) A clear anterior area from the front to the first nuclei, (2) an irregular transverse spot situated 21·5 per cent. of the length of the body from the anterior end; (3) a V-shaped or transverse irregular spot at 30 per cent. of the length, called V-spot by Manson; (4) a median line, the central viscus of Manson, whose centre is at 63 per cent. of the length; (5) an irregular oval spot often present at 85 per cent., called the tail-spot by Manson; (6) a small central spot only occasionally present at 91·7 per cent.; (7) the clear posterior area behind the last nucleus.

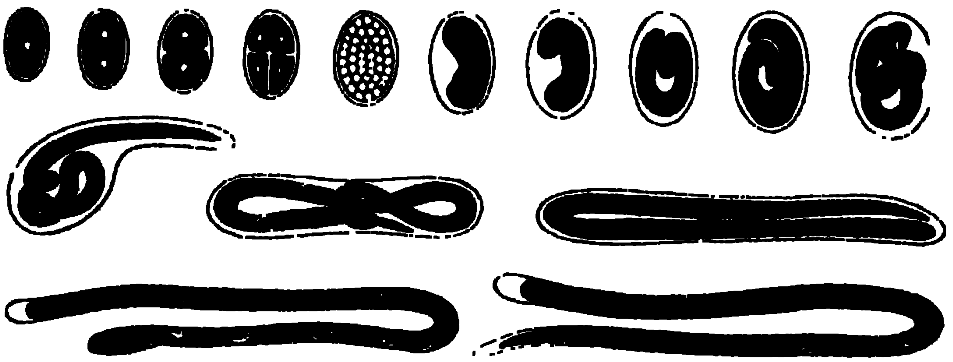

FIG. 268.—DIAGRAM OF THE DEVELOPMENT OF A MICROFILARIA (*Loa loa* STILES).

(After Penel.)

Leiper points out that these areas are not peculiar to the Filaria embryos, but occur also in other forms. The V-spot is the excretory vesicle and the tail-spot the proctodæum. The morphology of the worm has been studied in detail by Fülleborn, whose diagram is reproduced on p. 637.

These *Microfilariæ* occur in the peripheral blood at night, as has just been stated, beginning about 5 to 7 p.m., and increasing in numbers till midnight, and then diminishing till about 7 to 8 a.m., when only a stray one may be met with, as, indeed, can be observed all through the day until the evening increase begins. There is, therefore, a definite periodicity—at night the *Microfilariæ* abound in the blood, while in the day-time they do not.

In the day it appears that they live mostly in the lungs and in the large vessels of the thorax. This was shown by Manson by the careful examination of films and sections taken from the different organs of a man who had *Microfilaria bancrofti* in his peripheral blood, as well as a lymph scrotum and varicose groin glands. The post-mortem was made six hours after death, which took place almost instantaneously at 8.30 a.m., being due to drinking hydrocyanic acid. By far the largest number of parasites were to be found in the lungs and carotid artery, and then in the heart muscle, while a few were found elsewhere, especially in the kidney.

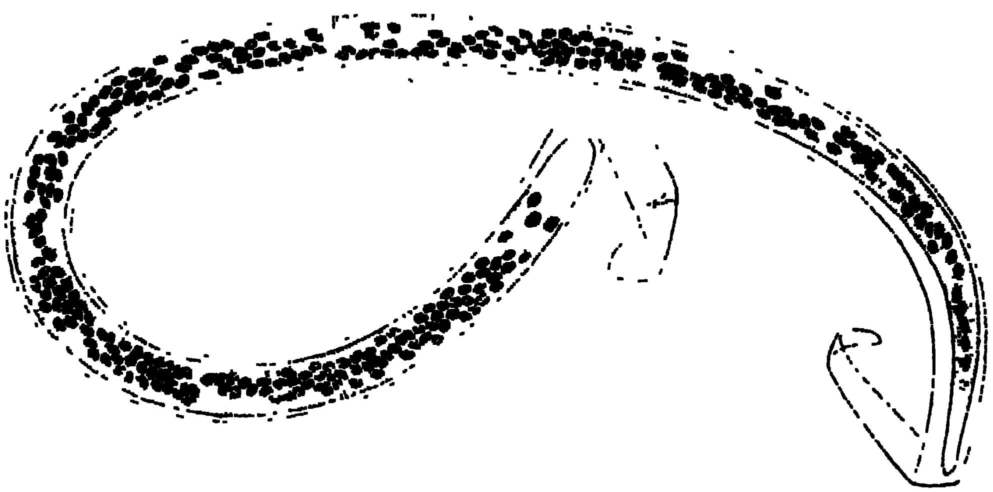

Fig. 269.—*Microfilaria bancrofti* Cobbold.

These facts have been confirmed, but the question as to what induces the parasites to live in the peripheral blood in the night and the thoracic organs in the day is not clear. True, it enables the *Microfilaria* to enter the mosquito, but that does not explain the problem. Neither variations in atmospheric temperature nor in pressure, in light, or in darkness seem to have any effect. Nor does the pulse-rate or the individual's temperature make much difference; but there is one factor, first shown by Mackenzie and since confirmed by Manson and others, that it is in some way connected with sleep; for if a person with *Microfilariæ* in his blood stays awake all night and sleeps during the day, the parasites will abound in his blood in the day, and not at night. Penel remarks that the problem of the periodicity of the *Microfilaria* and the periodicity of sleep in man are connected, and that when one is properly solved the other will also be elucidated.

Recently Bahr has shown that the microfilaria of *F. bancrofti*

in Fiji does not develop so well in *Culex fatigans* as it does in *Stegomyia pseudoscutellaris* Theobald, 1910.

This latter mosquito feeds only by day, and in Fiji Bahr has found that the microfilaria occur in the peripheral blood both during the day and during the night, and believes that the periodicity usually observed in the microfilaria is dependent upon the habits of the insect host.

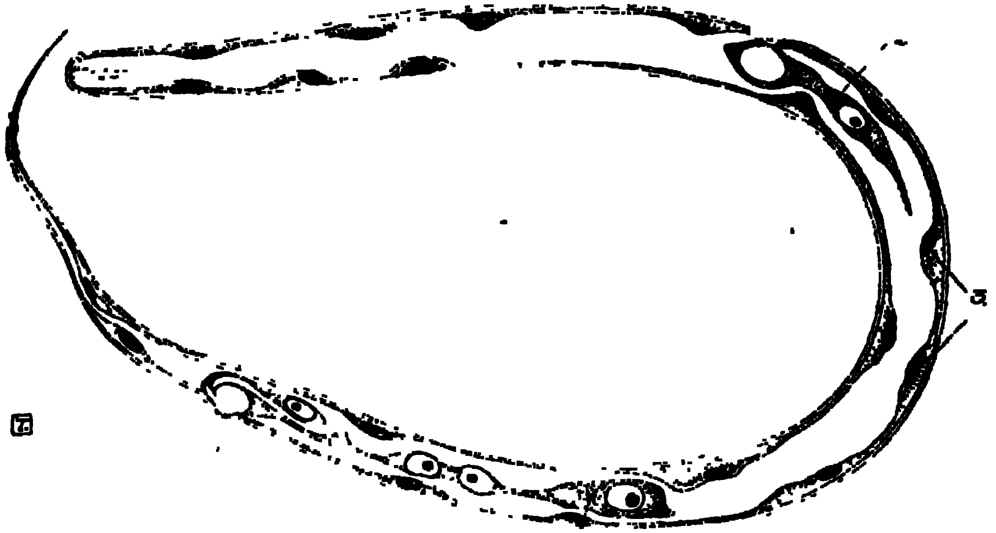

FIG. 270.—SCHEME OF THE STRUCTURE OF A MICROFILARIA, SHOWING (1) THE EXCRETORY PORE, (2) THE CELLS, WHICH WILL FORM THE EXCRETORY APPARATUS, (3) THE SUBCUTICULAR CELLS, (4) THE GENITAL CELLS; (5) ANUS.

(After Fulleborn.)

The number of *Microfilariæ* in the blood varies from very few up to quite considerable numbers, reaching, according to Manson, up to 500 in a single film, which gives some 40,000,000 to 50,000,000 in an average-sized man. This naturally raises the question of, How many adults do these come from? How long does an adult live? How long does a *Microfilaria* live? What finally happens to the *Microfilaria*?

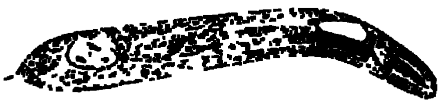

FIG. 271.- EARLY STAGE OF THE DEVELOPMENT OF *Filaria bancrofti* COBBOLD IN THE MUSCLES OF *Culex fatigans*.

(After Looss, from Mense's 'Tropenkrankheiten.)

It would seem probable that a given *Filaria* can live several years in the human body, and, of course, give rise to many embryos. Further, numbers of *Filaria* can be met with in one individual.

Fülleborn has shown that *Microfilariæ* can live in the blood for several months, and observers have thought that they may be destroyed by leucocytes and endothelial cells. It is, however, evident that they develop no further in the human body, and require to be taken into the body of a mosquito before further development is possible.

In the Mosquito.—Abounding as they do in the peripheral blood at night, there is no difficulty for the *Microfilariæ* to reach the stomach of a mosquito in the tropics, and here and in its thorax development proceeds.

The mosquitoes known to be capable of serving as efficient hosts for this development are: *Culex fatigans* Wied in the West Indies, *Myzomyia rossii* Giles in India, *Pyretophorus costalis* Loew in Nigeria, *Panoplites africanus* in Central Africa

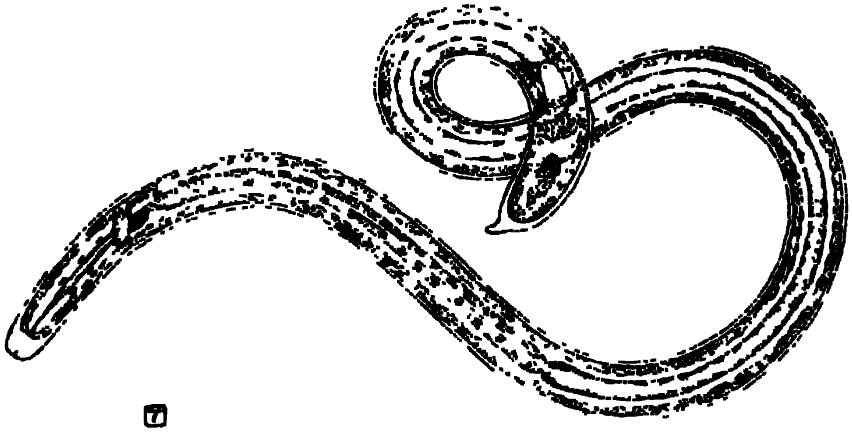

FIG. 272.—LATE STAGE OF THE DEVELOPMENT OF *Filaria bancrofti* COBBOLD IN *Culex fatigans*.

(After Looss from Mense's 'Tropenkrankheiten.')

Incomplete results have been obtained with *Culex microannulatus*, *C. albopictus*, *C. teniatus*, *Cellia albimana*, and negative results in *C. notoscriptus*, *C. annulirostris*, *C. hispidosus*, *C. vigilax*, *C. nigrithorax*, *C. procax*, *A. musivus*, *Myzomyia funesta*, *A. maculipennis*, *Pulex serraticeps*, *Stomoxys* (?), *Clinocoris lectularius*.

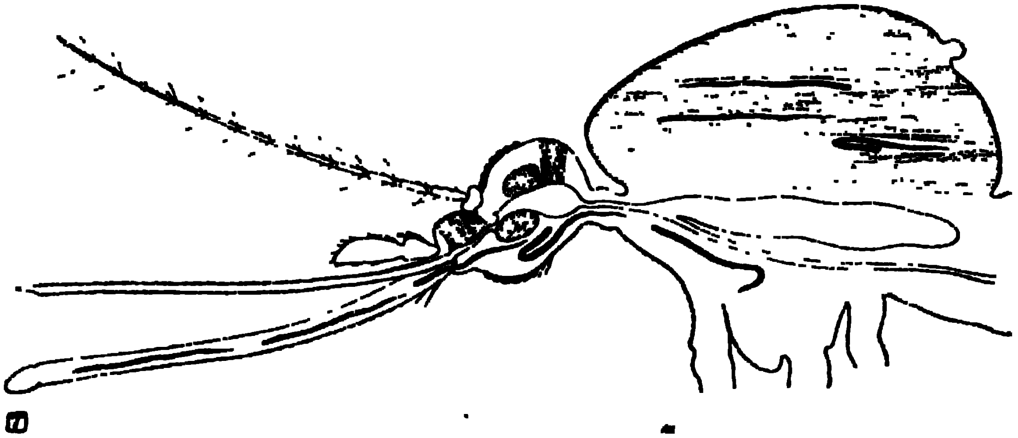

FIG. 273.—DIAGRAM OF THE DEVELOPMENT OF *Filaria bancrofti* COBBOLD IN THE THORAX, HEAD, AND LABIUM OF A MOSQUITO.

The *Microfilaria* enter with the blood into the mosquito's stomach, and there escape from the sheath by rupturing it at the anterior extremity.

They then pierce the wall of the stomach, and find their way into the muscles of the thorax, where they grow considerably till 1·5 millimetres long and 0·25 millimetre broad.

They also undergo development, obtaining an alimentary canal and a three-lobed tail. When so far developed, they leave the thorax and pass through the prothorax and head into the labium, where they remain until the mosquito bites a man, when they escape into the skin by making their way through Dutton's membrane, which is a thin membrane between the labella and the chitinous skeleton of the labium, as was demonstrated by Lebredo. (For further details see Chapter LXVI.)

Their further development in man is not known, but in due course they become adults.

Pathogenicity.—Usually non-pathogenic, these worms under certain circumstances can cause elephantoid fever, elephantiasis, lymph scrotum, etc., or, in other words, filariasis.

Filaria taniguchi Penel, 1905.

This *Filaria* was found in a lymphatic gland from a person living in Aida Kusha in Japan. Only the female and the microfilaria are known.

The former measured 68 millimetres in length and 0·2 millimetre in breadth, and had a non-striated cuticle, a terminal mouth with two pairs of papillae, an anus 0·25 millimetre in front of the posterior extremity, and a vulva 1·5 millimetres behind the mouth.

The latter measured 104 μ long by 8 μ broad, possessed a sheath and a truncated tail, and showed a nocturnal periodicity. Leiper regards this species as the same as *F. bancrofti*.

Life-History.—Not known.

Pathogenicity.—Not known.

Filaria ozzardi Manson, 1897.

Synonyms.—*Filaria ozzardi* Manson, 1897; *F. juncea* Railliet, 1908.

In 1895 Manson discovered a microfilaria in blood-films from natives of St. Vincent in the West Indies, which he named *Filaria demarquayi*, after the discoverer of the microfilaria of *F. bancrofti*. In 1897 he found in blood films from Carib Indians of British Guiana another microfilaria, which is the same as that called *F. demarquayi*, but which he provisionally considered to be a different species, and called *F. ozzardi*. The name *demarquayi* is preoccupied

Lately Penel and Manson have come to regard them as identical. Galgey found the adult females in the West Indies.

It is found in St. Vincent, Dominica, Trinidad, St. Lucia, in the West Indies, and in British Guiana, where it is found in jungly districts. The adults live in the connective tissue at the root of the mesentery and elsewhere.

Morphology.—The male has not yet been described, and only a fragment of a posterior end has been found. The female measures 65 to 80 millimetres in length and 0·21 to 0·25 millimetre in breadth, with a bulbous cuticular expansion at the tip of the tail. Anus 0·25 millimetre in front of the posterior extremity, vulva 0·71 millimetre behind the anterior end.

Life-History.—The egg develops into a microfilaria which has no sheath, shows no periodicity, and measures 200 μ by 5 μ. Its tail is tapering and sharp pointed, and it moves actively. Nothing further is known as to the life-history.

Pathogenicity.—Nil.

Filaria inermis Grassi.

Synonyms.—(?) *Hamularia lymphatica* Treutler; (?) ***Filaria palpebralis*** Pace, 1867; (?) *Filaria labialis*, etc.

Several female filaria worms have been described from Southern Europe as occurring in subcutaneous swellings in various parts of the body in man and horses. These resemble the forms recorded by Addario and Alessandrini under the name *Filaria conjunctivæ*, but differ, however, in the position of the vulva.

(Microfilaria) Le Dantec, 1904.

A collective group of the larvæ of unknown adult Filariidæ found in the blood of man and other vertebrates.

(Microfilaria) powelli Penel, 1905.

This microfilaria was found by Powell in 1903 in the blood of a Bombay policeman.

It showed a nocturnal periodicity (?), was provided with a sheath, measured 131 μ by 5·3 μ, and had a truncated tail.

(Microfilaria) philippinensis Ashburn and Craig, 1906.

Ashburn and Craig described this blood filaria in May, 1906. It measures 0·29 to 0·335 millimetre in length, has no periodicity, is actively and progressively motile, and is enclosed in a tight fitting sheath, within which it cannot slip backwards and forwards, and which is only clearly seen at the extremities. The anterior extremity is broad, with a serrated prepuce, and supports a small retractile spicule. The body has an outer striated musculo cutaneous coat and an inner clear portion, with an anterior **V**-spot situate 0·105 millimetre from the anterior end, and piercing the outer coat by its apex, and opening on the surface.

The central viscus is seen as a convoluted or spiral tube in the posterior part of the middle third of the body. The tail-spot is in the centre of the posterior third of the body, and opens by the apex of its **V** on the surface, where there is a distinct papilla. The tail begins to taper at a point midway between the tail-spot and the posterior end, and ends in a fine threadlike point. It is thought that this end disappears during later development.

The column of nuclei runs the whole length of the worm, being broken by unstained areas here and there. In stained species the **V**-spots and central viscus are not seen.

Life-History.—This microfilaria develops in *Culex fatigans* Wied. On entering the stomach of the mosquito it escapes from its sheath within twenty-four hours, and has pierced the stomach-wall and appeared free in the cœlom, where many die, but others develop rapidly, and complete their mosquito cycle. Generally by the third day they have left this position and travelled into the thoracic muscles, where they develop. At first there is a decrease in length from 0·32 to 0·21 millimetre, but an increase in breadth from 0·0065 to 0·01 millimetre.

By the eighth day the *Filaria* has increased in length and breadth, and shows an alimentary canal along its whole length.

From this till the eleventh day the development is rapid, and the worm now measures from 1·2 to 1·6 millimetres in length by 0·04 to 0·02 millimetre in breadth, and has a mouth, œsophagus, chyle intestine, and an anus, and the tail has three well-defined papillæ.

From the eleventh to twelfth day the worms are found in the head, and by the fourteenth to fifteenth day in the labium, lying side by side, with their heads pointing forwards.

Remarks.—There appears to be every reason to consider this microfilaria as merely the microfilaria of *F. bancrofti* Cobbold, 1877, because, as Low and Bahr have pointed out, they are morphologically identical, while both nematodes live in the tissues and are associated with the same pathological signs. Finally, the same mosquito, *Stegomyia pseudoscutellaris* Theobald, 1910, is an efficient host for both. Bahr suggests that the loss of periodicity is, probably, a partial adaptation to the habits of the intermediary host, *S. pseudoscutellaris*, which only feeds by day. This correlationship between parasite and host Sambon has long insisted upon.

(Agamofilaria) Stiles, 1906.

A purely collective group, made to contain agamic forms of Filariidæ which have not yet reached a stage in their development permitting their generic determination.

Species.—(*Agamofilaria*) *conjunctivæ* Addario, 1885; (*A.*) *labialis* Pane, 1864; (*A.*) *georgiana* Stiles, 1906; (*A.*) *oculi* Diesing, 1851; (*A.*) *palpebralis* Pace, 1867.

(Agamofilaria) conjunctivæ Addario, 1885.

Synonyms.—*F. peritonei hominis* Babès, 1880, *F. inermis* Grassi, 1887, *F. apapillocephala* Condorelli Francaviglia, 1892.

Remarks.—This worm was first discovered by Dubini in the eye of a man in Milan, then by Babès in the gastro-splenic omentum of a woman in Budapest, then by Vadela in the conjunctiva of a woman in Sicily. Perhaps *F. palpebralis* Pace, 1867, and *F. oculi humani* van Nordmann belong to this group. It is possible that the *F. loa* described in India was one of these parasites.

Morphology.—Several females are known. It is white in colour and measures 16 to 20 centimetres in length and 0·5 millimetre in breadth. The cuticle is striated except just around the mouth, but there are neither papillæ nor lips. The anus is subterminal, and the vulva close behind the mouth. There is a single vagina and a double uterus containing eggs and embryos.

Graham Forbes has recently recorded a male specimen from a soldier in Macedonia.

Life-History and Pathogenicity.—Intermediary is unknown. The worms produce subcutaneous tumours.

(Agamofilaria) labialis Pane, 1864.

This parasite was extracted from a small pustule on the inner surface of the upper lip of a person in Naples in 1864, and was not again described until Pierantoni, in 1908, again found it occurring in Naples. In both cases the female has been found, varying from 130 to 30 millimetres in length, with a whitish-yellow body, and a pointed anterior extremity, on which the terminal mouth, guarded by four papillæ, opens. The anus opens 150 µ anterior to the posterior end, and the vulva opens 3 millimetres behind the anterior extremity. The uterus bifurcates into two branches.

(Agamofilaria) georgiana Stiles, 1906.

These immature *Filariæ* were obtained by Graham from a sore on the leg of a negress at Darien.

They were cylindrical in shape, with a more or less uniform diameter, gradually attenuating towards both extremities. Mouth terminal, central, circular, small, unarmed, and surrounded by six papillæ, four of which were prominent and sub-median; two were smaller and latero-median. Anus a transverse slit, situated from 64 to 128 µ from the posterior end. Tip of the tail, with conical projections, 8 to 13 µ in length by 4 µ in breadth. Excretory pore 0·432 to 0·520 millimetre from anterior end.

Cuticle without striation, except some very fine transverse lines near the anus. Median lines visible in glycerine specimens. Lateral bands rather prominent, with longitudinal, sinuous ridges hanging into the body cavity, and with longitudinal canal emptying into excretory pore. Œsophagus simple, 2·5 to 2·9 millimetres in length, triradiate on section. Chyle intestine straight. Rectum 200 µ long. Body-cavity almost completely occupied by the intestine, lateral longitudinal glands, and reticular formation, which is probably the primordium (*Anlage*) of the genital apparatus.

(Agamofilaria) oculi von Nordmann, 1832.

Synonyms.—*Filaria oculi humani* von Nordmann, 1882; *F. lentis* Diesing, 1851.

These are immature filarial worms, found in cataracts by von Nordmann, Gescheidt, and Kuhnt. Braun rejects those by Quadri, Fano, Schoeler, and Everbusch. The common error here appears to be to mistake the remains of the hyaloid artery for a parasite. The worms measured from 0·38 millimetre up to 12·0 millimetres in length.

(Agamofilaria) palpebralis Pace, 1867, nec Wilson, 1844.

This *Filaria* was removed from a tumour in the upper eyelid of a boy.

Acanthocheilonema Cobbold, 1870.

Filariidæ with thin filiform bodies provided with smooth cuticle, which is only striated longitudinally. Mouth unarmed. Posterior extremity in both sexes provided with two short conical cuticular terminal appendages situate near the terminal point. Males with four pairs of pre-anal and one pair of post-anal papillæ and two unequal rod-like spicules. Female viviparous; vulva situate in the œsophageal region. Parasites in serous cavities of Carnivora and Primates. Embryos in general circulation.

Type.—*Acanthocheilonema dracunculoides* Cobbold, 1870.

Other species are *A. perstans* Manson, 1891 (*A. recondita* Grassi, 1890; and *A. grassii* Noè, 1907.)

Acanthocheilonema perstans Manson, 1891.

Synonyms.—*Filaria perstans* Manson, 1891; *F. sanguinis hominis minor* Manson, 1891; *F. sanguinis hominis perstans* Manson, 1891; *F. ozzardi* (variety truncated) Manson, 1897.

History.—The microfilaria was first found by Manson in the blood of negroes from the Congo. Daniels found the adults in British Guiana. The geographical distribution known at present is Tropical Africa and British Guiana.

Morphology.—The adults are found, as a rule, free in the connective tissue at the base of the mesentery, around the pancreas, behind the pericardium, and behind the abdominal aorta and the suprarenal capsules. The body is cylindrical, uniform, except towards both ends, when it tapers a little.

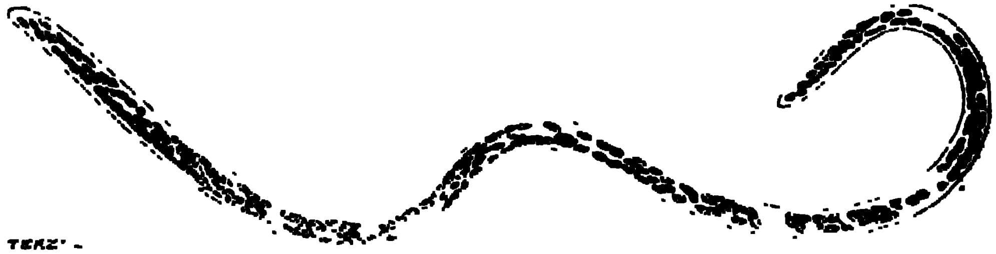

Fig. 274.—Embryo of *Acanthocheilonema perstans* Manson.

The male, rarely met with, is 45 millimetres in length by 0·6 millimetre broad, with a greatly curved tail, which ends in a bifid prolongation of the cuticle. Low describes two unequal spicules and four pairs of pre-anal and one of post-anal papillæ, all of which are very small. According to Leiper there are two pairs of post-anals.

The female is 70 to 80 millimetres in length and 0·12 millimetre in breadth, with a rounded head and a long neck. The incurved tail ends in two triangular cuticular lobes. The mouth is simple and small, and the alimentary canal shows no differentiation into œsophagus or intestine. The anus opens upon a papilla 0·145 millimetre in front of the tip of the tail. The uterus is double, and, when full of eggs and embryos in various stages of development, nearly fills the body. The vulva is 0·6 millimetre behind the anterior extremity.

Life-History.—The egg undergoes its development in the uterus, and the microfilaria escapes from its egg membrane and appears in the peripheral circulation without a sheath, and, consequently, can move about on a slide. It measures 190 to 210 μ in length and 4·5 to 5 μ in breadth. It is covered with a finely striated cuticle, and has a retractile spine, situated (apparently) upon a papilla at the anterior end of the body. The posterior two-thirds of the body tapers to the tip of the tail, which is abruptly rounded off.

It does not appear to have the central viscus seen in microfilaria of *F. bancrofti*. In stained specimens there is an area free from nuclei anteriorly, a transverse break at 34 μ, a V-spot at 49 μ, and the tail-spot at 125 μ.

A short type, measuring 90 to 100 μ, has been noted. There is no periodicity in its appearance in the peripheral blood. It never occurs in large numbers, but it is always there day and night.

Many unsuccessful attempts have been made to trace its life-history. Its larvæ are said to have been found in the thorax in *Panoplites (africanus ?)*, *Stegomyia fasciata*, and *Tæniorhynchus fuscopennatus*. It will not develop in a large number of blood-suckers, e.g., species of *Anopheles*, *Culex*, *Pulex*, *Pediculus*, and *Uranotænia*. Wellman and Feldham claim to have found its development in a tick (*Ornithodoros moubata*), as first suggested by Christy. According to Leiper, however, these are spermatophores!

It is to be noted that it only occurs in areas covered with dense forest and possessing swamps, which indicates that the host probably requires shade in the day and water to lay its eggs in.

Pathogenicity. Nil.

Dirofilaria Railliet and Henry, 1911.

Filariidæ with very long filiform body, with a striated cuticle unprovided with bosses, mouth unarmed, with six cephalic papillæ. Males with a spiral tail. Female with vulva in anterior hundredth of body. Viviparous.

Type. -*Dirofilaria immitis* Leidy, 1856.

Dirofilaria magalhæsi Blanchard, 1895.

Synonym. *F. bancrofti* Magalhæs, 1892, *nec* Cobbold, 1877.

In 1887 Magalhæs described male and female forms of a *Filaria* found by Figueira de Saboia in the left ventricle of the heart of a child in Rio de Janeiro.

For a time it was mistaken for *F. bancrofti*, but in 1894 Manson pointed out that it was a different species, and in 1895 Blanchard gave it the present name.

Morphology.- The worms were white, opalescent, and transversely striated, the head club shaped and simple, mouth terminal, œsophagus with a bulb, and there was a rounded tail. The male measured 83 millimetres in length and 0·28 to 0·4 millimetre in breadth, and possessed a rounded tail, with a cloaca 0·11 millimetre from its tip, with two spicules and four pre-anal and three post-anal pairs of papillæ.

The female was 155 millimetres in length, and 0·6 to 0·8 millimetre in breadth, with a vulval opening 2·56 millimetres behind the mouth, and an anal opening 0·13 millimetre in front of the tip of the tail.

Life-History and Pathogenicity.--Unknown.

Dirofilaria immitis Leidy, 1856.

This worm lives in the right heart and in the veins of the dog, and also of the wolf and the fox, in Europe and tropical regions. It is very common in China and Japan.

Bowlby is commonly reported to have found it in the portal vein, kidneys, bladder, ureters, and lungs of an Arab, and also in a rectal tumour in a youth, but this is quite erroneous, as he never made any such statement, for the eggs in the bladder and rectum, and the parasites in the portal vein of the Arab, were *Schistosoma hæmatobium*, as he carefully reported, never mentioning *D. immitis*. Braun, however, seems to think it possible that this worm may occur in man.

Morphology.—The worm is long, measuring 12 to 18 centimetres by 0·7 to 0·9 millimetre in the male and 25 to 30 centimetres by 1·0 to 1·3 millimetres in the female, and filiform, with a smooth rounded cuticle and a rounded anterior extremity, on which is situated the terminal mouth with six small papillæ. The anus is subterminal, and the posterior extremity pointed.

The male has a twisted tail with a cuticular fold on each side, and four pre-anal and post-anal papillæ. In the female the vulva is 7 millimetres from the anterior extremity. Viviparous.

Life-History.—The young larvæ 285 to 295 μ by 5 μ, are not enclosed in an egg case, and have a tapering posterior extremity. They appear in the peripheral blood particularly at night, when they may enter a mosquito if it bites the dog.

They enter the Malpighian tubules or their epithelial cells, where they moult and grow, eventually passing via the body cavity to the labium.

They escape through Dutton's membrane on to the skin when the mosquito bites, and so enter the dog.

Loa Stiles, 1905.

Filariidæ with bosses on the cuticle and with large caudal papillæ.

Species.—*Loa loa* Guiyot, 1778.

Loa loa Guyot, 1778.

Synonyms.—*Filaria oculi* Gervais and van Beneden, 1859; *Dracunculus oculi* Diesing, 1860, *D. loa* Cobbold, 1864, *F. subconjunctivalis* Guyon, 1864.

The larval names are: *F. sanguinis hominis* var. *major* Manson, 1891; *F. diurna* Manson, 1891.

History.—That a *Filaria* occurred in the eye appears to have been known since the end of the sixteenth century in Europe, and probably in Africa, especially in Angola, where it was called 'loa.' That knowledge must have been very ancient. Mongin in 1770 appears to have been the first person to record the presence of a worm in the eye. Guyot, in 1778 and 1805, thought it was a *Strongylus*, and used the term 'loa' for the first time in European literature. In 1891 Manson found a microfilaria in the blood of several negroes from the Congo which differed from those already described, and which he named *Filaria diurna*, and further suggested that it might be the larva of *L. loa*. Since then this hypothesis has been proved to be correct by the observations of Penel, Prout, Henly, Brumpt, Wurtz, and Kerr. *L. loa* and *Microfilaria diurna* are, therefore, simply different stages in the life-history of the same parasite.

L. loa is a parasite of the superficial connective tissue—the conjunctiva, the subcutaneous fat, and the superficial aponeuroses, in all parts of the body. It probably only occurs in man, for its alleged existence in sheep and goats in the Cameroons requires further investigation. Its endemic area is on the West Coast of Africa from Sierra Leone to Benguela, being most common in Old Calabar, the Cameroons, and the Ogowé River. It is, however, by no means confined to the coast, for it is known to penetrate at least 600 miles into the interior of Africa.

The cases reported from India are of doubtful validity, and the cases from the West Indies and South America appear to have all been imported from the West Coast of Africa.

The parasite appears to have never become endemic outside a given area, which means that the animal by which it is spread has a restricted geographical range.

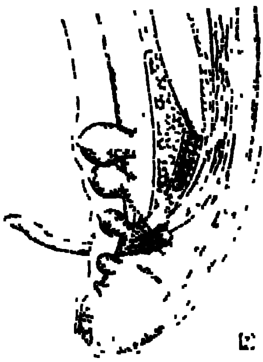

FIG. 275.—*Loa loa* COBBOLD. POSTERIOR EXTREMITY OF THE MALE.

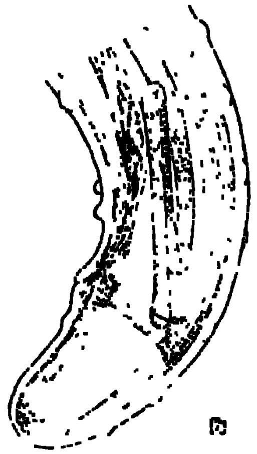

FIG. 276.—*Loa loa* COBBOLD. POSTERIOR EXTREMITY OF THE FEMALE.

(After Looss.)

Morphology. The male is a thin, white, almost transparent worm, with a body tapering to each extremity, and measuring 25 to 34 millimetres in length and 0·273 to 0·430 millimetre in breadth. The head is like a truncated cone; the neck is but feebly indicated. The tail, more or less incurved, has a rounded tip, from which the anus is distant 74 to 82 μ. There are three pairs of well marked pre-anal and two pairs of post anal papillæ, with sometimes a little tubercle on each side of the middle line far posteriorly.

The spicules are two in number and unequal, and are usually stated to differ but little in length. Penel says that the larger is traversed by a fine canal, opening laterally a little distance from the free extremity.

The cuticle consists of a superficial, thin, translucent layer and a deeper perpendicularly striated layer. Scattered over this cuticle there are rounded thickenings, or bosses, the smaller being 9 to 11 μ and the larger 14 to 16 μ in height. The thickness at the posterior extremity is variable, as also is the constriction corresponding to the neck. The viscera are enclosed in a cylindrical musculo-cutaneous tube. The mouth is terminal, small, unarmed, and surrounded by a powerful muscular cone; the œsophagus is short, and without a bulb; the intestine opens via the rectum at the anus, near the posterior extremity. The excretory pore is 0·65 millimetre from the anterior end of the body.

The genital apparatus consists of a tubular testis and vas deferens, filled with spherical spermatozoa, which terminates in a vesicula seminalis situate in the neighbourhood of the bases of the spicules.

The female is larger and thicker than the male, measuring in the fresh condition 44 to 63 millimetres (may be from 32 to 57 millimetres in different conditions of preservation) in length, and from 0·38 to 0·49 millimetre in thickness. The cuticle and anterior extremity resemble those of the male.

The genital system consists of a vulva situated on a little elevation 23 μ in height, and distant some 2·5 millimetres from the anterior extremity. This vulva leads into a thick-walled canal—the vagina—from which the two uterine tubes full of embryos and eggs diverge, and end in the ovaries.

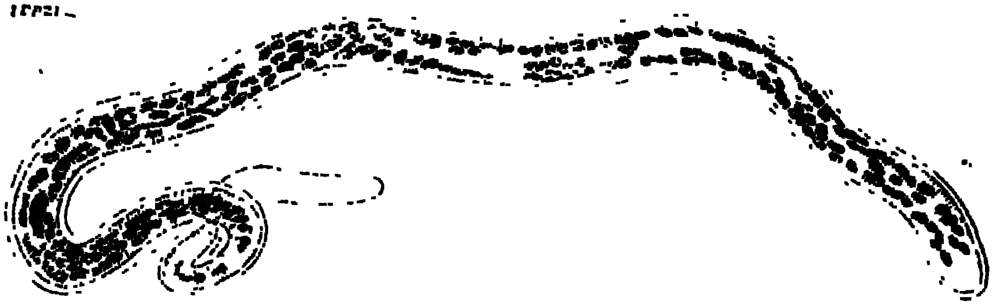

FIG. 277.—EMBRYO OF *Loa loa* GUYOT.

Life-History.—The life-history, unfortunately, is not well known. The unsegmented egg, starting in the uterus with a length of 32 μ and a breadth of 17 μ, grows into 40 by 25 μ in the morula stage, and 50 by 25 μ in the stage when a twisted and rolled-up embryo can be seen. It now approaches the vulva, and the embryo unrolls and elongates itself inside the egg membrane, which is now considerably lengthened, measuring 250 to 260 μ in length by 5·5 to 6·6 μ in breadth. The embryo now escapes from the mother, and passes via the lymph-stream into the blood, where it is known as *Microfilaria diurna*, and is noticed to have increased somewhat in size, which Penel considers is due to imbibition of fluid by osmosis, and now measures 298 by 7·5 μ. It will be noted, however, that it does not quite fill up its sheath, which is generally empty in front and behind for a short space. These embryos are only to be found in the peripheral blood during the day, and not at night, but they have no relation to sleep in the host like *M. bancrofti*, as they are unaffected by altering the habits of the host, and making him sleep in the day and work at night. When examined under the microscope, they can be seen in irregular curves, which are different from the graceful curves of *M. bancrofti*. The anterior **V**-spot can be seen, and probably opens at the apex to the exterior, as Penel has observed that the stain penetrated easily at that spot; probably there is also an opening at the tail-spot. In stained specimens the first 8 μ is clear, without nuclei; at 62 μ the column of nuclei is broken by an irregular transverse spot; at 99 μ by a triangular spot; at 253 μ by a large and at 207 μ by a small spot. The last nuclei are arranged in single file. One noticeable thing about these embryos is the scarcity with which they are met with in the peripheral blood as compared with those of *F. bancrofti*. No explanation of this is forthcoming at present.

It has been thought by Manson that the further stages of the life-history will be found in a mango-fly (*Chrysops dimidiatus*), and this has been shown to be the case by Leiper, who also finds a development in *C. silacea*, but the method of infection of man is unknown.

After entering the human body, it would appear probable that the worm takes some three to four years to reach sexual maturity, and that it is long lived—*i.e.* fifteen or more years. The reason for believing this is the fact that immature forms may be noted in children and the fully grown worm found in the adult. When the worm dies, it may become cretified.

TABLE SHOWING THE DIFFERENCES BETWEEN THE EMBRYOS OF *Filaria bancrofti* AND *Loa loa*. (MODIFIED FROM DR. G. C. LOW.)

	Filaria bancrofti Embryos	*Loa loa Embryos.*
Average length	0·317 millimetre	0·245 millimetre
Average breadth ..	0·0081-0·0075 millimetre	0·0075-0·0070 millimetre
Break in cells from head	0·050 millimetre	0·042 millimetre
V-spot from head ..	0·060 millimetre	0·060 millimetre
Eggs (average)	0·050 × 0·033 millimetre	0·042 × 0·033 millimetre
Character of curves in dried specimens on slides	Spiral coils	In wavy lines
Periodicity .. .	In blood at night (or in equal numbers in blood by day and night, Fiji, etc.)	In blood by day
Periodicity when habits of sleeping and waking changed	Inverted	No change

Pathogenicity.—It may be noted under the skin of the finger, the back, the breast, the scrotum and penis, the eyelid, under the conjunctiva, the mucosa of the tongue. It moves quickly, and may cause itching, creeping sensations, so-called Calabar swellings, irritation of the eyes and of the glottis (see Chapter LXXXVIII.).

Setaria Viborg, 1795.

Synonyms.—*Hamularia* Treutzler, 1793; *Tentacularia* Zeder, 1800, *nec* Bosc, 1797.

Definition. *Filariidæ* with chitinous ring (and papillæ around the mouth) which is deeply notched laterally and less so dorsally and ventrally. Tail in both sexes with caudal appendages. Parasitic in serous cavities of ruminants.

Setaria equi Gmelin, 1789.

Synonyms.—*Gordius equinus* Abbild, 1789; *Filaria equi* Gmelin, 1789; *Hamularia lymphatica* Treutzler; *Tentacularia subcompressa* Zeder, 1800; *Filaria papillosa* Rudolphi, 1802; *F. hominis bronchialis* Rudolphi, 1829; *F. hominis* Diesing, 1851; *Strongylus bronchialis* Cobbold, 1879.

History.—*Setaria equi* is frequently found in horses and asses, generally in the abdominal cavity, but also in the liver, female genitalia, and cranium.

It is doubtful whether the immature *Filariæ*, so commonly met with in horses' eyes in India and Ceylon, belong to this species. Railliet has recently put forth the view that they are due to the cattle filaria *F. labiato-papillosa*. Other cases have been noticed by Blanchard, Brera, and von Linstow.

Morphology.—Whitish filiform body, pointed posteriorly. Cuticle with delicate transverse striata, and mouth small, round, with chitinous ring and two lips, and papilliform processes dorsally and ventrally and two submedian papillæ.

Male 6 to 8 centimetres in length, with posterior extremity spiral, with four pre-anal and four post-anal papillæ, and two unequal spicules.

Female 9 to 12 centimetres.

Pathogenicity.—Nil.

SUBFAMILY ONCHOCERCINÆ Leiper, 1911.

Onchocerca Diesing, 1841.

Synonym. *Oncocerca* Creplin, 1846.

Filariidæ with thick cuticle possessing spiroid thickenings. Male with always four pre-anal papilla; female very long, with vulva situated anteriorly. Viviparous. Name derived from ὄγκος ('a hook') and κέρκος ('a tail').

Species.—*Onchocerca volvulus* Leuckart, 1893.

Other species are common in cattle, *e.g.*, *O. gibsoni* Cleland and Johnston, 1910, in Australia, *O. gutturosa* Neumann, 1910, in Algeria and Tunis. They cause onchocerciasis. Cleland and Johnston suspect that *O. gibsoni* is spread by lice, especially *Hæmatopinus vituli*. They report finding a Protozoal parasite somewhat like a Herpetomonas or a Crithidia in *O. gibsoni*.

Onchocerca volvulus Leuckart, 1893.

This worm was discovered by a German medical missionary in two tumours on the scalp and chest of negroes in the Gold Coast Colony, West Africa. Labadie, Lagrave, and Deguy found another specimen in a small swelling in the arm of a soldier from Dahomey. Prout next described two cases in Sierra Leone, and Brumpt a number of cases in his tour in West Africa, and Fulleborn has thoroughly studied the condition.

It is found in Sierra Leone, Gold Coast, and Dahomey; but on the Welle, between Dongon and M'Bini, it is said to occur in 5 per cent., and on the Itimbiri, between Bonta and Idembo, in 1 per cent. of the population. It has not been recorded as far south as the Congo. Thèze has recorded three cases from Dutch Guiana, and Leiper has recently confirmed its occurrence in Guatemala, where, according to Robles, the infection is very common.

Morphology.—The male worm has a white filiform body, slightly attenuated at the ends, covered with a transversely striated cuticle, measuring 30 to 35 millimetres in length and 0·14 millimetre in breadth.

The head is rounded, the mouth unarmed, the alimentary canal straight and undifferentiated, the anus subterminal 0·049 millimetre in front of the posterior end. Other canals are reported, which probably belong to the generative and excretory systems.

The tail is strongly recurved, and somewhat flattened on its concave aspect. Brumpt reports three pairs of papillæ on each side of the anus and three pairs of post-anal papillæ. There are two unequal spicules, the larger 177 μ and the smaller 82 μ in length.

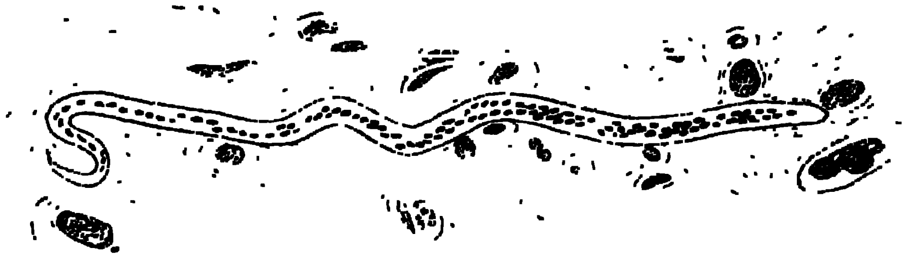

FIG. 278.—MICROFILARIA OF *Onchocerca volvulus* LEUCKART.
(After Fülleborn.)

The female is longer and thicker than the male, measuring 60 to 70 millimetres in length and 0·30 millimetre in breadth. The cuticular striations are ring-like and well marked. The tail is recurved. The uterus is seen full of eggs and larvæ, and the vulva is 0·70 millimetre from the anterior end.

Life-History.—The worm is said to lie in a lymphatic, which becomes inflamed, and a perilymphangitis causes a condensation of connective tissue, in which males and females are embedded, leaving the posterior end of the male and the anterior end of the female free in the lymph space. The embryos pass out of the uterus into this space, where they can be found 250 to 300 μ in length, and 5 to 6 μ in breadth, with a rounded head and a body which tapers during the last fifth, and terminates in a pointed tail. There is no sheath. The anterior V spot is clearly seen. The microfilaria have not been seen in the blood, and their further development is quite unknown.

The embryos have recently been found in the blood, and Brumpt is inclined to think that the further development will be in a tsetse-fly. The adults live for years in the human body.

Pathogenicity.—Lymphangitis, perilymphangitis, sometimes acute and with fever, and resulting in small tumours, are their pathological signs.

FAMILY 7. DRACUNCULIDÆ Leiper, 1912.

Dracunculus Kniphoff, 1759.

Nematodes with small males and long females. In the latter a vagina is wholly absent; the embryos being discharged by rupture of the gravid female.

Dracunculus medinensis (Linnæus, 1758).

Synonyms.—*Dracunculus veterum* Velsch, 1674; *Vena medinensis* Velsch, 1674; *Dracunculus persarum* Kämpfer, 1691, *Gordius medinensis* Linnæus, 1758; *Filaria dracunculus* Bremser, 1819; *F. æthiopica* Valenciennes, 1856; *Dracunculus medinensis* Cobbold, 1864.

Dracunculus medinensis, commonly called the guinea-worm, the dracunculus, Beinwurm, Brachwa-serwurm, tankworm, or dragonneau, is endemic in tropical Africa, India, Persia, Turkestan, Arabia, and some places in South America, to which it was imported from Africa.

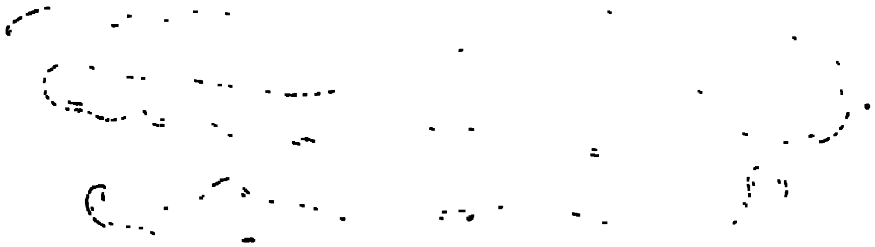

FIG 279.—*Dracunculus medinensis* LINNÆUS.

It has been known since the most remote periods, and it was probably the fiery serpent mentioned by Moses who apparently knew the method of twisting the worm out on a stick, as he appears to have made a model of this method of extraction. Galen called the disease caused by these worms dracontiasis.

The anatomy of the worm was carefully studied by Bastian in 1863, and the infection of *Cyclops* with the larva was observed by Fedschenko in 1870, and confirmed later by Manson. Charles found a calcified guinea worm in 1892, which he described as the male.

Leiper, 1907, has repeated these experiments, and has further proved that when monkeys are fed on infected *Cyclops* the males and females can be found.

Morphology.—The female is a long white filiform worm 50 to 80 centimetres in length and 0·5 to 1·7 millimetres in diameter.

The anterior end is bluntly rounded, and carries the small terminal mouth, which has two lips and two lateral and four submedian papillæ. It leads into a straight alimentary canal, which atrophies considerably in the fully developed condition. The large uterus, which occupies the whole length of the body when filled with embryos, evacuates its contents by a rupture close to the mouth and just external to the papillæ. The tail is rounded off, and carries a small bent chitinous hook.

Leiper states that the male is only 22 millimetres in length, and has five pairs of papillæ.

Life-History.—The males and females live in the connective tissue about the mesentery, and after copulation probably the males die off. When the female is gravid, she moves, head first, apparently in search of water, usually downwards towards the leg or foot; more rarely she moves to the hand or arm, and very rarely to the head. Arrived under the epidermis, she bores her way through the deep layers, while a little bulla on the surface marks her presence.

When this bulla bursts, a small hole is seen, at the bottom of which lies the vulva, through which the tube of the uterus has prolapsed, bending the head to one side. Clear fluid can be seen escaping from this tube, which, when examined, is found to be full of embryos.

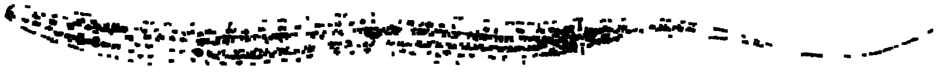

FIG. 280.—LARVA OF *Dracunculus medinensis* LINNÆUS.
(After Looss, from Mense's 'Tropenkrankheiten.')

The segmentation of the egg takes place in the uterus, and the embryos are born alive. They are flat, pointed little bodies, 0·6 millimetre in length and 17·5 μ in breadth, with a narrow, very pointed tail. The mouth is at the anterior end, and leads into an alimentary canal with an anus. There is a little sac on each side of the root of the tail. According to Leiper, these little larvæ cannot swim, but either die or are swallowed by a *Cyclops*. In this crustacean they pass from the stomach into the cœlom, where they develop for four weeks. Leiper describes the first ecdysis as taking place about the seventh to ninth day, and the second between the tenth and eleventh day, after which progressive histological changes occur. After the fourth week no further change takes place, though they can live for forty-one days in the *Cyclops*. When placed in 0·22 per cent. solution of hydrochloric acid, the *Cyclops* is promptly killed, while the larva appears to be stimulated, undergoing ecdysis, and escaping from the *Cyclops* by boring its way through the chitinous cuticle. In a monkey fed with infected *Cyclops*, three females and two males were found. It is, therefore, correct to assume that man is infected by ingesting infected *Cyclops* with his drinking-water, and it is probable that, set free in the stomach, the larvæ enter the connective tissue by boring their way through the stomach-wall.

Pathogenicity.—The worm causes dracontiasis (see Chapter LXXXVIII.).

FAMILY 8. MERMITHIDÆ.

Nematoda with a diagonal fibre system in the cuticle, without anus, and with six mouth papillæ.

The male has two spicules and three rows of numerous papillæ.

Genus.—*Mermis* Dujardin.

Mermis Dujardin, 1845.

Mermithidæ possessing the characters of the family.

Subgenus (Agamomermis) Stiles, 1903.

A purely collective group, which contains forms sexually immature and not capable of being definitely placed.

(Agamomermis) restiformis Leidy, 1880.

Synonym.—*Filaria restiformis* Leidy, 1880.

In 1880 Leidy received from Woodward a worm which was supposed to have come from the urethra of a man living in America. Stiles has re-examined this specimen, and concludes that it is an Agamomermis.

The cuticle is 32 to 48 μ thick, with a diagonal fibre system. The head end is attenuated, and possesses a very small terminal mouth without lips, behind which are six papillæ. The excretory pore (?) is 0·112 millimetre behind the mouth. The pharynx is straight, and opens into the cylindrical intestine, which is a dark cæcal structure; but there is no anus and no caudal papillæ. The tail is curved ventrally and bluntly rounded.

On one side of the œsophagus there is a blind sac, which probably represents the fat body.

Filaria (?) hominis oris Leidy, 1850. Perhaps this worm ought to be classified here instead of under Filaria.

FAMILY 9. ASCARIDÆ Cobbold, 1864.

Definition. Nematoda with three lips, one median dorsal and two submedian ventral, touching one another in ventral median line; œsophagus with a bulb. Male with (one or) two spicules; female with two ovaries. Oviparous. Development believed to be direct.

Genera.—*Ascaris*, *Toxascaris*, *Belascaris*, and *Lagochilascaris*.

Ascaris Linnæus, 1758.

Synonyms. *Stomachida* Pereboom, 1870; *Fusaria* Zeder, 1800.

Definition.—Ascaridæ in which the oral cavity is surrounded by three large lips provided generally with denticulated borders, one placed dorsally and two ventrally. Male with two equal spicules and numerous pre-anal and post-anal papillæ. Vulva in front of the middle of the body. Shell of egg thick, with outer albuminous layer often raised into numerous projections.

Species.—*Ascaris lumbricoides*, *A. texana*, *A. maritima*.

Ascaris lumbricoides Linnæus, 1758.

Definition.—*Ascaris* with reddish-yellow colour in fresh condition. Oral papillæ finely toothed, without interlabia.

Remarks.—This is one of the most common parasites in the tropics. It is, however, possible that other species escape recognition by being casually considered to be *Ascaris lumbricoides*. It is usually met with in the small bowel, but may be found post mortem in the stomach, œsophagus, mouth, nose, larynx, trachea, or bronchi. It may also be found escaping from the anus. More rarely it has been seen in the liver, causing abscesses, in the pancreatic duct, and in the vermiform appendix, and in worm abscesses in the body-wall. Usually it gives rise to no symptoms, but at times, when in large numbers, it may cause pathological effects.

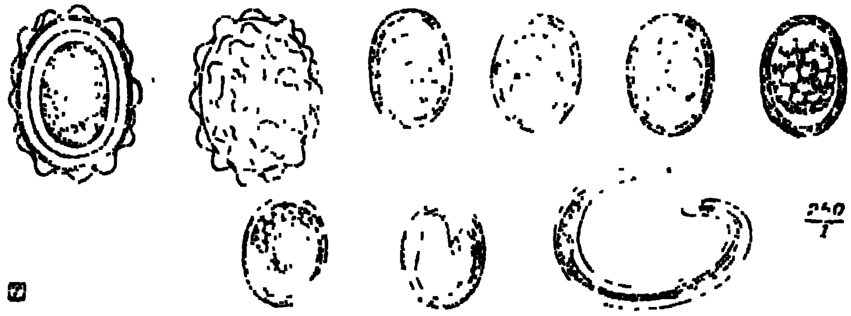

FIG. 281.—DEVELOPMENT OF *Ascaris lumbricoides*. (After Stiles.)

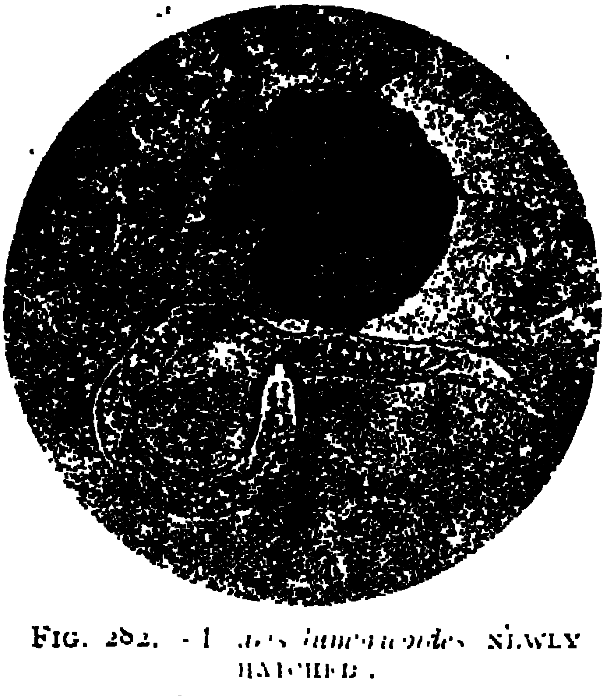

FIG. 282.—*Ascaris lumbricoides* NEWLY HATCHED.
(Microphotograph by J. J. Bell.)

Morphology.—It is yellowish in colour, with often a faint trace of a reddish tinge. In form it is spindle-shaped. Male is 15 to 25 centimetres in length and 3 millimetres in diameter. The posterior extremity is conical, and bent ventrally, with two spicules 2 millimetres in length, and broader at the tips. On each side of the cloaca there are seventy to seventy-five papillæ, of which seven pairs are post-anal. Female [illegible] 20 to 40 centimetres in length by 5 millimetres in breadth. The vulva is at the junction of the anterior and middle thirds of the body.

Life-History.—The eggs are laid in the small intestine, and appear unsegmented in the fæces. They measure 50 to 70 μ in length by 40 to 50 μ in breadth, surrounded by a thick transparent shell, which has an externally irregular coating of albumin, which is stained brownish-yellow by the stercobilin of the fæces. These eggs can stand alteration in temperature and moisture. In warm, moist earth the embryo appears in about a month in the form of a spiral roll, but does not hatch until it reaches the interior of man, when it develops into an adult, as was shown by the experiments of Davaine, Grassi, Calandruccio, Lutz, and Epstein.

Leuckart and von Linstow believed that an intermediate host was necessary. Stewart has shown that the larval forms after hatching from the eggs pass into the liver and thence by the blood-stream to the lungs, whence they reach the stomach by migrating up the bronchii and trachea.

Stiles found that the house-fly could carry the egg, which passed through its alimentary canal unaltered. The worm matures, and deposits ova in one month from entering the body.

Pathogenicity. It is only pathogenic in large numbers, or when it invades the liver, causing abscess, or the appendix, causing appendicitis. The larvæ in the lungs apparently cause bronchitic symptoms.

Animals.—Monkeys, dogs, and perhaps pigs.

Ascaris (?) **maritima** Leuckart, 1870.

An immature worm, possibly accidentally swallowed in food, was vomited by a child in North Greenland in 1865, and was supposed to be an immature female *Ascaris*.

Ascaris (?) **texana** Smith and Goethe, 1904.

Stiles appears very doubtful as to whether this worm is an *Ascaris*. The female only is known, measuring 58 to 60 millimetres in length. Uterine eggs 60 by 50 μ. It was found in a man in Texas.

Toxascaris Leiper, 1907.

Definition. Ascaridæ with the anterior end of the body bent dorsally, cuticle finely striated, œsophagus simple, without a bulbous portion. Palpi of lips club-shaped. Male with a tapering, acicular tail, and without ventral protuberance behind anus. Six pairs of post-anal papillæ in two groups, the ventral pairs continuous, with a pre-anal row on each side of the body, and three lateral pairs on the outer aspect of the tail. Testis lies in the anterior part of the posterior half of the body. Seminal vesicle long and tubular. Ejaculatory duct short. Female with vulva about the centre of the body. Egg oval and smooth.

Species.—Of the species belonging to this genus, only one, *Toxascaris canis* Werner, 1782, is known in man.

Toxascaris canis Werner, 1782.

Synonyms.—*Lumbricus canis* Werner, 1782; *Ascaris canis* Gmelin, 1789; *A. marginata* Rudolphi, 1802; *Toxascaris limbata* Railliet and Henry, 1911.

Remarks. — *Toxascaris canis* is the common *Ascaris* of dogs, which used to be called *A. canis*, but recently Leiper, when examining a number of specimens of *A. lumbricoides* in Egypt, found among them several smaller and apparently younger forms. On examining these he found that they had winged expansions on either side of the head, which indicated that they were not *A. lumbricoides*. On further examination they proved to be the same species as that found in dogs, but differed from that found in cats. Up to that time *A. canis* in the dog and *A. mystax* in the cat were supposed to be identical. Finally, on careful anatomical examination, it was found that the two not merely differed considerably from one another, but also from *A. lumbricoides*. He therefore formed two new genera—*Toxascaris* and *Belascaris*. So far, *Toxascaris* has only been recorded once in man.

Morphology. Body white or reddish, head curved dorsally, with two membranous lateral expansions, broader behind than in front. Male 5 to 10 centimetres in length, with curved tail, possessing two small lateral membranous wings and twenty-six papillæ. Female 9 to 12 centimetres in length, with an obtuse tail. Eggs 75 to 80 μ in diameter.

Life-History. Development is similar to *A. lumbricoides*.

Pathogenicity. It often causes intestinal and nerve symptoms in dogs. Post mortem the mucosa of the intestine is tumefied and catarrhal.

Belascaris Leiper, 1907.

Definition. Ascaridæ with the anterior end of the body bent ventrally, cuticle coarsely striated, œsophagus with a distinct bulbous portion. Male with a probular tail, *i.e.*, like a closed fist, with forefinger semi-extended. Immediately behind the anus there is a protuberance, with a pair of papillæ. On the tail there are two ventral and two lateral pairs of papillæ, the tips of which support a slight expansion of the cuticle. The testis is situate in the anterior half of the body. The vesicula seminalis is remarkably long, and there is a short ejaculatory duct. Female with vulva situated in the anterior part of the body. Egg with a honeycombed shell.

Type. *Belascaris cati* Schrank, 1788.

Belascaris cati Schrank, 1788.

Synonyms.— *Fusaria mystax* Zeder, 1800; *Ascaris alata* Bellingham, 1839.

This *Ascaris* is common in cats, and has been recorded nine times in man.

Morphology. Head curved ventrally, with two membranous lateral expansions. Male 4 to 6 centimetres in length; female 4 to 10 centimetres in length.

Life-History.—Similar to *A. lumbricoides*.

Pathogenicity.—It rarely causes any symptoms.

Genus Lagochilascaris Leiper, 1909.

Definition.—*Ascaridæ* with dense cuticular lips and interlabia surrounded by a ridge and furrow, separating the lips from the rest of the body. Œsophagus simple. Shallow ledge-like cuticular alæ extend along either side of the body to near the tail. Eggs mosaic.

Type Species.—*Lagochilascaris major* Leiper, 1909, in the lion.

Lagochilascaris minor Leiper, 1910.

This species has been found in the pus of subcutaneous abscess in man in Trinidad.

Morphology.—Males 9 millimetres in length by 0·5 millimetre in breadth, with bent posterior part of body. Female 15 millimetres in length, straight posteriorly. The vulva, with two projecting lips, opens 6 millimetres from the anterior end.

Hosts.—Possibly one of the Carnivora. Man is an accidental host.

Habitat.—Probably intestinal in its normal host. The specimens were found in abscesses under the skin in man. An allied species, *A. major*, occurs in the intestine of the lion in East Africa.

FAMILY 10. OXYURIDÆ Dujardin.

Genus Oxyuris Rudolphi, 1803.

Definition.—*Nematoda* in which the three labial papillæ are not very distinct. Œsophagus long, with a double dilatation. Skin markedly striated. Male with curved posterior end, one spicule, and two pairs of pre-anal papillæ. Female with straight posterior end, which tapers to a point. Vulva in the anterior part of the body.

Type.—*Oxyuris vermicularis* Linnæus, 1767.

Oxyuris vermicularis Linnæus, 1767.

Synonyms.—*Ascaris vermicularis* Linnæus, 1767; *Fusiaria vermicularis* Zeder, 1803.

Remarks.—*Oxyuris vermicularis* is the pin or thread worm, and occurs, as far as is known, only in man and all over the world. It is believed to live in the lower part of the small intestine at first, and then the gravid females travel to the large bowel. It has been known from the earliest times.

Morphology.—It is a minute white round worm, with transversally striated cuticle, which forms two ridges along the ventral and dorsal surfaces corresponding to the lateral ridges.

Male is 3 to 5 millimetres in length, with a spirally rolled posterior extremity, with one spicule and six papillæ. Female is 10 millimetres in length and 0·6 millimetre in breadth, with a long pointed tail.

Life-History.—The egg, when deposited from the uterus, measures 50 to 52 μ by 16 to 24 μ, with a thin shell and a fairly well-developed embryo. The dorsal surface of the egg is more convex than the ventral. These eggs escape in the fæces. They are then reintro-

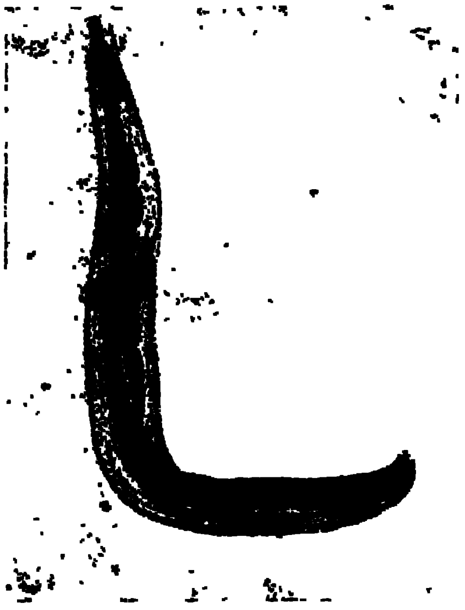

FIG. 283.—*Oxyuris vermicularis* (LINNÆUS, 1767): MALE.

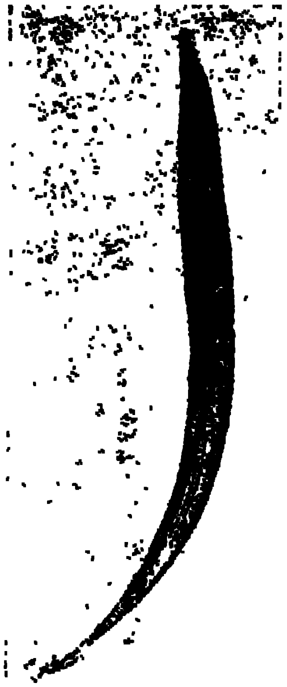

FIG. 284.—*Oxyuris vermicularis* (LINNÆUS, 1767): FEMALE.

(From a photograph by J. J. Bell.)

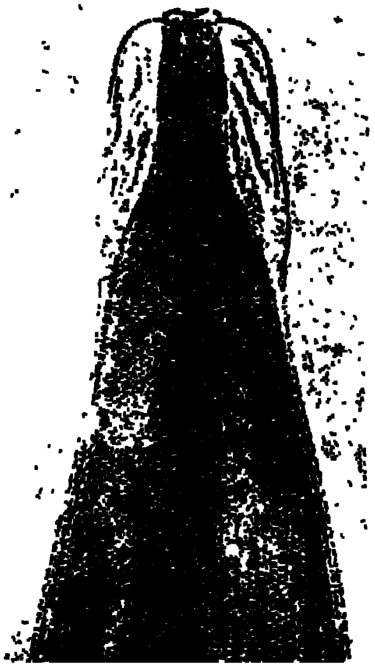

FIG. 285.—*Oxyuris vermicularis* (LINNÆUS, 1767): HEAD. (From a photograph by J. J. Bell.)

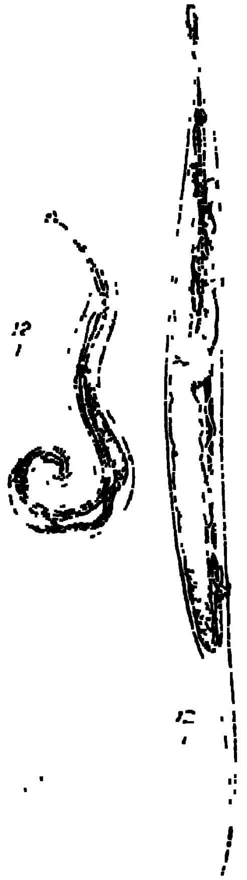

FIG. 286.—*Oxyuris vermicularis*. The male is to the left, the female to the right. (After Claus.)

duced into the mouth or nose by self-infection, fruits, vegetables, etc., hatch, and grow in the small intestine into male and females.

After fertilization the males die off and the females travel into the caecum, and later into the colon, and have a great tendency to wander through the anus to the outside. The duration of life of *O. vermicularis* in the human body is not known.

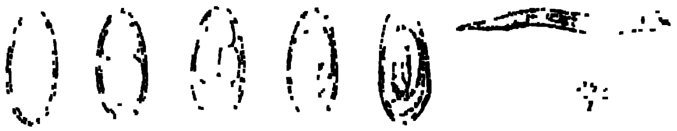

FIG. 287. DEVELOPMENT OF *Oxyuris vermicularis*
(After Leuckart, from Stiles.)

Pathogenicity. In large numbers may set up enterocolitis, in small numbers it causes only irritation.

DIVISION BURSATA.

Definition. Nematoda with true cuticular bursa in the male.

Classification. Leiper gives the following table for the differentiation of the various bursate families represented by species in man:

A. Mouth with simple pore, no buccal capsule:
  (a) Male with large bursa and elongated rays; female oviparous, uteri divergent, ovijectors present. Intestinal parasites. *Trichostrongylidæ.*
  (b) Male with short bursa and stunted rays; female oviparous, uteri convergent, ovijectors absent. Lung parasites. *Metastrongylidæ.*

B. Mouth a simple opening, leading into a large buccal capsule guarded by chitinous structures:
  (a) Mouth capsule bent dorsally and guarded by paired bilaterally arranged plates. *Ancylostomidæ.*
    Plates with smooth edge. *Necator.*
    Plates with toothed edge. *Ancylostoma.*
  (b) Mouth capsule terminal guarded by ring of setæ. *Strongylidæ.*

BURSATA.

FAMILY II. STRONGYLIDÆ Cobbold, 1864.

Nematoda with cylindroid, rarely filiform bodies, mouth usually with wide buccal capsule, with ring of chitinous armature, and an œsophagus more or less enlarged posteriorly. Male with a bursa copulatrix and two equal spicules. Female with two ovaries; vulva situated medially or posteriorly. As a rule, the species are small. Oviparous.

Type Genus.—*Strongylus* Mueller, 1780.

Other Genera.—*Triodontophorus* Looss, 1901; *Œsophagostomum* Molin, 1860.

Triodontophorus Looss, 1901.

Synonyms.—*Triodontus* Looss, 1901, *nec* Westwood, 1845; *Ternidens* Railliet and Henry, 1909.

Strongylidæ with small, almost spherical, thick-walled oral cavity, arising from the floor of which three teeth are found, each of which consists of two surfaces joined together at an acute angle. Male bursa is finely serrated at the edge. The female genital orifice is situate a short distance in front of the tip of the tail.

Found in horses and men.

Triodontophorus deminutus Railliet and Henry, 1905.

Synonym.—*Ternidens deminutus* (Railliet and Henry, 1905).

Railliet and Henry in 1905 discovered that a male and female parasite presented in 1865 by Monestier to the Paris Natural History Museum, and collected post-mortem from an American negro who died in Mayotte, were not ankylostomes, but belonged to Looss's genus *Triodontophorus*. They named them *deminutus* because of their small size. Leiper also met with some specimens of the same species collected in Nyasaland and Lorenço Marques. It has now been recorded in a number of cases. It is also found in monkeys. Their normal habitat is the large intestine.

Morphology.—To the naked eye their size and general appearance resemble those of ankylostomes. The body is white, cylindrical, tapering towards the end. Cuticle transversely striated, and forms an overhanging transverse fold across the ventral surface of the body at the level of the excretory pore.

The mouth-collar is moderately developed, with a depth of 0·04 millimetre. The anterior surface carries four small knob-like submedian papillæ, and the edge surrounds the entrance to the mouth with a double series of delicate fringes composed of cuticle. These two rows constitute the external and internal crowns of the corona radiata.

The buccal capsule is a barrel-shaped chitinous structure capped and covered in by the mouth-collar and the corona radiata. Posteriorly it touches the dilated end of the œsophagus, whose chitinous lining expands into a funnel uniting with the cuticle on the outside of the œsophagus, and coming near the cuticle of the buccal cavity. It shows three cuticular edges projecting into the lumen, which are continued forwards as three stout chitinous prongs or teeth, one dorsal and two ventral. The characters of these teeth are specifically important. They are formed of two plates curved longitudinally and meet to form a keel. The œsophagus is muscular, 0·8 millimetre long, with three fleshy valves guarding its entrance into the chyle intestine. The rectum is short and ends in the anus, which is 0·24 millimetre from the tip of the tail. The excretory system opens on the ventral surface halfway between the posterior limit of the buccal cavity and the nerve ring.

The male is 9·5 millimetres long by 0·56 millimetre in breadth, with a spicule 0·9 millimetre long. Female is 14 to 16 millimetres in length, and 0·73 millimetre in breadth, with a tapering posterior extremity. The vulva is nearly 0·48 millimetre from the hinder end. The vagina is short, and opens into two uterine tubules. The uterine eggs are 60 to 80 μ by 40 μ, with a delicate shell and often a morula.

Life-History and Pathogenicity.—Unknown.

Œsophagostomum Molin, 1861.

Strongylidæ in which the mouth is small and circular, with a chitinous ring, which carries a fold and six papillæ. There is a marked swelling just behind the anterior extremity. Male bursa with two equal spicules; female with two ovaries, and the vulva opening situate near the anus.

Type Species.—*Œ. subulatum* Molin, 1861; *Œ. dentatum* (Rudolphi, 1803).

Species.—*Œsophagostomum apiostomum* and *Œ. stephanostomum*, var. *thomasi* Railliet and Henry, 1909, are known in man, but other species are found in the gorilla, chimpanzee, and other monkeys.

Œsophagostomum apiostomum Willach.

Synonym.—*Œsophagostomum brumpti* Railliet and Henry 1905.

This worm was found by Brumpt in cyst-like nodules in the cæcum and colon of a negro on the Omo River near Rudolph's Sea in East Africa. Found also in monkeys.

According to Leiper, this parasite occurs in 5 per cent. of the natives of Northern Nigeria.

Morphology.—Female 8·5 to 10·2 millimetres long by 0·295 to 0·325 millimetre broad, white and cylindrical, tapering towards the posterior end. Cuticle transversely striated. There is a distension behind the oral cavity which is formed of a cuticular band with a crown with twelve spines; on the front and inner side lamellæ; six head papillæ (two lateral, four submedian). Posterior end rounded off with three broad undulations.

Life-History.—Outside the body similar to that of the Ankylostomes.

Pathogenicity.—The young form cyst-like nodules in the large intestine.

Œsophagostomum stephanostomum var. thomasi Railliet and Henry, 1909.

This species was found by Wolferston Thomas in tumours, numbering 187, in the large and small intestines of a man in Brazil. The tumours were in some instances large enough to diminish the lumen of the bowel. Each tumour contained a male and a female worm. The species *Œ. stephanostomum* Stossich 1904, was found in the large intestine of the gorilla, and a variety *Œ. stephanostomum* var. *dentigera* Railliet and Henry, 1909, is found in the chimpanzee.

Morphology.—Body cylindrical, thick, only attenuated towards the extremities. Buccal capsule with an external crown of 38 lamellæ. Male 17 to 22 millimetres in length and 0·75 millimetre broad. Bursa thick at the sides, with one spicule 1·38 to 1·475 millimetres long. Female 10 to 20 millimetres long by 0·9 millimetre broad. Vulva in front of the anus, 0·5 to 0·525 millimetre from the posterior end.

Life-History.—Not known.

Pathogenicity.—Forms tumours in the wall of the small and large intestines.

FAMILY 12: METASTRONGYLIDÆ Leiper, 1912.

Nematoda with simple mouth, very small cavity, and not enlarged to form a buccal capsule, and a bursa in the male with true but stunted rays. Two spicules.

This family includes a number of genera, parasitic in the lungs of domesticated animals.

Metastrongylinæ Leiper, 1908

Metastrongylus Molin, 1861.

Metastrongylidæ with mouth surrounded by six small papillæ. Male with a bursa copulatrix and two spicules. Female with two ovaries and a tapering posterior end, vulva situate in the hinder half of the body. Embryos without teeth, and with slightly developed œsophageal bulb.

Metastrongylus apri Gmelin, 1789.

Synonyms. *Gordius pulmonalis apri* Ebel, 1777; *Ascaris apri* Gmelin, 1789; *Strongylus suis* Rudolphi, 1809; *S. paradoxus* Mehlis, 1831; *S. elongatus* Dujardin, 1845; *S. longevaginatus* Diesing, 1851.

Metastrongylus apri is not uncommonly found in the bronchial tubes of pigs in Germany (60 per cent. Berlin; 15 to 52 per cent. Leipzig), occasionally it infects other animals including man. (*Filaria trachealis* Rainey, 1855, found by Rainey and by Bristowe, may be infection of man with this parasite.) Diesing recognized the worm in the lungs of a boy aged six in Klausenburg in 1845. It is said to also occur in the intestine, but this is looked upon as accidental, as its usual habitat is the lungs, where it may cause pneumonia and bronchitis.

Morphology.—Body relatively short, colour white or brown; mouth with six lips, of which the two lateral are the largest. Male: 12 to 25 millimetres in length, with bilobed bursa with five ribs in each lobe, and thin spicules about 4 millimetres in length. Female: 20 to 50 millimetres in length, with a curved posterior end, close in front of which is the anus, while the vulva opens on a papilla just in front of this. Eggs elliptical, 50 to 100 μ by 39 to 72 μ; when oviposited, they already contain an embryo.

Life-History. Only the embryonic and larval development appear to have been studied. From analogy with Ankylostoma a skin infection would be presumed nowadays, and further the fact that the worms have been noted in the alimentary canal bears quite a different significance from what it did years ago, as it may be natural for the worms at times to travel from the lungs to the bowel like the Ankylostoma. It is interesting to note that Leuckart failed to infect sheep by feeding them with bronchial mucus full of embryos.

Pathogenicity.—This subject has recently been studied by Santiocchi, and consists essentially of bronchitis, broncho-pneumonia, and pneumonia.

FAMILY 13: TRICHOSTRONGYLIDÆ Leiper, 1912.

Nematoda with filiform bodies; cuticle markedly striated transversely or longitudinally; mouth without buccal capsule or tooth armature; bursa large, with well developed rays; genital pore in posterior half of body; ovejectors present; oviparous. Intestinal parasites.

Nematodirus Ransom, 1907.

Trichostrongylidæ with bursa provided with double ventral median ribs, two dorsal ribs, spicules long and filiform, without accessory piece. Head 50 microns in diameter; cuticle with eighteen distinct longitudinal ridges. Cervical papillæ absent.

Type Species.—*Nematodirus filicollis* Rudolphi, 1802.

Remarks.—The subgenus *Mecistocirrus* Railliet, 1912, with distinct cervical papillæ and cuticular ridges little apparent, contains the human parasite.

Mecistocirrus fordi Daniels, 1908.

Synonym.—*Nematodirus gibsoni* Stephens, 1909.

This worm was discovered by Bell in the fæces of a Chinaman in Hong Kong, and described by Stephens

Morphology.—The male measures 21 millimetres by 0·4 millimetre, and possesses an attenuated head with two cervical papillæ, and a mouth with two lateral papillæ. The bursa shows two well marked lobes, continued dorsally on to the body as a **V**-shaped slit. There is one pair of ventral rays and six pairs of dorsal rays an anterior, two middle, and two posterior, which last arise from a common stem. The spicules are very long (7 millimetres) and delicate.

The female measures 25 millimetres long and possesses a pointed tail, on which the anus opens 0·2 millimetre from the tip, while the genital pore is 0·5 millimetre from the same extremity The uterine egg measures 110 μ by 53 μ.

Life-History.—Nothing is known as to the life history.

Pathogenicity. It is not stated whether it is or is not pathogenic.

Hæmonchus Cobb, 1898.

Synonyms. *Hæmonchus* Stiles, 1903, *Strongylus* O. F. Muller, *pro parte.*

Strongylidæ with unarmed mouth Male bursa trilobed, with median lobe asymmetrical, spicules short with an accessory piece, female with vulva situate posteriorly and protected by some tegumentary appendages.

Type Species.—*Hæmonchus contortus* Rudolphi, 1803.

Hæmonchus contortus Rudolphi, 1803.

Synonyms.—*Strongylus contortus* Rudolphi 1803; *S. filicollis* Molin, 1861; *S. placei* Place, 1893.

This worm was found by de Magalhães in a case of anæmia supposed to be due to *Ankylostoma duodenale*, and from which the specimens were obtained by treatment with thymol, after which treatment the patient rapidly recovered.

Morphology.—Body red or white, filiform, with attenuated extremities Anterior extremity with two cervical papillæ in the form of teeth directed backwards. Cuticle finely striated Male: 10 to 20 millimetres in length, with bursa provided with two lobes of which the right carries an asymmetrical median lobe. The two spicules measure 0·3 to 0·[illegible] millimetre in length and are each furnished with an accessory portion Female: 20 to 30 millimetres in length, with caudal extremity pointed Vulva situated in the posterior fifth of the body. Eggs are ellipsoidal, 70 to 95 μ long by 43 to 54 μ broad.

Life-History.—The eggs quickly develop when placed in pure or muddy water, producing rhabditic embryos; the latter undergo ecdysis.

Habitat.—The intestine of the goat, sheep, etc.

Pathogenicity.—Produces anæmia, resembling that of ankylostomiasis, and has a hæmolytic toxin.

Trichostrongylus Looss, 1905.

Trichostrongylidæ with body tapering gradually from the genital opening anteriorly. Head with three small lips and blunt or pointed papillæ, without cuticular protuberances or neck papillæ. Cuticle transversely striated; œsophagus long. Male with the bursa closed round by large side flaps, without evident median folds; spicules spoon-like, with a boat-shaped accessory piece. Female with the genital opening in the posterior half of the body. Tail short, with two small papillæ near the tip. Egg thin-shelled.

Type Species. -*Trichostrongylus retortæformis* Zeder.

Four species of interest in tropical pathology: *Trichostrongylus colubriformis*, *T. probolurus*, *T. vitrinus*, and *T. orientalis*.

Trichostrongylus colubriformis Giles, 1892.

Synonyms.- -*Strongylus colubriformis* Giles, 1892; *S. instabilis* Railliet, 1893; *S. subtilis* Looss, 1895.

This species was found by Looss in post-mortems on fellahs in Alexandria and Cairo, and also by Ijima in a woman in Japan. In man, however, it is only an accidental parasite, being usually found in the duodenum, rarely in the stomach, of sheep, antelopes, dromedaries in Egypt, monkeys in North America, and sheep in India.

Morphology.- Male 4 to 5 millimetres in length, and 0·08 millimetre in thickness just in front of the bursa. Spicule 1.35 to 1.45 μ in length, and the accessory portion 70 μ in length, with a long muscular œsophagus. Bursa with two lateral semicircular wings connected by a cross bridge. Ribs arranged asymmetrically. Female 5 to 6 millimetres in length, and about 0·09 millimetre in breadth. Posterior extremity tapers to a pointed tail, in front of which the anus is situated, 0·055 to 0·07 millimetre, and the vulva 1·05 to 1·2 millimetres. Eggs 72 to 80 μ by 40 to 43 μ; when oviposited, generally contain eight to twelve celled embryo.

Life-History.- Resembles that of *Ancylostoma duodenale* outside the body, according to Leiper.

Pathogenicity. -Believed to be unimportant.

Trichostrongylus orientalis.

Synonym. *Trichostrongylus subtilis* Looss, 1895.

Trichostrongylus eggs have recently been found in the fæces of a considerable percentage of the agricultural population of certain districts in Japan, and is probably the same as that recorded previously from Japan by Ijima and Looss as *Trichostrongylus subtilis* (*vide T. colubriformis*, *supra*). This species differs slightly in details of ray-disposition in the bursa and in configuration of the spicules.

Trichostrongylus probolurus Railliet, 1896.

Synonym.- -*Strongylus probolurus* Railliet, 1896.

This parasite lives in the duodenum of sheep, antelopes, and dromedaries in Egypt, and has also been found in man in Egypt.

Morphology.—Male 4·5 to 5·5 millimetres in length, 0·08 millimetre in breadth just in front of the bursa. Spicule 126 to 134 μ, accessory piece 75 to 80 μ in length.

Female 4·5 to 6 millimetres in length, anus 0·04 to 0·05 millimetre, and vulva 1·08 to 1·25 millimetres in front of the tip of the tail, which is short. Egg 76 to 80 μ by 43 to 46 μ

Life-History.—This is unknown.

Pathogenicity.—Believed to be unimportant.

Trichostrongylus vitrinus Looss, 1905.

T. vitrinus is found in the duodenum of sheep and dromedaries, and also in man in Egypt.

Male 4 to 5·5 millimetres in length by 0·085 millimetre in breadth in front of the bursa, which is larger than in the other two species. Spicule 160 to 170 μ, accessory piece 85 to 95 μ in length.

Female 5 to 6·5 millimetres long; vulva 1·15 to 1·25 millimetres in front of the tip of the tail; egg 84 to 90 μ by 46 to 50 μ.

Life-History.—This is not known.

Pathogenicity.—Believed to be unimportant.

FAMILY 14: ANCYLOSTOMIDÆ LOOSS, 1911

Strongyles with armed mouth and bursa copulatrix provided with ribs.

Subfamilies.—Ancylostominæ and Bunostominæ.

SUBFAMILY ANCYLOSTOMINÆ, LOOSS, 1911.

Ankylostomidæ with more or less funnel shaped mouth capsule, its walls on the ventral side, and, especially towards the anterior edge, provided on each side with two longitudinal thickenings projecting outwards like ridges. In the gutter-like depressions between the ridges lie the terminations of the dorsal and lateral papillary nerves. Floor of the mouth cavity with one pair of inner ventral teeth, otherwise free from tooth like structures. Aperture of the dorsal œsophageal gland situated in the wall of the mouth capsule. Bursa of the male closed all round. Only one third of the dorsal ray is cleft. The course of the genital tubes is longitudinal.

Type Genus.—*Ancylostoma* Dubini, 1843. Other genus: *Uncinaria* Frölich, 1789.

Ancylostoma Dubini, 1843.

Synonym.—*Dochmius* Dujardin, 1845, *pro parte*.

Ancylostominæ with the head end, where the mouth is situated, abruptly truncated. Mouth large, round, with its ventral margin armed with two pairs of strong hook-like teeth, the points of which are bent backwards, while the bases are continuous posteriorly with longitudinal rib-like thickenings of the external surface of the capsule wall. The aperture of the dorsal œsophageal gland can be seen in the dorsal wall of the mouth capsule.

Male with a three-lobed bursa, broader than long, with two spicules. Female with vulva behind the middle of the body.

Species.—A number of species are known in man, dogs, bears, civet cats, and other carnivora.

Ancylostoma duodenale Dubini, 1843.

Synonyms.—*Strongylus quadridentatus* von Siebold, 1851; *Dochmius ancylostomum* Molin, 1860; *Sclerostoma duodenale* Cobbold; *Strongylus duodenale* Schneider, 1866; *Dochmius duodenalis* Leuckart, 1876, *pro parte*.

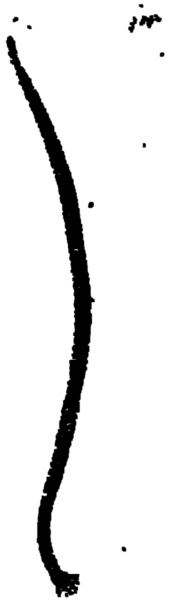

FIG. 2[illegible].—*Ancylostoma duodenale* DUBINI 1843. MALE.

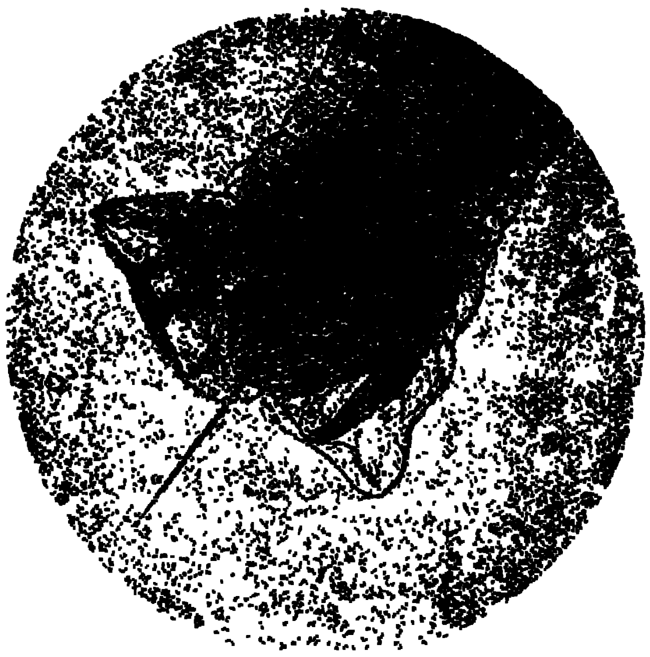

FIG. [illegible].—*Ancylostoma duodenale* DUBINI, MALE BURSA.

(From photographs by Bell.)

This worm, which is the great cause of tropical anæmia, was perhaps known to the ancient Egyptians under the term 'Heltu,' mentioned in the 'Ebers Papyrus,' which is supposed to have been written some 1550 years B.C., the disease being called A.A.A., and a remedy being advised. Perhaps the same anæmia is referred to in the 'Harita Samhita' under the term 'pandu roga,' which was said to be caused by swallowing clay. If this is correct, then knowledge of anæmia due to geophagy is very old indeed. If the ancients did really know about this worm, and the disease caused thereby, the knowledge was totally lost, and it was not till Dubini in 1838 discovered the worm in a peasant woman in Milan that modern medicine knew anything about its existence. Pruner, in 1846, found the parasites in Egypt, and Griesinger, in 1851, showed that it was the cause of Egyptian anæmia. Wucherer, in 1872, found that it was the cause of tropical anæmia in Brazil (called 'oppilação'). Perroncito found that it was the cause of the anæmia which badly affected the miners employed in the St. Gothard tunnel. Grassi and Parona in 1878 discovered the eggs in the fæces, thus enabling a diagnosis to be made during life. The wide geographical distribution of the parasite, and the amount of disease which it causes, is slowly being realized, and the deaths from anæmia, general dropsy, and so-called beri beri, etc., in different tropical regions are being found to be due to this animal.

The development and method of infection have been completely traced out by Looss in Egypt in a most masterly manner.

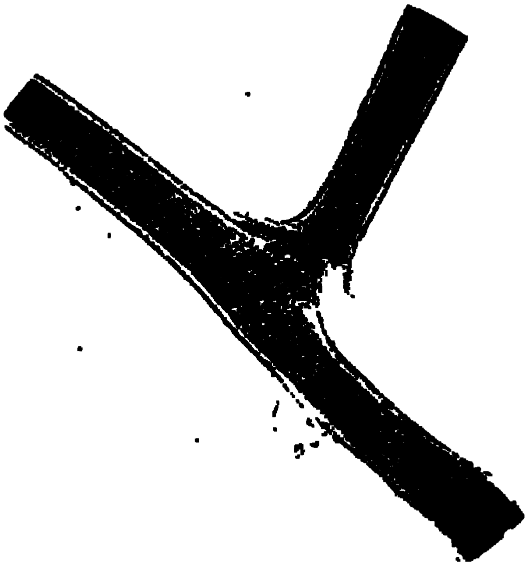

FIG. 290.—COPULATION OF AN[illegible]
(From a photograph by J. J. [illegible]

In 1902 Stiles found that under the term *Ancylostoma* two different parasites were being confused, one corresponding to Dubini's *Ancylostoma duodenale*, and the other new, which he named *Necator americanus*. Leiper has shown how widespread this latter parasite is in the Old World.

The geographical distribution is probably not fully known, because in many places it is confounded with *Necator*. It is supposed to be cosmopolitan in tropical regions, and in mines and tunnels in colder climates, in which, of course, the air-temperature is higher than that of the outside.

Morphology.—The body is cylindrical, tapering from back to front in both sexes. During life it is flesh-coloured. The cuticle is ringed. The mouth is terminal, with a chitinous wall, which ventrally carries two pairs of hook like teeth, and dorsally one pair. Close to the base of the outer ventral tooth opens the single-celled head gland, which runs through nearly half the length of the body. In the floor of the mouth there are two ventral chitinous plates, and the prominent opening of the dorsal head gland (often called a tooth).

Male measures about 10 millimetres in length by 0·4 to 0·5 millimetre in breadth, and possesses a bursa copulatrix at the posterior end, which is umbrella-shaped and supported by chitinous rods which are arranged as follows: In the median dorsal line is the costa dorsalis, which divides dorsally into two small branches, which are ramified at their tips. Postero-laterally there is one root on each side—the single costa dorsalis externa, in front of which is a single broad lateral root, which divides into the costa lateralis posterior, the costa lateralis media and the costa lateralis externa; while anteriorly also on each side is the costa ventralis. Through the opening of this bursa project the two spicules, unless they are retracted, which are long and slender, and measure about 2 millimetres in length. The male generative apparatus consists of a testis in the form of a tube, an oval vesicula seminalis, and a long cement gland, whose secretion fixes the male to the female during conjugation, and a spicule sac.

The female measures 12 to 18 millimetres in length, and has the vulva at the junction of the middle and hinder parts of the body, from which a short vagina opens into two tubes, which are divisible into ovijector, uterus, receptaculum seminis, and an ovary.

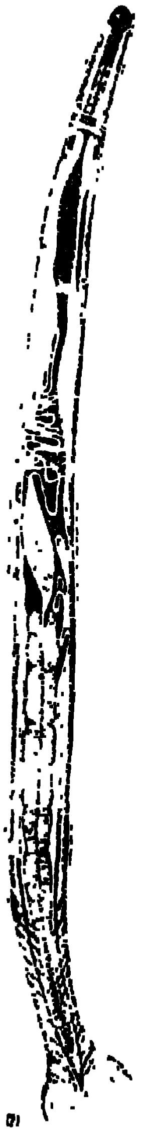

FIG. 291.—*Ancylostoma duodenale* DUBINI: MALE.

(After Looss.)

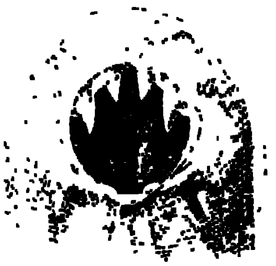

FIG. 292.—ANTERIOR END OF *Ancylostoma duodenale* DUBINI.

(After Looss, from Mense's 'Tropenkrankheiten.')

Life-History. The adult worms live chiefly in the jejunum of the host, where they feed upon the villi. Blood is only accidentally found in a worm. Here the females lay the eggs, which are oval in form, with broad rounded poles, surrounded by a colourless shell, which is really double, but looks single, inside which lies an oval granular mass separated from the shell by a considerable space. As the egg travels down the alimentary canal the granular mass divides into two, and finally into four segments, in which condition the egg is usually found in the fæces. Development proceeds in the fæces, depending upon the temperature of the atmospheric air. In twenty-four hours, if supplied with air, water, and heat, the embryo can be seen coiled up in the egg, from which it escapes as a larva, and feeds on the fæcal material. The larva is needle-shaped, pointed posteriorly, and measures 200 to 250 μ in length by 15 to 17 μ in breadth, and is rhabdite in form, with a long cylindrical terminal mouth, opening into an œsophagus, which, after narrowing, swells out into a bulb with three valves. The straight intestine surrounded by granular material opens into an anus situate some distance in front of the tip of the tail. This larva undergoes a first ecdysis when it becomes narrower, and the œsophagus and mouth lose their characteristic appearance, while it forms a new skin inside the chitinous cuticle, so that (at the end of five days in the tropics) it now ceases to grow and feed, and takes to water or moist earth, where it can remain unchanged for months, living on the food material enclosed in its own cells (stage of encystment). During this condition it may be quite active, and can swim and climb up any surface which is wet. This is an important factor in explaining the production of certain kinds of skin eruptions. It is now ready to infect man, which it does through the hair-follicles of the skin causing eruptions or sores—e.g., ground itch.

From the hair follicles it forces its way via the subcutaneous tissue into the venous bloodvessels and lymphatics. In the former it reaches the right heart and the lungs easily; in the

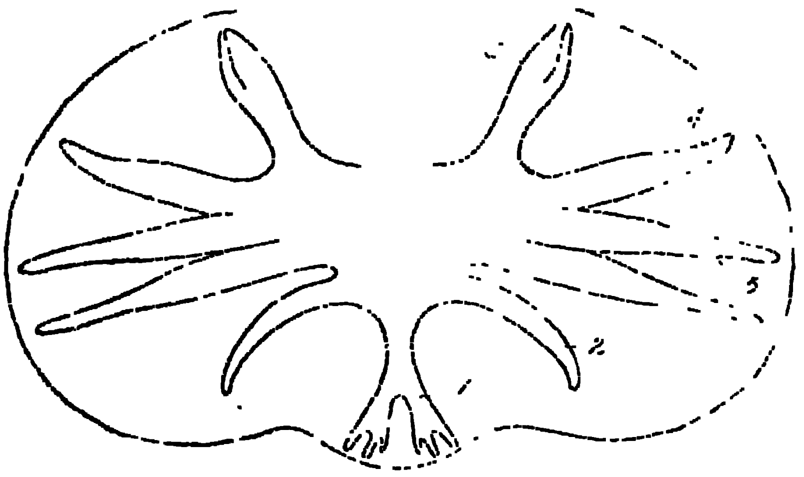

FIG. 293.—THE MEDIAN AND EXTERNAL CAUDAL BURSA OF *Ancylostoma duodenale* DUBINI.

1, Costa dorsalis; 2, costa dorsalis externa; 3, costa lateralis posterior et externa; 4, costa lateralis media; 5, costa ventralis.

(After Railliet from Stiles's Report.)

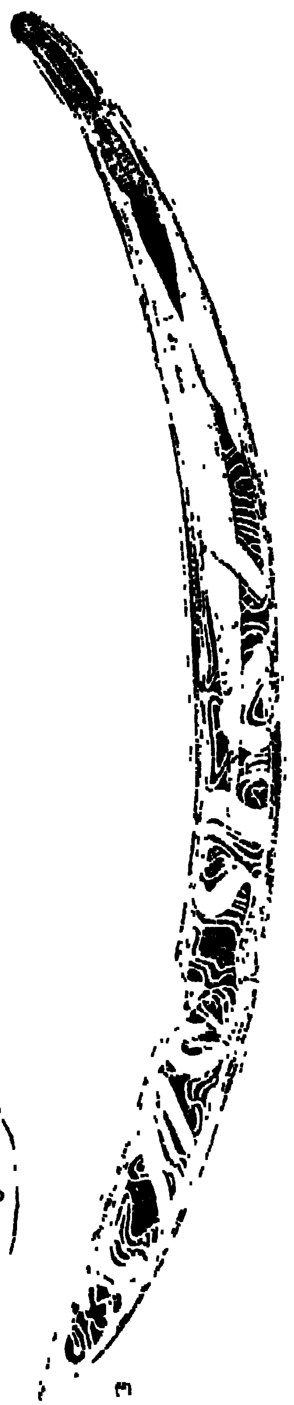

FIG. 294.—*Ancylostoma duodenale* DUBINI. FEMALE. (After Looss.)

latter many are killed in the lymphatic glands, but some get through to the blood, and in this way are carried to the lungs. They now work their way out of the capillaries into the lumen of the air cells, and travel up the bronchi, trachea, and larynx into the œsophagus (they might by chance get into the mouth), and so through the stomach to the intestine. The time occupied by this journey is believed to be from seven to ten days. In the skin they undergo their second ecdysis, and later a third and fourth ecdysis takes place in the alimentary canal, the third in four to five days and the fourth from four to six days after their arrival. They now measure 3 to 5 millimetres in length, and eight days later the generative organs begin to attain maturity, and the first copulations take place, and a few days later the first eggs appear in the faeces, thus completing the cycle of development, of which the portion after infection occupies four to six weeks.

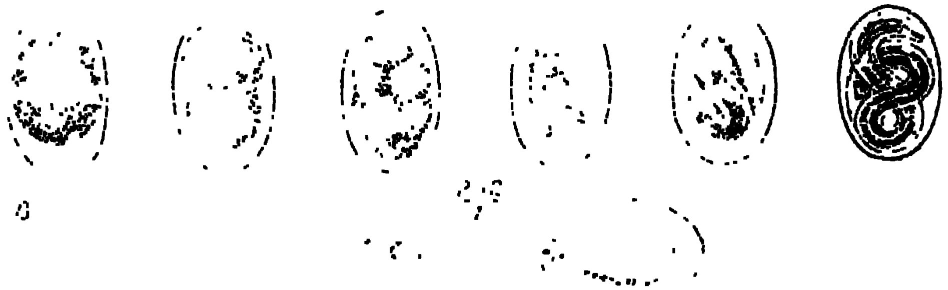

FIG. 295.—*Ancylostoma duodenale* DUBINI: DEVELOPMENT OF THE EXTRA-UTERINE EMBRYO.
(After Looss except the last figure which is after Perroncito.)

FIG. 296.—HATCHING OF EGG OF *Ancylostoma duodenale* DUBINI, 1843.
(From a photograph by [illegible])

The more important morphological changes which take place in the human body may be briefly recapitulated.

On entering the skin the third stage of development begins, during which the provisional buccal capsule is formed. A third ecdysis ushers in the fourth stage characterized by the provisional buccal capsule armed with a dorsal and a ventral pair of teeth. During this stage the sexes become differentiated and the permanent buccal capsule is formed. The fourth ecdysis results in the appearance of the adult worms.

The number of females can be calculated from the number of eggs in the fæces by the formula $X = \frac{A}{47}$, where X is the number of females and A the number of eggs in a gramme of fæces.

This history has been pieced together by Looss from observations on the infection of *Ancylostoma duodenale* in man and *A. caninum* in dogs.

These discoveries of Looss have been confirmed by Lambinet. Sambon, while agreeing with the view that the worms penetrate the skin and work their way to the lungs, considers that they pass from the pulmonary artery to the pulmonary veins, and in this way reach the general blood stream, and in due course the jejunum, the mucosa of which they pierce, and enter the lumen of the bowel. He believes that the worms seen in the trachea, larynx, and stomach by Looss are merely stray specimens which have escaped in the air cells from the vessels of the lungs. His reasons for this belief are:—

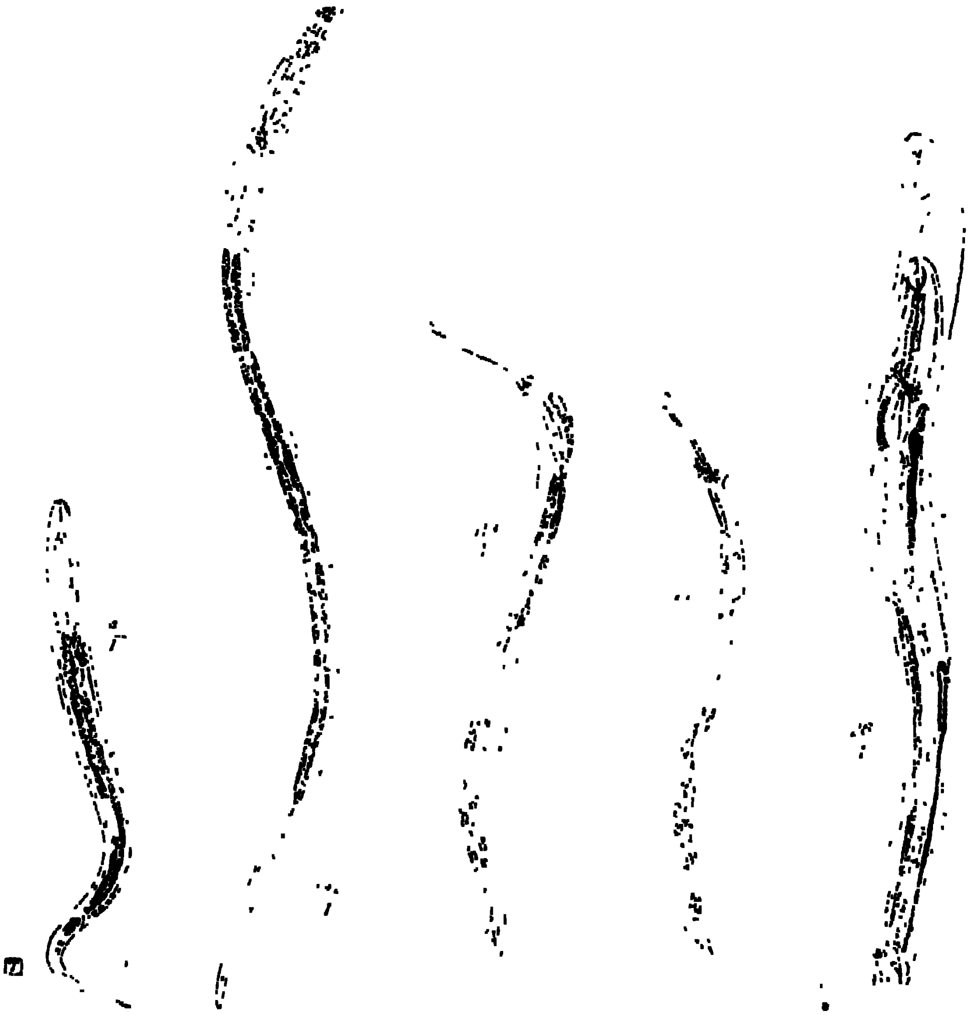

FIG. 297. FIG. 298. FIG. 299. FIG. 300. FIG. 301.

FIGS. 297-301.—DEVELOPMENT OF *Ancylostoma duodenale* DUBINI. (After Looss from Mense.)

1. The larval forms of *A. duodenale* have seldom been found in the stomach and when found in this organ are lodged beneath the epithelium.
2. They are invariably absent from the duodenum.
3. They have been found in the left heart, in the pulmonary and azygos veins, in the thoracic duct, in the peritoneum, in the kidneys, in the lymph glands, and in the connective tissue of various regions.
4. At the beginning of the infection there is always an intense hæmorrhagic inflammation of the jejunum, which entirely subsides later on, notwithstanding the presence of enormous numbers of parasites in the intestine.

5. Immature forms have been found again and again in blood-filled spaces beneath the intestinal mucosa by Bilharz, Griesinger, Sonsino, Grassi, and many other competent investigators.

6. A number of other worms which inhabit the intestinal cavity at maturity, such as *Œsophagostomum Sclerostomum*, *Ascaris*, *Gnathostoma*, etc., in an earlier developmental stage are usually found either free or encysted beneath the intestinal mucosa

He also considers that when the larvæ are taken in by way of the mouth they probably pierce through the walls of the œsophagus like the larvæ of *Hypoderma bovis* (see Chapter XXXIII.) and reach their intestinal habitat by way of the vessels in exactly the same way as those which penetrate the hair follicle.

Fülleborn and von Schilling-Torgau have re-investigated the subject by tracheotomizing dogs and inserting a cannula in such a way that the larvæ could not pass from the lungs to the œsophagus, but only to the exterior. The dogs were then infected with *Ancylostoma caninum* (Ercolani 1859), and after some time the secretion from the cannula in the trachea swarmed with larvæ. In other dogs the œsophagus, not the trachea, was cut across and its ends separately stitched to the skin, and after a time the secretion from the upper cut end contained larvæ. In both sets of experiments the dogs became infected intestinally with only a very small number of parasites.

It is thus seen that Sambon's hypothesis is theoretically correct, but Looss's route is the one by which the vast majority of the larvæ enter the body.

Pathogenicity.—It causes ankylostomiasis in man.

SUBFAMILY BUNOSTOMINÆ LOOSS, 1911.

Ancylostomidæ with small mouth capsule, with aperture narrowed anteriorly by plates with cutting edges springing from the sides, and more or less covering the ventral half of the aperture. At the base of the cone which carries the opening of the dorsal œsophageal gland there is on each side one tooth-like plate with smooth edges. Coils of the genital tubes very numerous and close. Externo-dorsal ray thin, more especially at the root. Spicule of the male barbed at the end.

Type Genus.—*Necator* Stiles, 1903.

There are seven genera in the subfamily—viz., *Bunostomum* Railliet, 1902; *Necator* Stiles, 1902; *Brachycionus* Railliet and Henry, 1910; *Gaigeria* Railliet and Henry, 1910; *Eumonodontus* Molin *emend.* Railliet and Henry; *Bathmostomum* Railliet and Henry, 1909; and *Grammocephalus* Railliet and Henry, 1910; but only *Necator* Stiles, 1903, concerns us.

Necator Stiles, 1903.

Bunostominæ closely resembling *Ancylostoma*, but distinguished therefrom by the small mouth capsule, which is armed only by semilunar plates. The head is strongly bent dorsally. In the male the bursa is bilobed. In the female the vulva lies in the anterior part of the body.

Type Species.—*Necator americanus* Stiles, 1902. Other species: *N. africanus* Looss, 1911, in the chimpanzee.

Necator americanus Stiles, 1902.

Synonyms.—*Dochmius duodenalis* R. Leuckart, *pro parte*; *Uncinaria americana* Stiles, 1902; *Ancylostoma americanum* von Linstow, 1903, *pro parte*.

In 1902 Stiles discovered that two distinct genera were being confused under the term *Ancylostoma*, and eventually called the new genus *Necator*. Leiper has recently shown that this new genus is very widely distributed over the world, and is the common cause of ankylostomiasis in Ceylon; while it occurs in India, Assam, Burma, the Philippine Islands, Fiji, Japan, America, and has been found in West and Central Africa and in North-West Rhodesia. In due course, no doubt, it will be reported in other places.

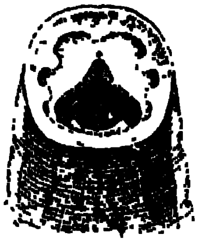

FIG. 302. — THE MOUTH CAPSULE OF *Necator americanus* STILES (After Looss, from Mense)

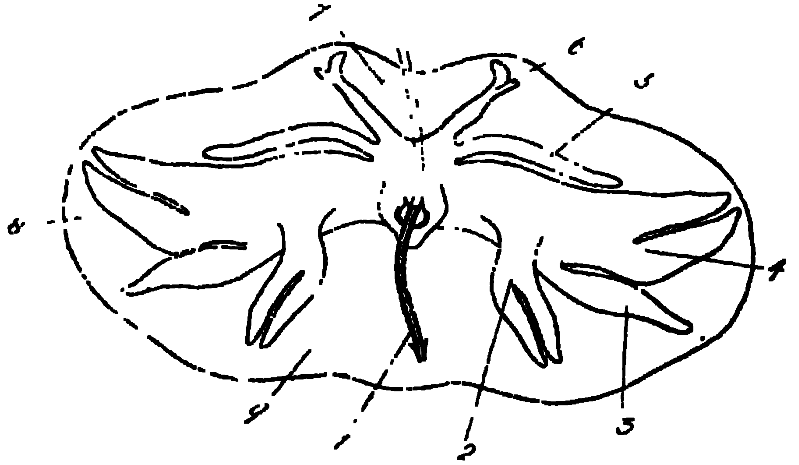

FIG. 303.—THE BURSA COPULATRIX OF A MALE *Necator americanus* STILES.

1, Spicules; 2, costa ventralis; 3, costa lateralis posterior; 4, costa lateralis externa et costa lateralis media; 5, costa dorsalis externa; 6 costa dorsalis; 7, dorsal lobe, 8 lateral lobe; 9, ventral lobe.

(After Stiles.)

Morphology.—The body is cylindrical, and somewhat attenuated anteriorly. Head acutely bent dorsally. Mouth with a ventral pair of prominent semilunar chitinous plates and a dorsal pair of slightly developed plates. Into the floor of the mouth projects the opening of the dorsal head gland, which appears like a dorsal conical tooth, while deep in the cavity appear one pair of dorsal and one pair of ventral submedian lancets. Excretory pore 0·5 millimetre behind the mouth, with cervical papillæ on either side.

Male 7 to 9 millimetres in length and 0·3 to 0·35 millimetre in breadth. The bursa consists of two large lateral lobes joined to a dorsal median lobe, which appears as if divided into two, and to an indistinct ventral lobe. There is a slight ventral enlargement just posterior to the point at which the bursa joins the body-wall. The costa dorsalis is divided at its base into two diverging branches, which are bipartite. The common base of the costa dorsalis and costa dorsalis externa is very short, while the latter ray is long, slender, and clavate. The costa lateralis externa is closely joined to the costa lateralis media. Two small precaudal papillæ can be seen anterior to the ventral rays. The spicules are long and slender, 0·92 millimetre in length, and terminate in barbed points.

Female is 9 to 12·6 millimetres in length; vulva in the anterior half of the body, but near the equator. Eggs 57·7 to 80 μ by 35 to 52·5 μ; average, 60 by 40 μ.

Life-History. This is the same as *Ancylostoma duodenale*.

Zoological Distribution.—Man and the gorilla.

Pathogenicity. It causes ankylostomiasis in certain regions.

Ancylostoma ceylanicum Looss, 1911.

Synonym. (?) *Ancylostoma braziliense* Gomez de Faria, 1910.

Definition. Ancylostoma with one large tooth at the anterior edge of the mouth capsule and below and behind this a very small tooth towards the middle line. Lobes of bursa almost as broad as long.

Remarks. This worm was found in cats and dogs in India, and is the same as that found in the civet cat in Ceylon, and in man in Bengal by Clayton-Lane, and called *A. ceylanicum*.

It has also been found by Darling in a Tamil and a Chinese in Kuala Lumpur, and also in dogs, in which they were frequently found.

Clayton-Lane suggests that the genus Ancylostoma should be divided into two subgenera—viz.:

$$\text{Subgenus } \textit{Ancylostoma} \begin{cases} \textit{A. duodenale.} \\ \textit{A. caninum.} \end{cases}$$

$$\text{Subgenus } \textit{Ceylancylostoma} \begin{cases} \textit{A. ceylanicum.} \\ \textit{A. malayanum.} \end{cases}$$

G. de Faria maintains that *A. braziliense* and *A. ceylanicum* are probably not the same, because of the character of the oral capsule and bursal rays.

PSEUDOSTRONGYLES Leiper, 1912.

Nematoda with simple mouth, and a cuticular bursa in the male without rays. One spicule.

FAMILY 15: EUSTRONGYLIDIDÆ Leiper, 1912.

SUBFAMILY DIOCTOPHYMINÆ Railliet.

Eustrongylidæ with unarmed mouth; bursa copulatrix without ribs or bands. Genus: *Dioctophyme* Collet-Megret, 1802.

Dioctophyme Collet-Megret, 1802.

Very large Strongylidæ with cylindrical bodies, mouth with six papillæ. Male with collar-like bursa and one spicule. Female with one ovary; vulva in the anterior half of the body.

Dioctophyme renale (Goeze, 1782).

Synonyms.—*Ascaris canis et martis* Schrenk, 1788; *A. visceralis et renalis* Gmelin, 1789; *Strongylus gigas* Rudolphi, 1802; *Eustrongylus gigas* Diesing, 1851; *Strongylus renalis* Moquin-Tandon, 1860; *Eustrongylus visceralis* Railliet, 1885.

This worm lives in South America in the pelvis of the kidney in the dog, seal, otter and wolf. It has been recorded twelve times in man if the records really refer to this worm.

Morphology.—The worm is blood-red in colour, but otherwise very like a large *Ascaris lumbricoides*. Along the lateral lines there are about 150 papillæ. The submedian ridges are well developed, and the anterior extremity somewhat attenuated. Cuticle finely striated transversely.

Male 40 centimetres long by 4 to 6 millimetres broad, bursa without rays, and with one very long, slender spicule 5 to 6 millimetres in length. Female 100 centimetres in length and 12 millimetres in thickness, with an obtuse, slightly curved posterior end, a single ovary, and a vulva situate 50 to 70 millimetres behind the anterior extremity. Eggs ovoid, with thick, brownish shell 68 to 80 μ by 40 to 43 μ, with numerous depressions.

Life-History.—Development begins in the uterus of the female, but stops at a certain stage and does not continue (Balbiani) until brought into contact with water or damp soil, when the egg hatches. The embryo is 240 μ by 14 μ, cylindrical, and gradually tapering posteriorly. The head is pointed, with a terminal mouth without papillæ, but which is thought to be provided with a small protractile dart. The further development is not known; it has been thought that it takes place in fish, but experiments have failed to justify this view.

Pathogenicity.—It is usually found in the kidney, which it destroys. In animals it has also been found in mammary and perineal tumours. Symptoms appear to be hæmaturia, and the diagnosis is made by the discovery of the eggs.

FAMILY 16. TRICHOSOMIDÆ.

Nematoda with the anterior portion of the body thin and whip-like; posterior portion thick with genitalia. Mouth small, without papillæ. Œsophagus very long, traversing a peculiar strand of cells.

Trichinellinæ Ransom, 1911.

Male without spicule. Female producing embryos.

Trichurinæ.

Male with spicule. Female producing barrel-shaped eggs.

Genus Trichinella Railliet, 1895.

Trichinella Railliet, 1895.

Synonym.—*Trichina* Owen, 1835, *nec* Meigen, 1830.

Very small Trichinellidæ, with thin, hair-like bodies. Posterior end of the male with two cone-like appendages, between which the cloaca is situate. Vulva placed far forwards.

Trichinella spiralis Owen, 1835.

Synonym.—*Trichina spiralis* Owen, 1835.

T. spiralis, though discovered by Paget in 1835 and described by Owen, had been previously seen by Peacock in 1828 and by Hilton in 1833.

It is really a parasite of the black rat (*Epimys rattus*) and the sewer rat (*E. norvegicus*), in which the rate of infection is placed from 8·3 to 100 per cent., according to the locality, but it spreads from the rat to pigs, dogs, cats, and many other animals.

Man becomes infected from the pig as a rule, for that animal is particularly liable to the disease, because it is apt to be fed upon scraps of raw meat. Further, the larva in the flesh of the pig is very difficult to kill, for it will resist a temperature of 80° C., pickling, smoking, and freezing. Hence, though ham be well boiled, it does not follow that the larvæ in its centre are killed. Sausages, however, are the greatest danger, for in them the larvæ can live well protected.

In order to infect man, there must be a source of infection for the pig, and this, in the first instance, can come from the rat, and afterwards be kept up in the pig, and then the transmission to man is easy.

As rats, pigs, and men are cosmopolitan, so trichiniasis is also cosmopolitan. It is not uncommon in certain parts of India, and is known in China. In considering the endemicity of the disease, it must not be forgotten that the wild boar (*Sus scrofa ferox*) is susceptible. The disease is supposed to have been introduced into Europe from Asia either by *Epimys norvegicus* at the end of the eighteenth century, or by the Chinese pig from 1820 to 1830. At present it is common also in America.

Morphology and Life-History.—It is usually found in human or pig's muscles, where it appears as minute white specks, which when magnified, are found to be encysted larvæ. These cysts are oval with their long axis in the same direction as that of the muscular fibres, measuring 400 by 250 μ. The cyst membrane is formed from inflamed connective tissue, which has invaded the infected muscular fibre. Inside the cyst is the coiled-up worm. In this condition the larvæ may live for years, but may be killed by calcification. They are mostly found in the diaphragm, the larynx, tongue, abdominal and intercostal muscles.

When these cysts reach the stomach of a man or animal, the gastric juice dissolves the cyst-wall, and the parasites escape, and, entering the duodenum and jejunum, they grow into adult males 3 to 4 millimetres long by 60 μ in diameter, and females 1·4 to 1·6 millimetres long by 40 μ in diameter, which copulate. The males now die off, and the females, increasing in size, penetrate the mucosa of the bowel until they reach a lymph-channel, where they deposit their larvæ, which are born alive. Leuckart says one female gives rise to 1,500 larvæ, which are carried by the lymph and blood streams all over the body. The larvæ now leave the capillaries and work their way into the tissues, and in about nine to ten days encapsule in the muscles, the attacked fibres of which degenerate and become inflamed, and the cyst already described is formed.

Pathogenicity.—When the female pierces the mucosa, and during the wandering through the lymph and blood of the larvæ, very severe symptoms called trichinosis or trichiniasis are produced.

SUBFAMILY TRICHURINÆ Ransom, 1911.

Type Genus.—*Trichuris*; also *Capillaria* Zeder, 1800.

Trichuris Roederer and Wagler, 1761.

Trichosomidæ, with the anterior part of the body very long and thread-like, and the posterior thicker portion sharply truncated, with a terminal anus. Male with a spirally rolled posterior end and one spicule; female with one ovary, and the vulva situated at the junction of the thinner and thicker parts of the body.

Species in man: *Trichuris trichiura* Linnæus, 1761.

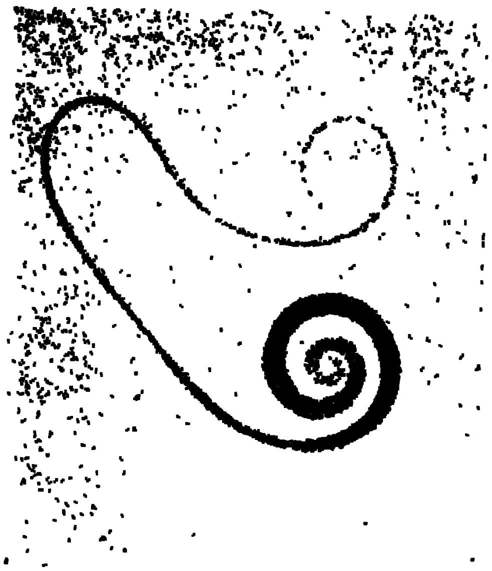

FIG. 304.—*Trichuris trichiura* (LINNÆUS, 1761): MALE.

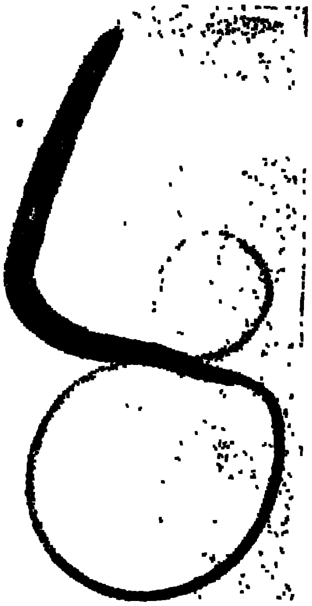

FIG. 305.—*Trichuris trichiura* (LINNÆUS, 1761): FEMALE.

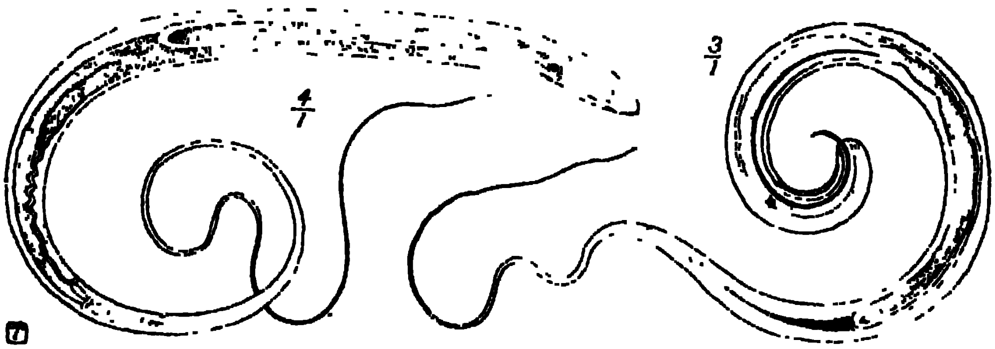
(From a photograph by J. J. Bell.)

Trichuris trichiura Linnæus, 1761.

Synonyms.—*Ascaris trichiura* L., 1771; *Trichocephalus hominis* Schrank, 1788; *T. dispar* Rudolphi, 1801.

This worm is very commonly met with in the tropics. Its eggs appear in the fæces, and it is met with in the cæcum and sometimes in the vermiform appendix during post-mortems. Its anterior end is frequently found buried in the mucous membrane, and while in this position it is possible for bacteria to enter and cause disease —*e.g.*, appendicitis.



FIGS. 306 AND 307.—*Trichuris trichiura* LINNÆUS: FEMALE AND MALE. (After Claus.)

It is commonly called the whip-worm, and is cosmopolitan in its distribution.

Morphology.—The male measures 40 to 45 millimetres in length, and is easily recognized by the spirally coiled posterior end. Its spicule, which lies in a retractile pouch, measures 2·5 millimetres. The female measures 45 to 50 millimetres in length. The ova are oval, brown, thick-shelled, with a pale, clear body at each pole, where the shell is deficient. They measure 50 to 54 by 23 μ.

Life-History.—When the egg appears in the faeces, it is unsegmented, and is said to take eighteen months before the embryo is fully developed. The egg with the enclosed embryo is then taken in through the mouth in contaminated food or water, there being no intermediate host. The shell is dissolved by the gastric juice, and the embryo reaches maturity in the intestine in about four to five weeks.

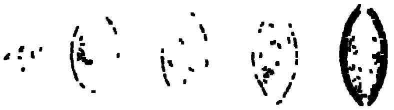


FIG. 308.—DEVELOPMENT OF THE EGG OF *Trichuris trichiura*. (After Stiles.)

Pathogenicity.—Usually harmless, but may give rise to intestinal disturbance and at times appendicitis.

Syngamus von Siebold, 1836.

Strongyles with broad head, mouth with a chitinous capsule. Male with two spicules. Female with two ovaries and a vulva situate in the anterior part of the body.

Syngamus kingi Leiper, 1913.

King forwarded quite recently a pair of specimens to Leiper purporting to come from a woman living in St. Lucia who suffered from chronic cough, when the worms were expectorated with blood. Leiper thinks that this may be an accidental infection of man with a parasite which is harboured possibly by a carnivore. It differs from *S. trachealis*, the common nematode of poultry, in the buccal capsules, these in the male and female are on the same level, whereas in *S. trachealis* that of the male is more anterior. Mouth capsules terminal. Tail of female bluntly pointed.

ORDER II. GORDIACEA.

Nemathelminthes with the intestinal canal always atrophied anteriorly in the adult, head without papillae, two testes, but never spicules in the male; vulva always united with the posterior portion of the intestine to form a cloaca; rare in man, only accidental parasites.

These worms are popularly known as horsehairs, and are supposed to cause serious and even fatal disease in man or animals if swallowed. Their pathogenicity has recently been studied by Stiles, who is unable to support the popular belief as to the serious nature of these parasites in man. They are very long, thin worms, like *Filaria*, which can be found in ditch-water swimming freely or twining round water plants.

The body is covered with a well-developed two layered cuticle. The mouth and the anterior part of the intestine is obliterated. The posterior end of the male is lobed, and without spicules. In the female there are two ovaries and the egg-sacs, which open by means of oviducts into a uterus. The males are often blackish brown, and the females light clay brown.

The life-history of *Parachordodes tolosanus* is very complicated: the first larva enters the larva of the alder-fly (*Sialis lutaria* L.), where it lives during the winter, and passes over to the imago of the same insect, which is eaten by a beetle (*Pterostichus niger*). The first larva changes, becoming a second larva, which lives in the beetle during the second winter, and finally escapes into the water about twenty months after hatching. In the water it soon becomes adult Gordiidæ.

The Gordiacea includes the family Gordiidæ, which is divided by Camerano into four genera: *Gordius* Linnæus, 1758; *Paragordius* Camerano, 1879; *Parachordodes* Camerano, 1897; *Chordodes*.

Without going into details, it may be said that the following species have been reported as parasitic in man:—

Gordius aquaticus L., 1758. Four recorded cases in Europe with abdominal symptoms, pain, vomiting, etc. and nervous symptoms, hysteria, and neuralgia.

G. chilensis E. Blanchard, 1849.—This is simply based on the legends of Chilian Indians, who fear the worm.

Paragordius varius Leidy, 1851.—Four cases of infection in North America. Worms were expelled *per anum* or by vomiting. Symptoms: unimportant.

P. tricuspidatus Dufour, 1828. One case in France. Symptoms: slight colic. Worm extracted from the throat.

P. cinctus von Linstow, 1900. From a man in Leydenburg in the Transvaal.

Parachordodes tolosanus Dujardin, 1842. Four cases, in one of which it is accused of causing epileptiform fits. Cases occurred in France and Italy.

P. pustulosus Baird, 1853. One case in Italy caused anal pruritus and discharge.

P. violaceus Baird, 1853. One case in France; it lodged in the throat before expulsion.

P. alpestris Villot, 1884. One case in France.

Undetermined.—Ward, in 1903, published the account of a case in which the genus of the worm was not determined.

CLASS II.

ORDER III. ACANTHOCEPHALA Rudolphi.

Nemathelminthes with a retractile proboscis armed with several rows of spines or hooks; intestine absent; parasitic in the intestine of vertebrates.

The Acanthocephala are elongated cylindrical worms, in which the body can be divided into proboscis, neck, and trunk. The proboscis is a hollow, finger-shaped, retractile process, covered with a thin cuticle, and armed with rings of hooks arranged in longitudinal rows. The neck is not always discernible. The trunk has a rounded posterior end, and consists of a body-wall with muscular layers, covered by a thin cuticle, enclosing the excretory and reproductive organs. The sexes are separate. The male organs are two oval testes, whose vasa efferentia unite into a vas deferens, which opens into a cirrus contained in a pouch or bursa, and provided with a prostate gland.

The female organs consist of two ovaries, which break down into masses of cells which escape into the cœlom. Here the ova are fertilized and the embryo is formed, and escapes through a funnel-shaped structure called 'the bell' into the uterus, and so through the vagina and the genital orifice at the posterior end of the body into the lumen of the host's intestine.

The embryo leaves the host with the fæces, and, getting into water, enters the alimentary canal of a crustacean, water-insect, or fish, inside which it hatches. It now bores its way through the intestinal wall into the cœlom, where it develops all its organs except the reproductive.

The crustacean, water-insect, or fish must now be eaten by a vertebrate, when the acanthocephalid becomes sexually mature in the intestine. They are very rarely found in man.

Classification.—The Acanthocephala are divided into four families by Hamann and Shipley:—Echinorhynchidæ, Gigantorhynchidæ, Neorhynchidæ, and Arhynchidæ. Human parasites, which are very rare, are only found in the first two families.

ECHINORHYNCHIDÆ.

Acanthocephala with elongated, smooth body; proboscis can be retracted into a sheath with double walls.

Genus.—*Echinorhynchus* Müller, 1776.

Echinorhynchus (Müller, 1776).

Echinorhynchus hominis Lambl, 1859.

This parasite was found in the intestine of a boy who died of leukæmia; it was 5·6 millimetres long. There appears to be much doubt as to whether this really was *Echinorhynchus*.

GIGANTORHYNCHIDÆ.

Gigantorhynchus Hamann, 1892.

Large Acanthocephala with ringed, flat, tæniform bodies.

Gigantorhynchus gigas (Goeze, 1782).

This parasite was alleged by Lindemann to occur in man in South Russia, where Schneider says Melolontha is eaten raw. It is 10 to 15 centimetres long; eggs 80 to 100 μ long, with three shells. Its usual life history is that the adult is found in pigs, and the larva in *Melolontha vulgaris*, *Cetonia aurata*, or *Lachnosterna arenata*.

Gigantorhynchus moniliformis (Bremser, 1911).

Synonym.— *Echinorhynchus moniliformis* Bremser, 1911.

Leiper records a parasite found in a Sudanese by Christopherson as probably belonging to this species. It has also been seen in man by Grassi and Calandruccio. The worm is found in Europe, Africa, and Brazil.

Morphology.—White body with attenuated ends with many rings, making it closely resemble a Porocephalus. Male 4 to 5 centimetres in length, with a bursa visible to the naked eye. Female 7 to 10 centimetres long. Eggs ellipsoidal, 85 μ by 45 μ.

Life-History.—The intermediate host is *Blaps mucronata*. Calandruccio has shown experimentally that it can develop in the human body.

CHAPTER XXVII

ANNULATA AND HIRUDINEA

Annulata—Hirudinea—Classification—Gnathobdellidæ—Hirudinæ—Hæmadipsinæ—Remaining orders—References

PHYLUM ANNULATA AUCTORES.

METAZOA with elongated bodies divided externally into a number of rings which represent a division of the internal parts into segments or somites (metameres), usually with an extensive cœlom. Nervous system consists of a cerebral ganglion, with double commissure and ventral nerve cord. Organs of excretion in the form of metamerically arranged pairs of nephridia.

The only class of this phylum which contains animals of importance in tropical medicine is the Hirudinea or Discophora—*i.e.*, the leeches.

CLASS HIRUDINEA SAVIGNY, 1817

Annulata with oval bodies, showing a dorso-ventral flattening and two suckers, one at each end.

Remarks.—Leeches are of interest in the tropics, first because they may be a considerable nuisance as ectoparasites—*e.g.*, land leeches or *Hæmadipsa*; and, secondly, they may be of considerable danger to the health and even the life of a person as endoparasites—*e.g.*, the water leeches, particularly *Limnatis*.

As ectoparasites they are apt to fasten on the legs of persons going through grass or jungle. In fact, in Ceylon, while standing on a piece of grass in certain parts of the low country, the leeches can be watched converging from all quarters of the compass towards the observer.

Very often the bite is not noticed, and the leech or leeches may have sucked a considerable amount of blood before any attention is paid to them, and tales are told of persons feeling faint before noticing that they were being attacked by these creatures.

They are apt to get into the nose, naso-pharynx, or larynx with drinking-water, and in this endoparasitic condition they may suck blood and cause epistaxis or hæmoptysis, and this may go on to such an extent that anæmia and even death may result.

It is hardly possible to believe that they can live in the stomach, for it is much more likely that they are at once killed by the gastric juice and digested.

A great many tropical countries appear to be plagued with leeches which affect men and animals as indicated above, but it is probable that Algeria, Palestine, and Ceylon are the most infested. Among the other places in which they are troublesome may be mentioned the Philippines, Java, Sumatra, Australia, Japan, and Chili. In Algeria and Palestine the leech lives in the pools of drinking-water, and here the endoparasitic form may be met with; whereas in Ceylon it is usually a land leech which attacks the individual, and therefore the ectoparasitic condition is common, while the endoparasitic is more rare, being due to ***Hirudo multistriata***.

Morphology.—Leeches have an elongated, more or less oval body, which is very retractile and extensile, and is marked by annuli or rings, of which several—usually five—form a somite. The number of rings to a somite is, however, reduced anteriorly and posteriorly, being abbreviated. At the anterior extremity is the oral sucker, and at the posterior the acetabulum. The skin possesses many unicellular dermal glands. The mouth-opening is situate in the anterior sucker, and the anus either in or just in front of the constriction which separates the posterior sucker from the body.

The male genital opening is placed on the twenty fourth annulus, and the female five annuli behind it in *H. medicinalis*; but the female orifice may vary with regard to the male in other genera. A number of nephridial orifices can be seen as paired openings on the posterior annuli of many of the somites. Eyes exist as small, dark dots on the dorsum of the body, behind the anterior sucker. The mouth may be armed or unarmed. In the former condition it possesses three jaws—one dorsal and two ventro-lateral—each with a thickened free edge notched with teeth. In the latter there may be only a proboscis. Into the mouth open the salivary glands, which secrete a fluid which prevents the coagulation of the blood. The pharynx is an oval sac, with strong muscular walls and radial muscles, which can alternately contract and dilate the cavity, thus forming a sucking-pump. From the pharynx an œsophagus leads to the crop, which is a straight, thin-walled tube with lateral diverticula.

Behind the crop comes the small stomach, which opens into a narrow straight tube—the intestine—which runs to the anus. The cœlom consists of a series of tubes containing red blood. The excretory system consists of the nephridia. There is a supra-œsophageal ganglion, a nerve collar, and a ventral nerve chain. The male reproductive organs are a number of testes, with vasa efferentia opening into two vasa deferentia, which, after coiling into epididymis run to the single penis. The female organs are a pair of ovaries and oviducts opening into a single vagina.

Biology.—Leeches appear to be essentially water animals, and though certain genera can live on land, still, they require a great deal of moisture. Hence land leeches retire into moist places under stones, earth, etc., and only come out when requiring food. In dry weather not a leech can be seen, while in damp weather they may be very abundant.

Any disturbance of the air appears to affect them. Hence they are quickly aroused from their retreats when a human being or animal approaches, and set forth at once, often with considerable speed, to the attack.

The bite is not always painful at first, and may not be noted until the flow of blood is observed. The leech, while biting, keeps itself and the skin of the victim moist by liquid excreted by the nephridia and the dermal glands. When it has gorged itself with blood it drops off, but its salivary secretion prevents the coagulation of the blood, and hence the site of the leech-bite bleeds considerably for some time. The blood is stored up in the crop and its cæcal diverticula, and only a little is used day by day for food.

Pathogenicity.—Leeches are hosts of trypanosomes and other parasites, and their bite may possibly introduce these parasites into the skin of the human victim as well as into that of animals.

The marked feature of the pathogenesis is loss of blood, not merely caused by the sucking of the leech, but also by the bleeding from the wound caused by the bite. Further, the punctures caused by *Hæmadipsa zeylanica* are extremely liable to become ulcers, which, according to Marshall and Davy, caused a high rate of mortality among the Madras sepoys and coolies during the Kandyan rebellion of 1818 in Ceylon. Short of death, amputation of the limb was necessary in those days. We are not inclined to consider these old statements as erroneous, because it is quite possible that some organism is often introduced into the affected part by the leech-bite. For a further discussion of the pathogenicity, see the chapters on Diseases of the Respiratory Organs and of the Skin.

Classification.—The class Hirudinea may be divided into several orders.—

Order I.: Rhynchobdellida.—Hirudinea without jaws, with an extensile proboscis and with colourless blood, living in salt and fresh water.

The Rhynchobdellida are divided into two families:

Family 1 Ichthyobdellidæ.—Rhynchobdellida with the anterior narrower part of the body distinct from the posterior and with both suckers distinct from the body.

To this family belong the genera *Piscicola* de Blainville 1818, and *Pontobdella* Leach, 1815, mentioned in the chapter on Protozoa.

Family 2 Glossiphoniidæ.—Rhynchobdella with the anterior sucker fused to the body, while the posterior is distinct.

Among the genera of this family is *Hæmentaria* de Filippi, 1849, of which *H. officinalis* de Filippi is found in Mexico, and is alleged to cause drowsiness, buzzing in the ears, and a painful rash, when it bites a person. The causation of these symptoms is obscure. Another species is *H. ghilianii* de Filippi, 1849.

Other genera are *Glossiphonia* Johnson 1816, *Hemiclepsis* Vejdovsky, 1883; and *Placobdella* R. Blanchard, 1893.

Order II.: Arhynchobdellida.—Hirudinea usually with jaws, without a proboscis, and with red blood, living in fresh water or on land. There are two families, Gnathobdellidæ and Herpobdellidæ, of which only the first concerns us.

FAMILY GNATHOBDELLIDÆ.

Arhynchobdellidæ with five or more, rarely four, pairs of eyes, and, except in the Semiscolinæ, with three denticulate jaws. Eggs enclosed in a spongy cocoon, which is deposited above water-line.

The Gnathobdellidæ are classified into the following subfamilies: Hirudininæ, Hæmadipsinæ, and Semiscoleeinæ, which last is not of interest to us.

SUBFAMILY HIRUDININÆ R. Blanchard, 1894.

Aquatic Gnathobdellidæ with ten eyes, and with an eyeless ring between the third and fourth pair of eyes, with denticulate jaws. Complete somite formed of five rings. The nephridial pores open near the margins of the body on the ventral surface.

In 1896 Blanchard divided this subfamily into two series: (1) Monostichodonta—jaws armed with one row of teeth; (2) Distichodonta—jaws armed with two rows of teeth.

The genera are: *Hirudo, Limnatis, Hæmopis, Hirudinaria, Limnobdella, Macrobdella,* and *Whitmania,* which are divided into two series.

Series 1: Monostichodonta.

Hirudininæ with jaws with or without papillæ, and armed with a single row of numerous sharp teeth.

Hirudo Linnæus, 1758

Synonyms. *Sanguisuga* Savigny, 1822, *Iatrobdella* de Blainville, 1827.

Hirudininæ with twenty-six somites of which the 1st and 2nd have each one ring; 3rd two rings, 4th, 5th, and 6th, each three rings; 7th to 22nd, each five rings, 23rd three rings, 24th 25th, and 26th, each two rings, making in all 102 rings.

Eyes are carried on the 1st, 2nd, 3rd, 5th, and 8th rings. The buccals are the 5th and 6th, and the post buccals the 7th and 8th. The first pair of nephridia is on the 13th and the last (the 17th) pair on the 93rd ring.

The male orifice is between the 30th and 31st rings which are the 2nd and 3rd of the 10th somite.

FIG. 300. *Hirudo multistriata* SCHMARDA.
The common water leech of Ceylon.

The female orifice is five rings behind that of the male—*i.e.*, between the 35th and 36th rings. The anus is situate on the 102nd ring, or between the 101st and 102nd.

Hirudo medicinalis Linnæus 1758, is found principally in Hungary. Variety *officinalis*.

H. troctina Johnston, 1816 is the medicinal leech of England, France, Spain and Algeria.

H. nipponia Whitman, 1886. Japan.
H. sinica de Blainville, 1827. China.
H. quinquestriata Schmarda. Australia.
H. saigonensis. Cochin-China.
H. asiatica R. Blanchard. Afghanistan and Persia.
H. timorensis R. Blanchard. Timor.
H. septemstriata Grube. South Africa.
H. hildebrandti R. Blanchard. East Africa, Victoria Nyanza.
H. multistriata Schmarda. Ceylon.

Series 2: Distichodonta.

Hirudininæ with jaws without papillæ, and armed with two rows of infrequent blunt, irregular teeth.

Hæmopis Savigny, 1817.

Synonym.—*Aulastoma* Moquin-Tandon, 1826.

Hirudininæ with 3 rings on the 23rd somite, and two rings to the 24th, 25th, and 26th somites. Crop with one pair of elongate lateral cæca reflected posteriorly. Genital openings usually separated by five rings. Upper lip of anterior sucker not divided inferiorly by a longitudinal groove. *H. sanguisuga* Linnæus, 1758 found in Europe, and *H. lacustre* Leidy in America.

Limnatis Moquin-Tandon, 1826.

Hirudininæ with a longitudinal groove on the inner surface of the upper lip of the anterior sucker. Jaws with more than 100 teeth.

Limnatis nilotica Savigny, 1820. This leech is 8 to 10 centimetres in length, and is common in North Africa, the Canaries, South Europe, and Asia Minor while it, or some other species, is found on the West Coast of Africa.

Limnatis mysomelas Serulias and Virey, 1829, is found in Senegambia, and *L. granulosa* Savigny, 1820, in India.

These leeches are of importance, because they are apt to get into the nose, naso-pharynx, pharynx, and larynx of persons drinking at pools of water, and to cause serious symptoms. Other species are *L. africana* R. Blanchard in Senegal and the Congo, *L. maculosa* Grube, 1859, in Singapore, *L. mysomelas* in Senegal, and *L. granulosa* in India.

Hirudinaria Whitman, 1886.

Hirudininæ with the sexual pores separated by several rings. Acetabulum very large.

H. javanica Wahlberg, 1855. In Batavia, Sumatra, and Burma.

Limnobdella R. Blanchard

Hirudininæ with 103 to 104 rings. Jaws without papillæ. The 6th somite with three rings, the 23rd with five rings.

L. grandis R. Blanchard. Timor, Sumatra, and Ceylon.
L. australis Bosisto, 1859. Sydney and New South Wales.
L. mexicana R. Blanchard. Mexico.

Macrobdella Verrill, 1872.

Hirudininæ, jaws without sensory papillæ, teeth not numerous, 103 body rings. Both genital openings on the 11th somite.

M. sestertia Whitman, 1886. America.

Whitmania R. Blanchard, 1884.

Hirudininæ with 105 to 107 rings; 6th segment with five rings; 23rd has always more than three rings. Teeth more or less rudimentary.

W. ferox R. Blanchard, 1886. London Zoological Gardens and in Asia.

SUBFAMILY HÆMADIPSINÆ R. Blanchard, 1894.

Gnathobdellidæ, small leeches, living on land, with ten eyes and no eyeless ring between the 3rd and 4th eyes. The three last body somites (twenty-three to twenty-six) with only one ring each. Dentition simple and complete.

Remarks.—The Hæmadipsinæ were monographed by Blanchard in July, 1917, in his usual masterly style.

Type Genus.—*Hæmadipsa* Tennent, 1861.

Hæmadipsa Tennent, 1861.

Synonyms.—*Hæmopis* Schmarda, 1861; *Chthonobdella* Grube, 1865.

Hæmadipsinæ, terrestrial in habit, 2 to 3 centimetres in length; subcylindrical, tapering slightly forwards, cephalic lobe, rounded when at rest, but pointed in extension; acetabulum moderately large, round, or oval, centrally attached, separated from the body only by a feeble constriction.

Eyes in five pairs, the rings bearing the 3rd and 4th pair, not separated by an intervening ring; the rings bearing the 4th and 5th pairs, separated by two rings. Œsophagus with three plications—one dorsal and two lateroventral. The three maxillæ covered with teeth, which increase in size towards the converging anterior ends of the jaws. Clitellum includes three somites and fifteen rings. Genital orifices separated by five rings, nephridial pores at the margin of the body, the last pair opening in the constriction between the body and the acetabulum.

Remarks.—The land leeches of Ceylon were separated from the genus *Hirudo* by Tennent in 1861, under the name of *Hæmadipsa*; and those of

Australia by Whitman in 1886, under the term *Geobdella*, altered to *Moquinia* by Blanchard.

Land leeches are mostly tropical, living in the area defined by the parallels 40° N. and 40° S. of the Equator, for they appear to prefer a warm, moist climate. In the Himalayas they ascend to a height of 11,000 feet; but in Ceylon they diminish in numbers above 4,000 feet. They are to be found in Ceylon, India, Java, Sumatra, Luzon, Mindanao, Pelew Islands, Japan, New Guinea, Celebes, New South Wales, Queensland, and the southern provinces of Chili and Trinidad. They live under damp leaves and loose rubbish, and appear when the air is disturbed by the approach of man or beast, and so quickly do they rush to the attack that they have earned the name of the 'jumping leech.' As a rule they bite gently, but make a deep wound the scar of which may take months to disappear. They fill themselves with blood in about thirty minutes and then drop off.

Classification.—Some of the species are as follows:

H. zeylanica de Blainville, 1827. Ceylon.
H. limbata Grube. Sydney.
H. fallax R. Blanchard. Madagascar.
H. morsitans R. Blanchard.
H. vagans R. Blanchard. Madagascar.
H. javanica Wahlberg. Java.
H. talagalla Meyen. Philippines.
H. japonica Whitman. Japan.

Other Genera.

Mesobdella R. Blanchard, 1893. With three rings to a somite.
M. gemmata R. Blanchard, 1894.
Philaemon R. Blanchard, 1893. With four rings to a somite.
P. pungens R. Blanchard. Java and Australia.
P. grandidieri R. Blanchard. Madagascar.
Phytobdella R. Blanchard, 1893.—With six rings to a somite.
P. meyeri R. Blanchard. Luzon.
P. moluccensis R. Blanchard. Salawati.
Planobdella R. Blanchard, 1894.—With seven rings to a somite.
P. quoyi R. Blanchard. North Celebes.
P. molesta R. Blanchard. Celebes.
Moquinia R. Blanchard, 1881.—With seven and a half rings between genital apertures.

Remaining Orders.

The remaining orders, Ichthyobdellida, Acanthobdellida, and Branchiobdellida, do not concern us.

CHAPTER XXVIII

ARTHROPODA

Arthropoda—Diplopoda—Acarina—Gamasoidea—Ixodoidea—Trombidoidea—Eupodoidea—Sarcoptoidea—Vermiformia—Linguatulida—Crustacea—Chilopoda—References.

PHYLUM ARTHROPODA v. Siebold and Stannius, 1845.

BILATERALLY symmetrical metazoa, with well-developed body cavity and heteronomously segmented body with hollow segmental appendages, moved by intrinsic muscles and penetrated by blood spaces. One or more pairs of appendages behind the mouth are densely chitinized and turned inwards so as to act as jaws.

The phylum Arthropoda is divided into the following grades and classes by Ray Lankester:—

GRADE A: PROTARTHROPODA.

Class I. Onchophora.

GRADE B: EUARTHROPODA Lankester.

Class II. Diplopoda.
Class III. Arachnida.
Class IV. Crustacea.
Class V. Chilopoda.
Class VI. Hexapoda.

The Onchophora, which includes the genus *Peripatus*, does not concern us, but the other classes all contain species of importance in medicine.

CLASS II. DIPLOPODA RAY LANKESTER, 1904.

Synonym.—*Chilognatha.*

Euarthropoda, in which the somites generally fuse after early development, forming double somites, with two pairs of appendages, or present legless and leg-bearing somites alternately. They are terrestrial, breathing by tracheæ.

The following orders are recognized:—(1) Juliformia; (2) Symphyla; and (3) Pauropoda. We shall only consider the first.

Order I. Juliformia—*Diplopoda with two pairs of appendages on each somite.*—Two families of the Juliformia need be mentioned:—

FAMILY JULIDÆ.—*Juliformia with large free head, without broad dorsal plates.*—Two species of Julus—viz., *J. terrestris* L. and *J. londinensis* Leach—have been found as occasional parasites (accidental) in the human alimentary canal in Europe.

FAMILY POLYDESMIDÆ.—*Juliformia with large free head and laterally extended dorsal plates.*—*Polydesmus complanatus* has once been recorded as an accidental parasite in the human alimentary canal in Europe.

Pathogenicity.—These parasites give rise to symptoms both direct and reflex.

CLASS III. ARACHNIDA Lamarck, 1815.

Euarthropoda with two pre-oral segments, the first bearing typical eyes, and the second antennæ or chelicerae, and six post-oral appendages, modified so as to function as jaws, but possessing also a well-developed ramus, which may be a leg, palpus, or chela. The primitive forms have branchial respiratory processes, and the higher pulmonary organs.

The Arachnida are classified by Lankester into:-

- Grade A: Anomomeristica.
- Grade B: Nomomeristica.
  - Subclass I. Pantapoda.
  - Subclass II. Euarachnida.
    - Grade *a*. Hydropneusta.
    - Grade *b*. Aeropneusta.
      - Section A. Pectinifera.
        - Order Scorpionidea.
      - Section B. Epectinata.
        - Order I. Pedipalpi.
        - Order II. Aranea.
        - Order III. Palpigrada.
        - Order IV. Solifuga.
        - Order V. Pseudoscorpiones.
        - Order VI. Podogona.
        - Order VII. Opiliones.
        - Order VIII. Acarina.
        - Order IX. Linguatulida (Incertæ sedis).

Details with regard to this classification may be obtained by reference to Ray Lankester's paper in the *Quarterly Journal of Microscopical Science*, 1904, vol. xlviii., p. 165.

We have already considered the effects of the bites of the Scorpionidea, the Aranea, and some of the Acarina, and now it is necessary to consider more particularly those which are parasitic, and cause or spread disease.

Two orders must be dealt with in some detail—viz., the Acarina and the Linguatulida.

ORDER ACARINA Nitzsch, 1818.

Synonym.—Rhynchostomi.

Definition.—Degenerate Arachnida with the basal segments of the second pair of appendages united in the middle line behind the mouth, while those of the third, fourth, fifth, and sixth appendages are widely separated, and take no part in mastication. The respiratory stigmata usually belong to the prosoma, and the primitive segmentation of the opisthosoma has either entirely or almost entirely disappeared.

Remarks.—The Acarina include the mites and ticks which have long been known to be human parasites, but it is only recently that the latter have come into notice as carriers of disease.

It is true that a mite, or rather its larva, has long been suspected to be the cause of Tsutsugamushi disease, but it is probable that at present we are not fully aware of the disease-carrying and producing effects of these small arachnids.

The Acarina are cosmopolitan in their distribution, and are said to be most numerous in temperate regions. They are abundant at high altitudes. Banks remarks that the parasites follow the distribution of the host—*i.e.*, of the food—a remark the importance of which has already been appreciated. The observer will find that a parasitic disease is often bounded by the distribution of the food of the insect, which spreads the real cause of the disease.

Morphology.—The morphology is described under the heading Ixodoidea.

Life-History. The female lays eggs covered by a shell and an inner membrane called the deutovum. A six-legged larva hatches out from the egg, and after a time, during which it may be active or quiescent, moults and produces the nympha, which is eight-legged, and resembles the adult, except in the non-development of the sexual organs and apertures. The leg which is added to the nympha is the fourth, or posterior. The nymph is usually energetic, and feeds on some host; eventually passing into a quiescent stage and undergoing considerable histological changes, it moults and becomes the adult male or female. The males are usually smaller and more active than the females. Both sexes suck fluid nourishment from the host, whether animal or plant. Their life-history will be found to vary with the different families and species.

Pathogenicity. The Acarina are important in the dissemination of disease both among men and animals. In men they are responsible for the spread of such fevers as Dutton's relapsing fever, the tick fever of the Rocky Mountains, Tsutsugamushi disease, and the disease associated with the Miana bug in Persia; also they are responsible for a number of skin diseases, among which may be mentioned scabies. In animals they are responsible for the spread of the Babesiases, and of some Spirochaetiases, as well as causing some forms of dermatitis. Incidentally it may be mentioned that they also cause disease in plants, producing galls, etc.

Enemies.—Hurtful as they are themselves, they are not, however, free from persecution on the part of other animals. Blood-sucking insects, particularly the Reduviidae, prey on some arachnids, sucking their blood. Wellman has reported that he has caught *Phonergates bicoloripes* Stal in the act of sucking the juices of *Ornithodoros moubata*, the tick responsible for the spread of Dutton's relapsing fever.

Classification.—The order Acarina is divided into the following suborders:—

SUBORDER NOTOSTIGMATA.—Acarina in which the opisthosoma is segmented by ten integumental grooves, of which the anterior four are furnished with a single pair of dorsally placed spiracles. (Family: Opilioacaridæ.) This suborder does not concern us.

SUBORDER II. CRYPTOSTIGMATA.—Acarina with a hard integument strengthened by chitinized dorsal and ventral sclerites. Stigmata on the acetabula of the third, fourth, fifth, and sixth pairs of appendages (Family: Oribatidæ.) This also does not concern us.

SUBORDER III. METASTIGMATA.—Acarina with a hard integument like the Cryptostigmata. One pair of stigmata above and behind the base of the fourth, fifth, or sixth pair of appendages.

Superfamily A: Gamasoidea.
Superfamily B: Ixodoidea.

SUBORDER IV. PROSTIGMATA.—Acarina with soft integument strengthened by special sclerites, those on the ventral surface of the prosoma apparently representing the basal segments of the legs embedded in the skin. Except in the aquatic species, there is a pair of stigmata close to or above the first pair of appendages.

Superfamily A: Trombidoidea.
Superfamily B: Eupodoidea.

SUBORDER V. ASTIGMATA.—Degenerate Acarina, mostly parasitic, like Prostigmata in the development of integumental sclerites and the softness of the skin, but with the respiratory system absent. (Superfamily: Sarcoptoidea.)

SUBORDER VI. VERMIFORMIA.—Degenerate parasitic Acarina without respiratory system, and with the body produced posteriorly into an annulated caudal prolongation. With the third, fourth, fifth, and sixth pairs of appendages short, and only three jointed. (Family: Demodicidæ.)

SUBORDER VII. TETRAPODA.—Degenerate attacheate Acarina with body as in the Vermiformia, but with the third and fourth pairs of appendages long and normally segmented, and the fifth and sixth entirely absent. (Family: Eriophyidæ.) This suborder, however, need not concern us.

SUBORDER III. METASTIGMATA.

The parasites included in this suborder would in popular language all be called ticks.

It is divided into two superfamilies:—

A. GAMASOIDEA.—With a small hypostome without teeth.

B. IXODOIDEA.—With a large hypostome armed with many recurved teeth.

SUPERFAMILY A: GAMASOIDEA.

The superfamily Gamasoidea is divided into three families: (1) Dermanyssidæ, (2) Uropodidæ, (3) Gamasidæ.

FAMILY 1: DERMANYSSIDÆ.

Gamasoidea parasitic on vertebrates, with mandibles fitted for piercing, with the body sometimes constricted, with soft integuments finely striated.

The Dermanyssidæ are divided into two subfamilies:—Dermanyssinæ, with an anal plate; Halarachninæ, without an anal plate.

SUBFAMILY DERMANYSSINÆ.

Dermanyssus Dugès, 1834.

Dermanyssinæ with a long body not distinctly constricted; peritreme on the venter, with chelate mandibles in the male and long styliform mandibles in the female. Parasitic on birds.

Dermanyssus gallinæ Redi, 1674.

Synonyms. *Pulex gallinæ* Redi, 1674; *Acarus gallinæ* de Geer, 1778; *Dermanyssus avium* Dugès, 1836.

This parasite lives in cracks, etc., in the hen house during the day, and attacks the fowls at night, sucking the blood. It is also found on many other birds and mammals, and occasionally on man, generally on poultry men, in whom it produces a papular eczematous dermatitis on the back of the hands and forearms. *D. hirundinis* Hermann, 1804, which is probably only a variety of this species, can also be found on man.

Morphology. Body egg-shaped, posterior end wider than anterior, abdomen with short, marginal, widely separated bristles.

Male, 0·6 millimetre by 0·32 millimetre; female, 0·7 millimetre by 0·4 millimetre.

Holothyrus Gervais, 1842.

Holothyrus coccinella Gervais, 1842.

This arachnid is found on ducks and geese in Mauritius, and is said to attack human beings, causing swelling of the affected part, which, if the lips or tongue of a child, may be dangerous. Some authorities consider that this arachnid should form a separate family of its own—Holothyridæ.

FAMILY 2: GAMASIDÆ.

In this family comes the genus *Lælaps* Koch, 1842, with its species *L. echidninus* Berlese, mentioned in the chapter on Protozoa, because Miller has traced the life-cycle of *Hæmogregarina muris* Balfour, 1905, in it and in the rat *Mus decumanus*.

SUPERFAMILY B: IXODOIDEA BANKS, 1894.

Synonyms. *Acarus* Linnæus, 1746, *pro parte*; *Ricinia* Latreille, 1804, *pro parte*; *Ixodides* Leach, 1815; *Ixodea* Burmeister, 1837; *Ricini* Koch, 1844 and 1847; *Ixodes* Gervais, 1844; *Ixodida* Küchenmeister, 1855; *Ixodidæ* Leach, 1863; *Ixodides* Donnadieu, 1875, and Mégnin, 1876; *Ixodæ* Wagner, 1876; *Metastigmata* Canestrini, 1892; *Cynorhæstea* Marx, 1892; *Arpagostoma* Lahille, 1905.

The term *Cynorhæstea* is derived from Aristotle, who speaks of these arachnids as κυνοραίστης (the dog-tormentors), because ticks were well known in his day to attack hunting dogs.

The Ixodoidea are the ticks, which have become of importance in tropical medicine not merely because of their unpleasant bite, but because of the spread of disease by their agency—as, for example, the tick fever of Africa, Tsutsugamushi disease, the tick fever of the Rocky Mountains, etc. They are parasitic on mammals, birds, and reptiles, but are not strictly confined to one host. The Argasidæ, one of the two families included in the superfamily, are now nocturnal in habits, and do not become greatly distended with blood; while the other family, Ixodidæ, or true ticks, are very common in tropical countries.

Morphology.—A tick is divisible into a head, rostrum, or capitulum, and a body. The capitulum is the small anterior structure with the mouth parts, and is easily visible from above in the Ixodidæ (*vide* Fig. 313), but must be viewed from below in the Argasidæ (Fig. 321). It joins the rest of the body at the camerostome. The capitulum consists of the following parts:—

1. *Neck.*—This is the junction of the rostrum with the rest of the body.

2. *Base.* This is the hard basal portion, and is usually quadrangular, but its outline varies.

In females of the Ixodidæ there are two porose areas on the upper surface (*vide* Fig. 311). Attached behind the base is the neck; in front, in the middle line, is the haustellum, composed of the hypostome and the mandibles and their sheaths, on each side of which lie the palpi.

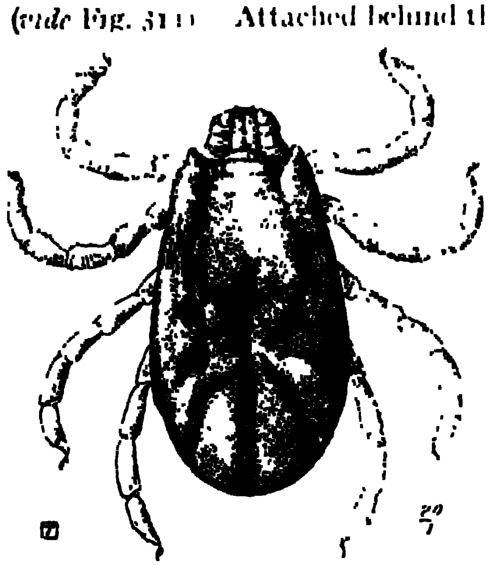

FIG. 310.—*Margaropus annulatus* VAR. *australis* SAY: DORSAL VIEW OF THE MALE.

3. The hypostome is an elongated structure composed of two symmetrical halves, with numerous minute teeth, called denticles, on its ventral surface.

4. The chelicera or mandibles, are two in number—one on each side of the median line, lying dorsal to the hypostome. The posterior portion enclosed in the body is swollen for the attachment of muscles, while the anterior is flat and narrow, and terminated by a hook-like digit, which has two or three processes—the apophyses—an internal, an external, and a middle, with hook-like teeth.

5. The mandibular sheath lies dorsal to the mandibles.

6. The palpi are composed of four segments or articles—basal, antepenultimate, penultimate, and apical. They are of importance in classification into genera, as they possess hairs, bristles, edges, angles, and spines, varying in different species. There is sometimes a group of long hairs on the internal aspect of the palpi, which are probably sensory.

The body varies greatly in form, colour, outline, and structure. It is divided into (1) Dorsal surface, (2) ventral surface; (3) to (5) anterior, posterior, and lateral margins.

1. *Dorsal Surface.* On the dorsal surface may be noted (Figs. 313 and 318):—

(*a*) The scutum, found in the *Ixodidæ* and well marked in the adult male but much smaller in the adult female. It is a hard, chitinous plate, with two longitudinal grooves (cervical grooves).

(*b*) The eyes, only sometimes present on each lateral margin of the scutum in Ixodidæ or near the first coxa in Argasidæ.

(*c*) The dorso-submedian porose plates are small, circular, or oval chitinous structures on each side of the median line, near the third and fourth legs.

(*d*) The postero-marginal festoons, when present, are eleven areas marked out by grooves lying along the posterior margin of the body between the stigmata.

(*e*) The dorsal grooves are usually longitudinal, and not always distinct, as they are due to muscular contractions.

(*f*) Pits, hairs, spines, etc., may be visible on the dorsal surface.

2. *Ventral Surface.*—The ventral surface exhibits (Fig. 324):—

(*a*) The genital pore, situated in the ventro-median line, between the coxæ of the first three pairs of legs.

(*b*) The anus, situate in the ventro-median line, behind the posterior pair of legs. It is surrounded by a valve, and in the male of certain genera has laterally the clypea or anal valves.

(*c*) The ventral shields of chitin are small sclerites covering the surface in the male.

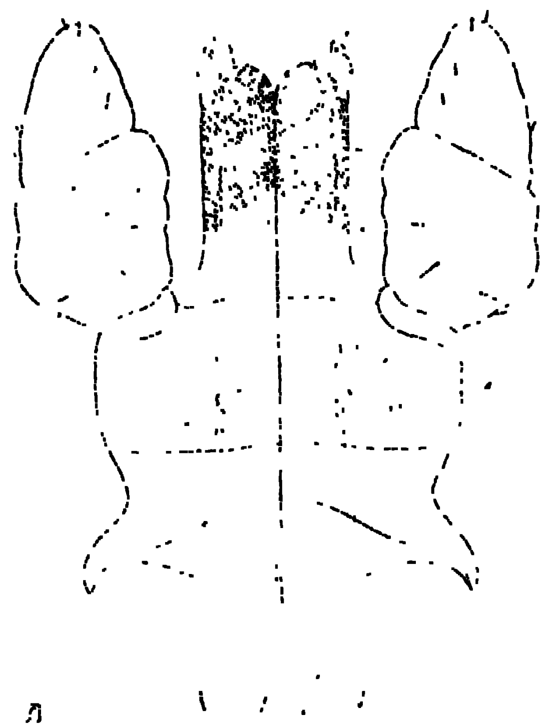

FIG. 311.—DORSAL VIEW OF THE CAPITULUM OF A TICK: FEMALE (*Haemaphysalis punctata* C. AND F.)

1, Cheliceræ; 2, hypostome; 3, palp; 4, porose area.

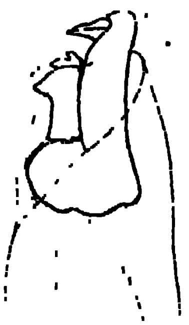

FIG. 312. CHELICERA OF *H. punctata*: MALE (C. AND F.).

(After Nuttall, Cooper, and Robinson, *Journal of Parasitology*)

(*d*) The stigmata lie one on each side of the body, between the 3rd and 4th pairs of legs in the Argasidæ, and behind the fourth in the Ixodidæ.

(*e*) There are often to be seen a pair of genital furrows and an anal furrow.

(*f*) Pits, pores, hairs, and punctations are to be found as on the dorsal surface.

3. *Anterior Margin.*—This varies as compared with the posterior, being sometimes straighter, sometimes emarginate, and receiving at the camerosome the rostrum.

4. *Posterior Margin.*—This is generally rounded, and often marked by the festoons already mentioned on the dorsal surface.

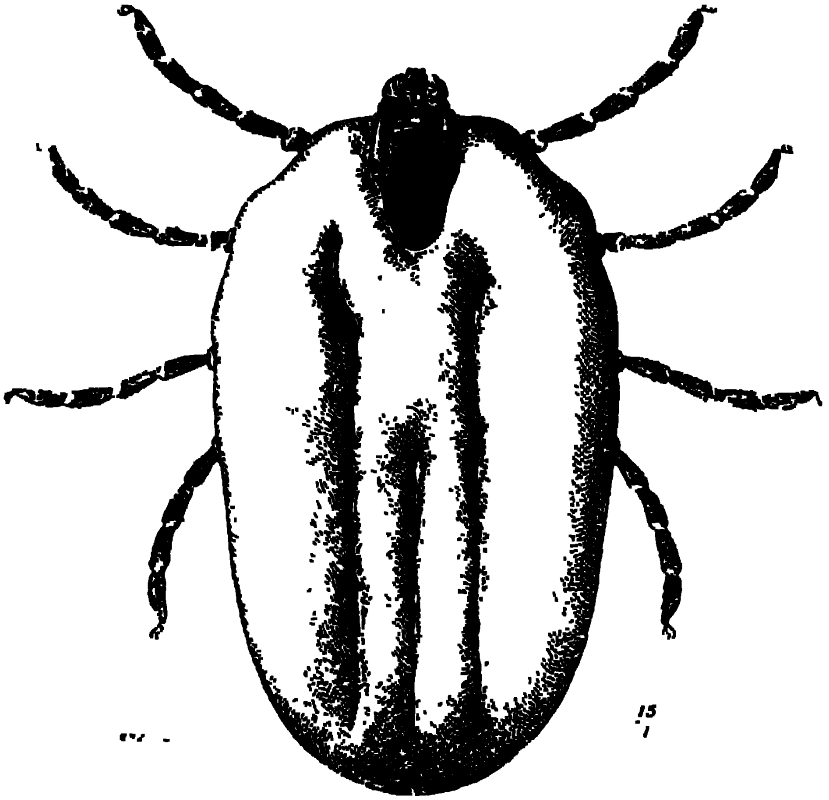
5. *Lateral Margins.*—They vary as to their straightness or degree of curvature.

The legs are segmented into the following articles: coxa, trochanter, femur, patella, tibia, and tarsus.

Internal Anatomy.—The internal anatomy has been studied by Christophers in *Ornithodoros savignyi*, and most elaborately by Bonnet in eight Ixodidæ and three Argasidæ, males and females.

The tegument consists of chitinous layers, under which lies the epidermis. On the surface are the openings of numerous glands. A large cephalic gland is present in some species, opening dorsally at the junction of the rostrum with the body.

The mouth, which is lined with chitin, is situated anteriorly between the mandibular sheath dorsally and the hypostome ventrally. In this position it is merely a horizontal slit, with open sides, but farther back these are closed by the junction of the hypostome with the mandibular sheaths. The cavity extends backwards some little distance, and ends blindly. Into its postero-lateral angles open the ducts of the salivary glands, two large racemose glands lying over the bases of the first pair of legs. The acini are globular, and their walls consist of large cells, as a rule laden with refractile granules staining deeply, or with indistinct granules staining less deeply.



Margaropus annulatus VAR *australis* SAY: DISTENDED FEMALE

In addition to the ordinary acini, there are groups of four or five cells, forming pear-shaped masses, which have a peculiar affinity for acid stains like eosin. These elements are really unicellular glands, which open into the principal salivary ducts, not into the small ductules. These glands, which are numerous in the Argasidæ, are probably poison glands.

On the floor of the mouth is a **V**-shaped opening, apex pointing forwards, which leads into the pharynx. This is a fusiform organ, narrow in front, where it turns upwards to open into the mouth, while behind it ends in the œsophagus. Its walls consist of chitinous plates arranged ventrally and laterally, so that the lumen is triradiate on transverse section. At the angles the chitinous plates are united together by double folds, allowing expansion and contraction, and brought about by the contraction and relaxation of muscles taking origin in the sclerites forming the endoskeleton of the head and inserted into these plates. It ends posteriorly in a narrow œsophagus which is without chitinous support, and therefore soft. This œsophagus runs backward, perforating a large ganglionic mass, and ends in the mid-gut. Its walls are composed of a layer of columnar cells internally and by muscular fibres externally. Just before it joins the mid-gut its wall thickens and forms a fold, the homologue of the proventriculus, which projects into that passage.

The œsophagus opens on the floor of the large central food reservoir or mid-gut, the main canal of which runs forward a little distance in front of this opening, and backwards to the neighbourhood of the rectum.

The central canal gives off diverticula, which may be classed into an anterior set, consisting of a single diverticulum; a lateral set, consisting of an antero-lateral diverticulum, subdivided into three branches a medio-lateral, into two or three, a postero-lateral, which is single, and a posterior set, which is also single.

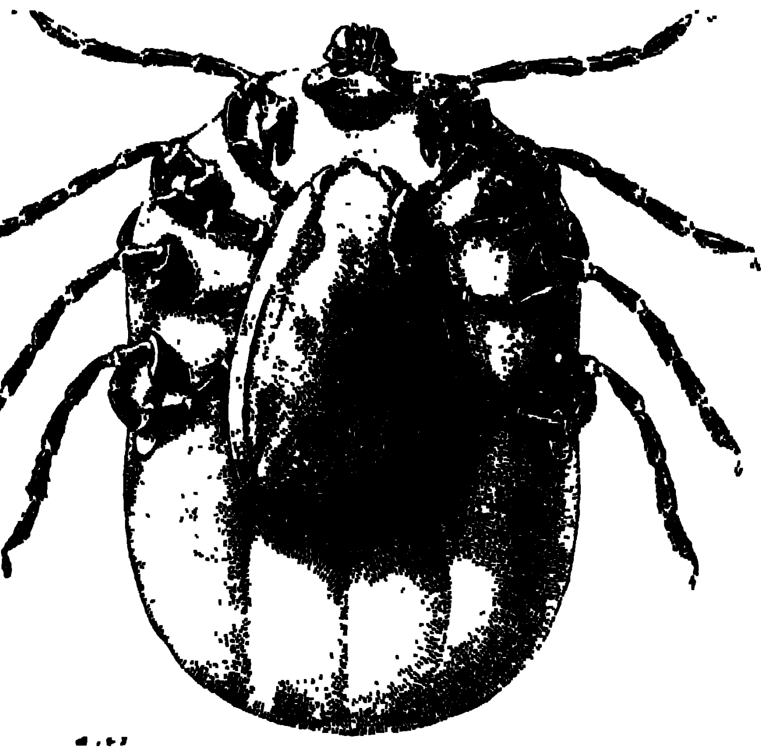


FIG. 314. COPULATION OF THE MALE AND FEMALE TICK
(After Sambon.)

The walls of the central tube and the diverticula consist of a single layer of large cells lying upon a thin basement membrane, external to which are large single muscular fibres arranged longitudinally and transversely in an open network. Digestion is assisted by free cells mingling with the coagulated blood filling the diverticula.

Posteriorly the central canal is connected with the rectum by means of a very fine canal, which appears to represent a functionless rudimentary intestine This communication is not admitted by Bonnet

Into the rectum open also two long, fine, much convoluted tubules -- the Malpighian tubes, which are composed of a single layer of large cells placed on a basement membrane. In females they may contain spherical corpuscles, which, though present in males, are much smaller. Berlese and Bonnet consider that these bodies are composed of guanine.

The rectum is a sacculated tube, with a wall composed of a single layer of flattened cells leading to the anus. Bonnet objects to the term 'anus, considering the tubules as renal, the rectum as a bladder, and the opening as an excretory pore; but this term must be kept for morphological reasons. Further, he states that this excretory matter is only expelled during moulting, collecting at other times in the rectum. The anus is a slit-like aperture, guarded by two lateral semicircular chitinous plates.

The male reproductive organs consist of a thin, transparent tubule—the testes—ending at either end in a vas deferens, which, after coiling upon itself, enters a lobulated structure—the white gland. The ejaculatory duct ends in the chitinous penis. The female reproductive organs consist of a single ovary, which lies across the abdomen just behind the central alimentary sac. This ends in two coiled oviducts, which open into a large spermatheca with thick walls, and from which a duct leads to the genital opening.

The tick breathes by a means of a system of tubes, lined by a spiral thread of chitin. These tubes are called tracheæ, and radiate, from the opening on the stigma called the 'spiracle,' all over the body. The circulatory system consists of a median heart and distributing vessels. The fat body is well marked.

There are a number of dermal glands, a coxal gland in the second coxal joints and opening on the first coxal joints by a minute pore, and a cephalic gland in the head.

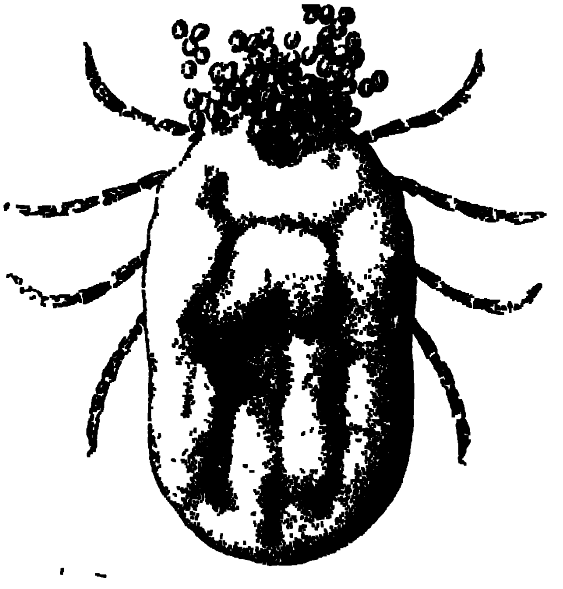

FIG. 315.—A TICK LAYING EGGS.
(After Sambon.)

Life-History.—While on the host sucking blood, the male and female parasites copulate, and the latter, growing to a large size, drops to the ground and lays a number of eggs. The egg consists of a shell with an inner membrane, enclosing food yolk and embryo, which eventually hatches as a six-legged larva, without sexual organs or stigmata. The digestive organs are, however, present, and the little larva, becoming parasitic on some animal, sucks its blood, drops off and moults, giving rise to the nympha. The nympha has eight legs and a pair of large stigmata, but is without reproductive openings or organs. The nymphæ now become parasitic, and feed, after which they drop off, moult, and become males or females with fully developed generative organs.

The adults now become parasitic and moult, and the young female, fixing itself to the host, grows considerably, but rarely changes her place: while the male, remaining small, wanders about looking for the female.

The life-history and the habits of the different divisions of the *Ixodidæ* are so various that they will be described under their separate heads. One example may, however, be mentioned here—viz., *Margaropus decoloratus*—whose life-history has been studied by Lounsbury. In this species the female, dropping off the host, completes oviposition in a time varying, according to the temperature of the air, from five days to four weeks, while the incubation of the egg varies from three weeks to three months. The larvæ, which are capable of remaining on grass without food for months, must obtain access to cattle, on which they feed, and grow for three days, after which they moult and form nymphs on the sixth day of their parasitic existence—*i.e.*, without leaving the host. The nymph sucks blood and grows till the eleventh day, and the adult is hatched on the thirteenth to sixteenth day without the nymph leaving the host.

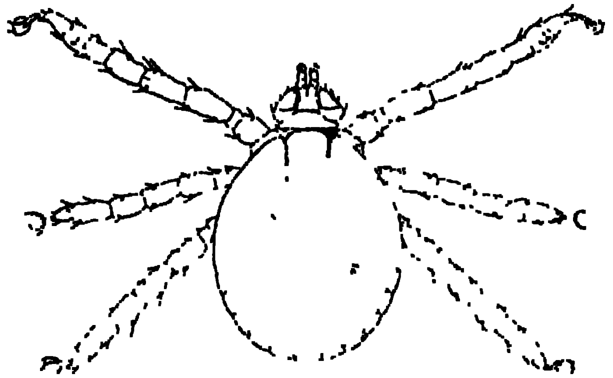

FIG. 316.—THE LARVA OF *Hæmaphysalis punctata* C. AND F. (× 10.)

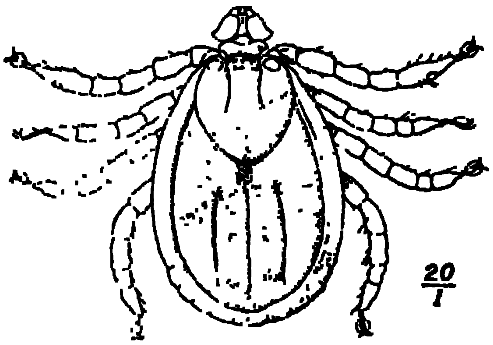

FIG. 317.—THE NYMPH OF *Hæmaphysalis punctata* C. AND F.

(After Nuttall, Cooper, and Robinson, *Journal of Parasitology*.)

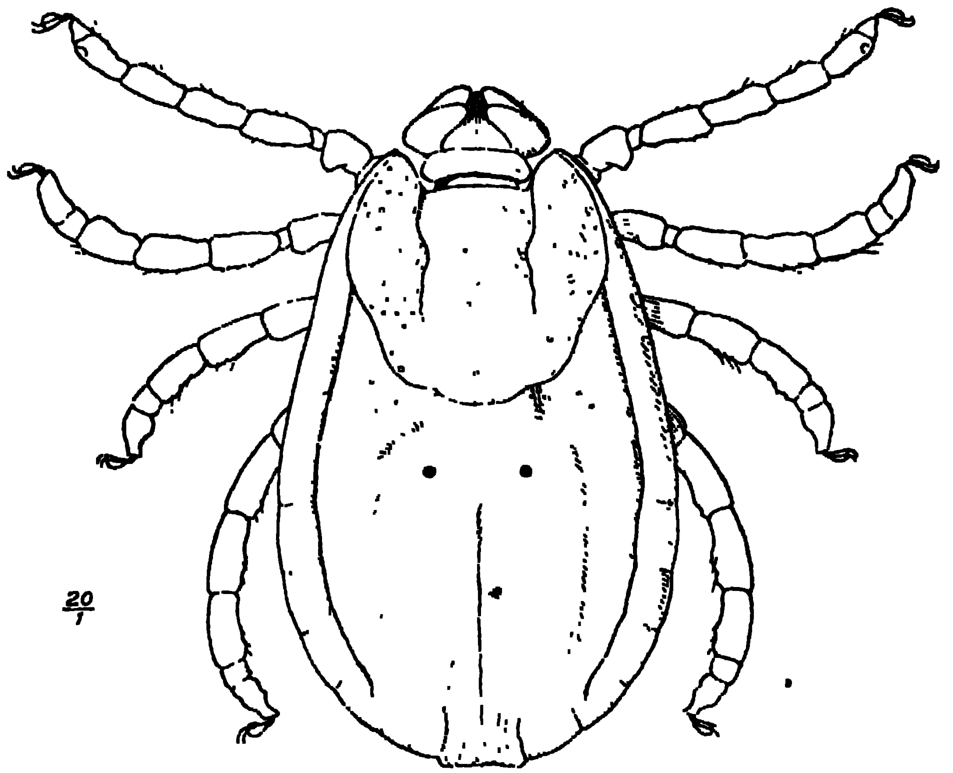

FIG. 318.—ADULT FEMALE OF *Hæmaphysalis punctata* C. AND F.
(After Nuttall, Cooper, and Robinson, *Journal of Parasitology*.)

Pairing takes place on the seventeenth to twentieth day, and the fertilized gorged female drops off the host on the twenty-fourth to thirty-first day. Thus, in this case the larva and nymph remain parasitic on the host, and do not drop off as described above.

Parasitic on Man.—The ticks known to be parasitic on man are:—(1) *Argas reflexus* Fabricius; (2) *A. persicus* Oken; (3) *Ornithodoros savignyi* Audouin; (4) *O. moubata* Murray; (5) *O. megnini* Dugès; (6) *O. turicata* Dugès; (7) *O. tholozani* Laboulbène and Mégnin; (8) *Alectorobius talaje* Guérin-Méneville; (9) *Eurhipicephalus sanguineus* Latreille; (10) *Margaropus annulatus* Say; (11) *Rhipicentor bicornis* Nuttall and Warburton; (12) *Dermacentor reticulatus* Fabricius; (13) *D. andersoni* Stiles; (14) *D. electus* Koch; (15) *D. modestus* Banks; (16) *Ixodes ricinus* Linnæus; (17) *I. hexagonus* Leach; (18) *Amblyomma americanum* Koch; (19) *A. dissimile* Koch; (20) *Hyalomma ægyptium* Linnæus.

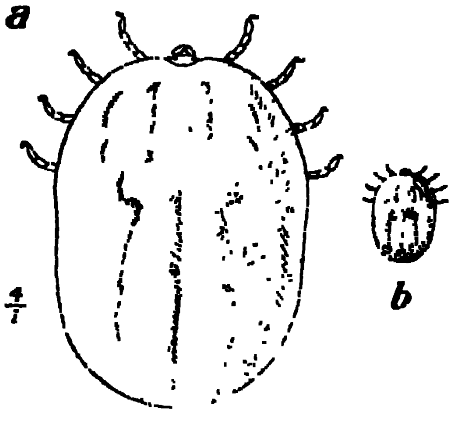

FIG. 319. FULLY REPLETE FEMALE OF *Hæmaphysalis punctata* C. AND F.

(After Nuttall, Cooper and Robinson, *Journal of Parasitology*.)

(*a*) Magnified, (*b*) natural size.

Pathogenicity. Ticks are spreaders of disease in man and animals. They may be classified into spreaders of *Spirochætidæ*, spreaders of *Babesia* and into spreaders of unknown germs.

1. Spreaders of Spirochætidæ.

1. *Ornithodoros moubata* carries *Spiroschaudinnia duttoni* Novy and Knapp, 1906, and causes African tick fever or Dutton's relapsing fever in man.

2. *Argas persicus* carries *Spiroschaudinnia marchouxi* Nuttall, 1904.

3. *Margaropus annulatus* carries *Spiroschaudinnia theileri* Laveran, 1904.

2. Spreaders of Piroplasma.

1. *Eurhipicephalus appendiculatus* carries *P. bigeminum.*
2. *E. simus* *P. bigeminum.*
3. *E. evertsi* *P. equi.*
4. *E. sanguineus* *P. canis.*
5. *E. bursa* *P. ovis.*
6. *Margaropus annulatus* *P. annulatum*
7. *Hæmaphysalis leachi* *P. canis.*

3. Spreaders of Unknown Germs.

1. *Argas persicus* causes a disease in Persia. 2. *Dermacentor venustus* (see *D. andersoni*) causes Rocky Mountain fever.

Experimentally, the nymphs of *D. marginatus* and *Amblyomma* *americanus* and the nymphs and adults of *D. variabilis* can transmit the virus of Rocky Mountain fever.

Enemies.—The enemies of ticks are numerous, and among them may be mentioned fowls and blackbirds.

Prophylaxis.—The prevention of ticks in cattle is a difficult proceeding. The following are some of the methods in use (from Balfour and Archibald):—

Cattle Washes and Dips.—Arsenic used to be employed (Cooper's Dip Powder), but was found to be dangerous. A useful oil is crude petroleum, 2 gallons; hard soap, ½ pound; and water, ½ gallon. The soap is dissolved in the hot water and the petroleum gradually added. Five days' spraying is advocated in place of the usual fortnightly dip.

Rotation of Crops. This is said to be useful in the United States.

Burning of Pastures.—Not a good plan.

Immunization.—Immunization by inoculation against babesia, etc. It is not very useful.

Quarantine. Quarantine of cattle and control over their movements is important.

There are, however, a good many practical points to be attended to in spraying or dipping cattle. Reference may be made to Cooper's paper in the *Journal of Agricultural Science*, vol. iii., or to Newstead's Report of Twenty-first Expedition of the Liverpool School of Tropical Medicine.

Classification.—The Ixodoidea are divided into two families:—

FAMILY 1: ARGASIDÆ Canestrini, 1890. Ixodoidea without a scutum; mouth parts of adult not prominent from above; no pulvillus attached to tarsus in adults.

FAMILY 2: IXODIDÆ Murray, 1877.—Ixodoidea with a scutum; mouth parts prominent from above; pulvillus present, attached to the tarsus in adults.

Remarks.—Neumann's classification is very different from the one used in this book. He recognizes Ixodidæ (= Ixodoidea) divided into Ixodinæ (= Argasidæ and Ixodidæ) and Spelæorhynchinæ, these last being parasites on bats. Other classifications are those by Lahille and by Banks.

FAMILY 1: ARGASIDÆ.

These arachnids are more like bugs than ticks in their habits. During the day they are concealed in cracks in walls or floors, or in gravel, but at night they come out and run about. Christophers says that if handled they sham death, and that when running about they have a curious habit of raising the first pair of legs as though to receive information about their surroundings. They can live for a long time (three to four years) without food. They generally feed after dark, being gorged in about fifteen minutes.

Donovan states that while feeding fluid is secreted by the coxal glands, and lies between the parasite and the skin of the host. This fluid is alkaline, and prevents coagulation of blood. After feeding, the tick drops to the ground, and, being wet with secretion, becomes covered with dust and dirt. At first they are much swollen, but in a few days this diminishes, though they may remain distended for weeks. Soon after feeding, the tick moults, and then becomes active again, and is ready for another feed.

The Argasidæ pair at various times, one female being fertilized by several males. The female now becomes quiescent, and passes out its ova, a process requiring a week or more to be completed. During this process the head is forcibly flexed on the body, so that the palpi lie on each side of the body, while above the head is the prolapsed duct of the cephalic gland, forming a protuberant mass. The ova are not as numerous as those of the cattle ticks, and are generally laid in a loosely adherent mass.

The six-legged larva hatches in less than a week. In *Ornithodoros* it appears to be quiescent, making no attempt to obtain food, and in *O. moubata* does not leave the egg. In three or four days it moults, and becomes the eight-legged nymph, which is an active little creature, feeding readily. In *Argas* the larva is more vigorous, and feeds. It appears as though there were great differences in the life-history of the different species of the Argasidæ.

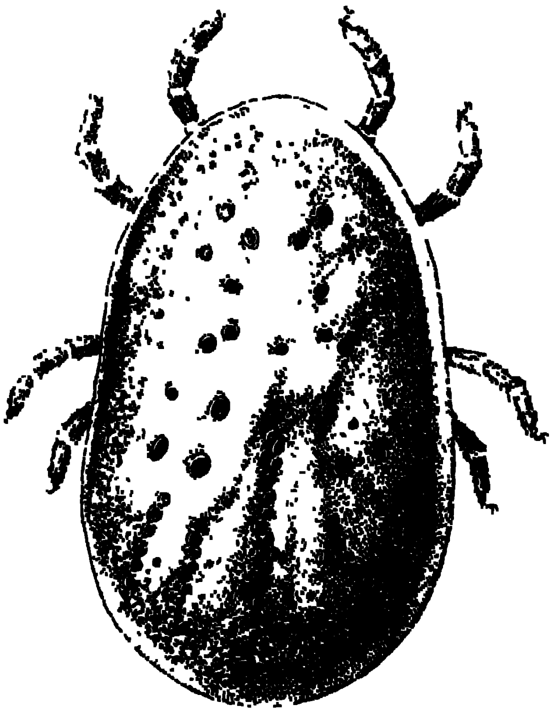

FIG. 320.—*Argas persicus* LATREILLE: FEMALE, DORSAL ASPECT.

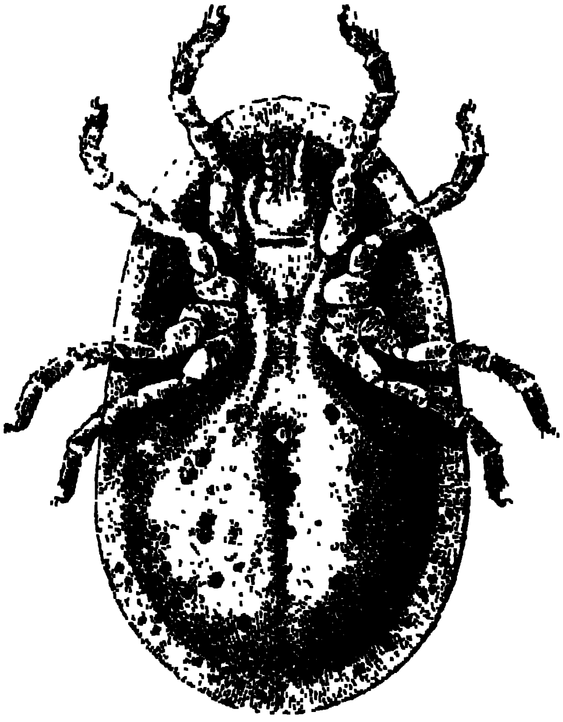

FIG. 321.—*Argas persicus* LATREILLE: FEMALE, VENTRAL ASPECT.

The adult Argasidæ appear to moult many times as they grow larger. They are preyed upon by insects.

Genera.—The Argasidæ are divided into four genera:—*Argas*, *Caris*, *Ornithodoros*, *Alectorobius*.

The diagnosis of these genera is as follows:—

1. Eyes absent, body usually flat, with thin borders, without deep ventral grooves: (*a*) No groove behind anus—*Argas*; (*b*) transverse groove behind anus—*Caris*.

2. Eyes present or absent; body more or less distended, with deep ventral grooves: (*a*) Without a fold of skin (sclerite) on each side of palpi—*Ornithodoros*; (*b*) with such a fold—*Alectorobius*.

There is, however, some doubt as to whether *Caris* is really entitled to be a separate genus.

Argas Latreille, 1796.

Synonyms.—*Nec Argas* Scoul, 1835; *Carois* Latreille, 1796; *Rhynchoporion* Hermann, 1804; *Caris* Latreille, 1806.

Definition.—Argasidæ with oval or flattened bodies, in which the rostrum is at least its own length from the anterior margin, which is less bluntly rounded than the posterior margin. No fold present around the base of the rostrum ventrally. Tegument roughened by wrinkles and folds, and marked by circular pits. Without eyes.

Type.—*Argas reflexus* Fabricius, 1794.

The number of species known is steadily increasing. The more important can be defined by the following table, modified from Neumann:—

- A. Posterior margin with rectangular festoons—*A. persicus*.
- B. Posterior margin with narrow festoons:—
  - I. Tegument with fine folds, body long, swollen—*A. hermanni*.
  - II. Tegument with large folds, body flat:
    - (α) Body narrower in front:—
      - (1) Anterior extremity flat and rounded—*A. reflexus*.
      - (2) Anterior extremity pointed:—
        - (*a*) With deep camerostome and dorsal hexagonal markings—*A. brumpti*.
        - (*b*) Without these—*A. æqualis*.
    - (β) Body almost as large in front as behind:
      - (1) Body short, a little longer than broad—*A. transgariepinus*.
      - (2) Body twice as long as broad—*A. cucumerinus*.

Argas reflexus Fabricius, 1794.

Synonyms.—*Acarus reflexus* Fabricius, 1794; *A. marginatus* Fabricius, 1794; *Rhynchoporion columbæ* Hermann, 1804.

Argas with yellowish body; male 4 by 3 millimetres, female 6 to 8 by 4 millimetres. Its distribution is mainly in Europe and America, where it lives in dovecots; but it can and does attack man, producing the symptoms already described.

Argas persicus Oken, 1818.

Synonyms.—*Rhynchoporion persicum* Oken, 1818; *Argas persicus* Fischer de Waldheim, 1820; *A. mauritianus* Guérin-Méneville; *A. miniatus* Koch, 1844; *A. americanus* Packard, 1872; *A. sanchezi* Dugès, 1891; *A. chinche* Goudot.

Argas with oval, brownish-red body. Male, 4 to 5 by 3 millimetres; female, 7 to 10 by 5 to 6 millimetres. Dorsal and ventral surfaces with pits in rows, and irregularly placed.

This *Argas* is widely distributed, being found in Asia, where, under the term 'garib-guez' (*punaise de Miana*), it has long had an evil reputation for causing sickness. It is also known in Quetta. In South Africa it occurs as a parasite of fowls and ducks, and is also known in the Sudan, Egypt, Turkestan, and Pekin. Under the name of *A. miniatus* it was described in the form of the chicken tick of the United States and the adobe tick of Mexico and Arizona. According to Balfour, it spreads the *Spirochæta marchouxi* in Sudanese fowls. Nuttall and Strickland have demonstrated the presence of an anticoagulin in the salivary glands and intestine of the tick.

Argas brumpti Neumann, 1907.

This tick was discovered by Brumpt in Somaliland. The dorsum is marked by symmetrical hexagonal depressed areas. Female, 20 by 13 millimetres. Nuttall says that, according to Brumpt, the bite is very painful, and causes pruritus lasting several days, and the site may remain indurated after seven years.

Argas cucumerinus Neumann, 1901.

Only the male of this tick is known. It has an oval elongated body, brownish-red in colour, 10 by 5 millimetres. It is found in Lima in Peru. Possibly this is merely a variety of *A. reflexus*.

Argas hermanni Audouin, 1827.

Argas with very fine skin folds and small rostrum. It is found in Abyssinia and Egypt. Possibly this also is only a variety of *A. reflexus*.

Argas æqualis Neumann, 1908.

Synonym. *Ornithodoros æqualis* Neumann, 1901.

Nuttall places this species with the Argasidæ. It was found in German East Africa by Fülleborn. In size it is 5 by 2·5 millimetres, with folded finely granulated integument.

Argas transgariepinus White, 1846.

Synonym. *Argas kochi* Neumann, 1901.

Argas with very compressed body, not much longer than broad—7·5 by 6 millimetres. Margin with irregular folds. Found in South Africa.

Caris Latreille, 1804.

Argasidæ with almost circular body, a little larger in front than behind, with a conspicuous transverse groove behind the anus.

Caris vespertilionis Latreille, 1796.

Synonyms.—*Carios vespertilionis* Latreille, 1796: *Argas pulchella* George, 1876.

Parasitic on bats.

Ornithodoros Koch, 1844.

Argasidæ with or without eyes. Rostrum surrounded ventrally by a camerostome. Tips of the palpi visible from above. Lateral borders of the body straight, sometimes concave. Integument mammillated, with hemispherical elevations. Two longitudinal coxal folds, a pair of supracoxal folds, one transverse pre-anal and one post-anal groove, and one longitudinal anal groove running from the anus to the post-anal groove.

Type.—*Ornithodoros savignyi* Audouin, 1827.

Eleven species are recorded: (1) *Ornithodoros savignyi* Audouin, 1827; (2) *O. moubata* Murray, 1877; (3) *O. turicatus* Dugès, 1876; (4) *O. megnini* Dugès, 1883; (5) *O. lahorensis* Neumann, 1908; (6) *O. tholozani* Laboulbène and Mégnin, 1882; (7) *O. pavimentosus* Neumann, 1901; (8) *O. furcosus* Neumann, 1908; (9) *O. erraticus* Lucas, 1849; (10) *O. coriaceus* Koch, 1844; (11) *O. canestrinii* Birula, 1895.

DIAGNOSTIC TABLE.

A. Eyes present:—

  Three knobs on the last segment of the fourth leg:—

    (*a*) Tegument with hemispherical protuberances:—

      (1) Eyes of equal size (Africa and India)— *O. savignyi*.

      (2) Anterior eyes larger (America)—*O. coriaceus*.

    (*b*) Tegument with flattened protuberances (Africa)— *O. pavimentosus*.

B. Eyes absent:—

  I. Subrectangular body nearly square (Mexico)— *O. turicatus*.

  II. Body more or less constricted behind the fourth pair of legs:—

    (*a*) With broad anterior end (Mexico)— *O. megnini*.

    (*b*) With narrow anterior end (Lahore)—*O. lahorensis*.

  III. Ovoid body, with broader posterior end:—

    (*a*) Anterior end broad and rounded (Central Africa)— *O. moubata*.

    (*b*) Anterior end tapering:—

      (1) Tarsi forked distally (Ecuador)— *O. furcosus*.

      (2) Tarsi slightly knobbed (Algeria)— *O. erraticus*.

      (3) Tarsi second to fourth markedly knobbed (Persia)—*O. tholozani*.

      (4) Tarsi first with three dorsal knobs, second to fourth with one knob (Persia)— *O. canestrinii*.

Ornithodoros savignyi Audouin, 1827.

Synonyms.—*Argas savignyi* Audouin, 1827; *Ornithodoros morbillosus* Gerstäcker, 1873; *Argas schinzii* Berlese, 1880.

This is the type species of the genus, and has been studied in detail by Neumann and Christophers.

It is common in Africa, India, and Aden, and perhaps elsewhere.

Morphology.—*Ornithodoros*, with two pairs of eyes appearing as circular, smooth, convex elevations, situated on the supracoxal fold above the bases of the first pair of legs, and between those of the second and third pairs. Body oval, constricted slightly between the third and fourth pairs of legs, yellow in colour when young, and blackish-brown when old. Integument covered with irregular hemispherical prominences pointed at their summits, between which are narrow depressions with hairs. Capitulum embedded in an infundibuliform camerostome, from which it is separated by a deep groove, in the dorsal portion of which can be seen the opening of the cephalic gland. Mandibles with a simple claw-like internal apophysis, and without middle apophysis. Teeth of the hypostome arranged in three longitudinal parallel rows. Two spines at the base of the hyposome, which is large.

Dorsum of the body marked by two transverse furrows, one just in front of the posterior border, and the other situate farther forward, marking off a median elevation with a central depression, and seven similar depressions, each of which becomes a deep sulcus posteriorly.

The ventral surface shows a well-marked pre-anal furrow, which laterally meets the supracoxal sulcus, which runs round the anterior aspect of the body as a well marked groove, defining the supracoxal fold, on which the eyes are situate. Behind the anus are three symmetrical longitudinal grooves, while a short V shaped depression abuts on the anus. The genital papilla is well marked, and surrounds the wide transverse opening.

The fourth pair of legs is one and a half times as long as the first The coxæ are contiguous, and diminish in size from the first to the fourth, and the first has the opening of the coxal gland. Christophers has observed that the fluid from this gland is alkaline and prevents coagulation of the blood. The stigmata are placed behind and above the supracoxal folds. The fifth joints of the first three pairs of legs with three teeth, the two proximal quadrangular, and the distal conical.

This tick is very hardy, and is said to be able to live for many months without food or moisture. It attacks human beings, and is found in Africa and India.

Pathogenicity. Not known.

Ornithodoros moubata Murray, 1877.

Synonyms.—*Argas moubata* Murray, 1877; *Ixodes moubata* Cobbold, 1882; *Ornithodoros savignyi* var. *cæca* Neumann, 1901.

O. moubata is of importance as the spreader of *Spiroschaudinnia duttoni*, the cause of Dutton's relapsing fever, or African tick-fever. The tick is distributed widely in Africa, where it is called bibo in Uganda, moubata in Angola, and tampan in Zambesi. Christy has described a similar tick in Brazil.

Morphology.—*Ornithodoros* without eyes, body oval, a little wider behind than in front, with a slight constriction between the third and fourth legs; colour varies with age from yellow-brown to dusky brown. Integument covered with irregular hemispherical prominences. Capitulum embedded in an infundibuliform camerostome. Mandible with external apophyses, with two widely separated teeth, and an internal apophysis, which is bidentate. Hypostome not much wider at the base than at the anterior third. Dorsum of the body marked by two short transverse grooves posteriorly and three pairs of pits, from each of which a sulcus runs backwards and inwards.

The ventral surface shows a well-marked pre-anal sulcus, which joins the supracoxal groove, as in *S. savignyi*; behind the anus are three pairs of longitudinal grooves. The stigmata are semilunar, situate above the supracoxal groove. The last segment of the fourth pair of legs is stout and compressed, with three knobs, the distance be n the first and second being equal to that between the second and third.

Tibiae and tarsi of the first three pairs of h three teeth -proximal, submedian and distal, the last being conica

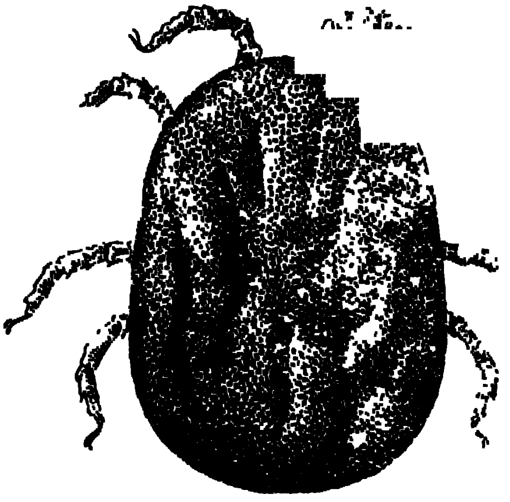

FIG 322 *Ornithodoros moubata* MURRAY: FEMALE DORSAL ASPECT. (× 1)

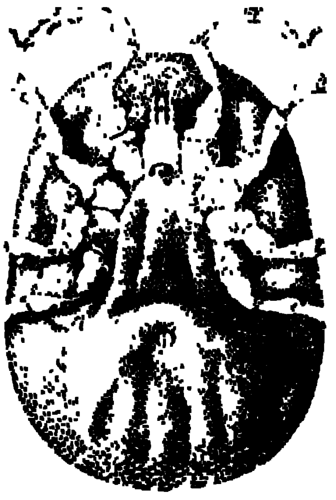

FIG. 323.- *Ornithodoros moubata* MURRAY: FEMALE, VENTRAL ASPECT. (1)

Life-History. -The female lays a variable number of eggs, from 70 to 130, which adhere together, and are golden-brown in colour; 881 by 776 μ. Inside these eggs the larva develop and moult, becoming nymphae, which hatch about the twentieth day at a temperature of 20° to 30° C. and a humidity of 71 to 77 per cent. After three or four days these nymphae suck blood. At first the position of the stigma is marked by only a small white spot and pit, but after the first moult this becomes clear. The genital pore is always absent until after the second moult.

The adult tick moults after each feed of blood, and may live about a year. They are night feeders, and rather resemble bugs in their habits. Leishman observed that the fluid secreted by the coxal glands prevents coagulation of the blood.

Pathogenicity. -It is the spreader of *Spiroschaudinnia duttoni*, and according to Wellman and Feldmann possibly of *Acanthocheilonema perstans*.

Ornithodoros turicatus Dugès, 1876.

Synonyms.—*Argas turicata* Dugès, 1876; *Ornithodoros americanus* Marx, 1895.

Ornithodoros without eyes; anteriorly the body is much narrowed. Tibiæ and tarsi with three small tubercles.

Habitat.—Mexico and Central America. Attacks men and fowls.

Ornithodoros megnini Dugès, 1883.

Synonyms.—*Argas megnini* Dugès, 1883; *A. americanum* Packard, 1893; *Rhynchoprion spinosum* Marx, 1895.

Ornithodoros with phial-shaped body; attenuated anteriorly. Females 5 to 6 millimetres by 3 to 4 millimetres. Males somewhat smaller.

This is the ear tick of American cattle, and has been found in the ear of man.

Ornithodoros lahorensis Neumann, 1908.

Ornithodoros without eyes. Male 8 by 4·5 millimetres. Female 10 by 5·6 millimetres Found at Lahore, India. Parasitic on sheep.

Ornithodoros tholozani Laboulbène and Mégnin, 1882.

Synonyms.—*A. tholozani* Laboulbène and Mégnin, 1882; *A. papillipes* Birula, 1895.

Ornithodoros without eyes. Males 4 to 6 millimetres in length and 2 to 4 millimetres in breadth Females 8 to 10 millimetres by 4 to 5 millimetres.

It is specially a parasite of sheep in Caucasia and Persia, but is very dangerous to man.

Ornithodoros pavimentosus Neumann, 1901.

Ornithodoros with eyes. Body covered with flat warts forming a pavement. South Africa. Only female known. 12 by 8 millimetres.

Ornithodoros furcosus Neumann, 1908.

Found in Ecuador. Female 10 by 5 millimetres.

Ornithodoros erraticus Lucas, 1849.

Synonyms.—*Argas erraticus* Lucas, 1849; *O. miliaris* Karsch, 1880.

Found in Algeria and Bengal. Length, 5 millimetres; breadth, 3 millimetres.

Ornithodoros coriaceus Koch, 1844.

Ornithodoros with eyes. Only one knob on the hind tarsus. America. Male 6·4 to 8·6 by 3·4 to 4·6 millimetres; female 9·5 to 13·8 by 5·3 to 8·2 millimetres.

Ornithodoros canestrinii Birula, 1895.

Synonym.—*Argas canestrinii* Birula, 1895.

Found in Persia. Male 10 by 5 millimetres; female 14 by 8 millimetres.

Alectorobius Pocock, 1907.

Argasidæ with folds of integument capable of being folded under the palpi. This genus is not recognized by Nuttall, as he considers it a synonym of *Ornithodoros*.

Type.—*A. talaje* Guérin-Méneville, 1849.

Alectorobius talaje Guérin Méneville, 1849.

Synonyms.—*O. talaje* Guérin and Méneville, 1849; *O. rudis* Karsch, 1880; *Alectorobius talaje* Pocock, 1907.

This is the chinch of South America and Mexico where it is a great pest. *A. coniceps* of South Europe and *A. capensis* of South Africa are varieties of this species.

FAMILY 2: IXODIDÆ Murray, 1877.

Synonyms.—*Ixodei* Duges 1834; *Ixodiden* Koch, 1844; *Ixodides* Gervais and van Beneden, 1859; *Ixodini* Canestrini and Fanzago, 1877; *Ixodinæ* Trouessart, 1892; *Anistomata* Marx, 1892.

Ixodoidea with a dorsal scutum and a terminal capitulum. The digit of the mandible has two apophyses, and the palpi are free.

Most of the ticks belong to this family, which has the following features:—

Morphology.—There is a dorsal scutum and a terminal capitulum. The mandible has a digit with two apophyses, of which the internal is short with one to four teeth, and the external long, with two to five teeth. The palpi are free. The second pair of legs is the shortest, and the fourth pair the longest. The tarsus has a pulvillum. The stigmata are situate posterior to the coxa of the fourth leg. The male is smaller and fatter than the female. The scutum covers the whole dorsum except a marginal region, the posterior portion of which, between the two stigmata, is generally divided into eleven festoons. The female has but a small scutum, situated anteriorly, and the capitulum has two symmetrical porose areas on its basal piece.

Type Genus.—*Ixodes* Latreille, 1796.

Life-History of the Ixodidæ.—When the pregnant female tick drops off the host, it at first appears to seek for a suitable place to lay its eggs. When this is found, it becomes quiescent, and the anterior part of the ventral surface between the first pair of legs becomes depressed, and forms a hollow, in which the head and genital orifice are situated. When an ovum passes out of the orifice, the tick moves slightly backwards. This oviposition takes about fifteen to twenty days. While it is proceeding the tick begins to shrivel and to show yellow areas, due to the distension of the Malpighian tubes with guanine. At the end of oviposition the tick dies.

From the egg comes a six legged larva, which generally climbs into some grass or bushes and waits to get on to a host. While so doing it may remain for months without food.

It now sucks blood, and drops off this first host and moults on the ground, becoming an eight-legged nymph, like an adult, but without generative apparatus, which again has to go in search of a second host and obtain a feed of blood, when it drops off and undergoes a second moult, turning this time into the sexually mature adult, which goes in search of a third host. Before feeding, the adult female is small, flat, and thin. When she arrives on the third host she drives her rostrum perpendicularly into the skin as far as its base, a hole being made by the mandibles.

The palpi do not enter the hole in the skin, but lie on each side.

The recurved hooks on the hypostome keep the tick in position, and can only with difficulty be detached. The tick now sucks the blood, and at the same time becomes fertilized and increases enormously in size by the addition of blood and the development of the eggs. She then drops off this third host and proceeds to lay her eggs.

The male does not gorge and does not increase so much in size, but sucks blood, which it requires for its fertilizing work.

The *Ixodidæ* are divided into two subfamilies.

SUBFAMILY 1. RHIPICEPHALINÆ Salmon and Stiles, 1901.

Synonyms. *Rhipistomidea* Koch, 1844; *Conipalpi* Canestrini, 1890; *Rhipicephalæ* Neumann, 1897; *Rhipistomidæ* Marx, 1896.

Ixodidæ in which the palpi are no longer than broad. Anterior portion of the body emarginate.

Type Genus. *Eurhipicephalus* Neumann, 1904.

Genera. *Eurhipicephalus, Margaropus, Hæmaphysalis, Dermacentor, Rhipicentor.*

SUBFAMILY 2. IXODINÆ Salmon and Stiles, 1901.

Synonyms. *Ixodidea* Koch, 1844; *Cultripalpi* Canestrini, 1890; *Ixodidæ* Marx, 1892; *Hæmalastoridæ* Marx, 1892; *Eschatocephalidæ* Marx, 1892; *Ixodæ* Neumann, 1899.

Ixodidæ with palpi longer than broad; rostrum long. Anterior portion of the body straight or emarginate.

Type Genus.—*Ixodes.*

Genera.—*Ixodes, Eschatocephalus, Ceratixodes, Aponomma, Amblyomma, Hyalomma.*

DIAGNOSTIC TABLE OF GENERA, FROM SALMON AND STILES.

RHIPICEPHALINÆ.

A. Eyes present:—
  I. Dorsal surface of capitulum hexagonal, sides drawn out laterally into sharp points.
    (*a*) Males with anal plates.
      1. Second and third palpal segments straight; stigmata comma-shaped- *Eurhipicephalus*.
      2. Second and third palpal segments drawn out laterally into sharp points: stigmata round *Margaropus*.
    (*b*) Males with rudimentary anal plates- *Rhipicentor*.
  II. Dorsal surface of capitulum rectangular, sides straight; male without anal plate *Dermacentor*.
B. Eyes absent- *Hæmaphysalis*.

Nuttall and Warburton's new classification of the Ixodidæ is as follows:—

Prostriata—Ixodidæ with anal grooves surrounding the anus in front—*Ixodes*.

Metastriata. Ixodidæ with anal groove contouring the anus behind, but this groove may be faint or obsolete.

Brevirostrata.—

Group I.: Inornate without eyes, but with festoons—*Hæmaphysalis*.
Group II.: Ornate or inornate with eyes, and with or without festoons
  Anal grooves marked.
    Ornate with festoons.
      Basis capituli rectangular dorsally—*Dermacentor*.
      Basis capituli hexagonal dorsally—*Rhipicentor*.
    Usually inornate with festoons
      Basis capituli usually hexagonal dorsally - *Rhipicephalus*.
  Anal grooves obsolete
    With short palpes *Margaropus*.
    With very short compressed palpes ridged dorsally and laterally—*Boophilus*.

Longirostrata.—

Group I.: Ornate or inornate, with eyes and with or without festoons basis capituli subtriangular dorsally. Male with a pair of adanal shields- *Hyalomma*.
Group II.: Generally ornate, with eyes and with festoons, basis capituli variable. Without adanal shields—*Amblyomma*.
  Subgenus *Aponomma* chiefly found on reptiles with poorly-developed or no eyes.

It will be observed that the genera Eschatocephalus and Ceratixodes are rejected and referred to the genus Ixodes. Another genus, *Neumanniella* Lahille, 1905, is also rejected, and it is referred to Aponomma.

SUBFAMILY RHIPICEPHALINÆ.

Eurhipicephalus Neumann, 1904.

Synonyms.—*Rhipicephalus* Koch, 1844; *Phauloixodes* Berlese, 1889.

Rhipicephalinæ with distinct eyes; base of the capitulum broader than long; hexagonal, or dorsal surface forming a projecting angle at each side. Palpi short and broad. First coxa with two large teeth. Male with one or two pairs of anal shield. (Fig. 324.)

Type Species.—*Eurhipicephalus sanguineus* Latreille, 1804.

Eurhipicephalus appendiculatus Neumann, 1901.

This is the brown tick of South Africa, where it spreads *Theileria parva* among cattle and buffaloes, causing 'coast fever.'

Morphology. Male, scutum does not quite cover the dorsum: festoons narrow; the median is prolonged into a caudal process. In front of the festoons, three wide longitudinal grooves. Size, 4 by 2·6 millimetres. Female, dorsal plate oval: porose area small.

Life-History. The eggs are laid in thousands on the grass, and hatch in about twenty-eight days into six-legged larvæ, which pass from the grass on to cattle, suck blood, and drop off replete in about three to four days.

They now remain dormant for about twenty-one days, and finally moult, giving rise to the eight-legged nymph.

The nymph proceeds to attack cattle and suck blood, taking the same length of time as the larva. It then drops off replete, and in about eighteen days moults and becomes an adult male or female tick, which again infests cattle. The female settles down quickly, and is joined by the male. In about four days the female, which has become fertilized and full of blood, drops off, and completes the life-cycle by laying the eggs, after which she dies.

What becomes of the male is not known.

Pathogenicity.—It spreads *Theileria parva*, the cause of coast fever in cattle, by the bites of the infected nymphs only—*i.e.*, infected larvæ and adults do not spread the disease, but the larva can hand the infection over to the nymph, which is the spreader.

Eurhipicephalus bursa Canestrini and Fanzago, 1878.

Synonym.—*Rhipicephalus bilenus* Pavesi, 1883.

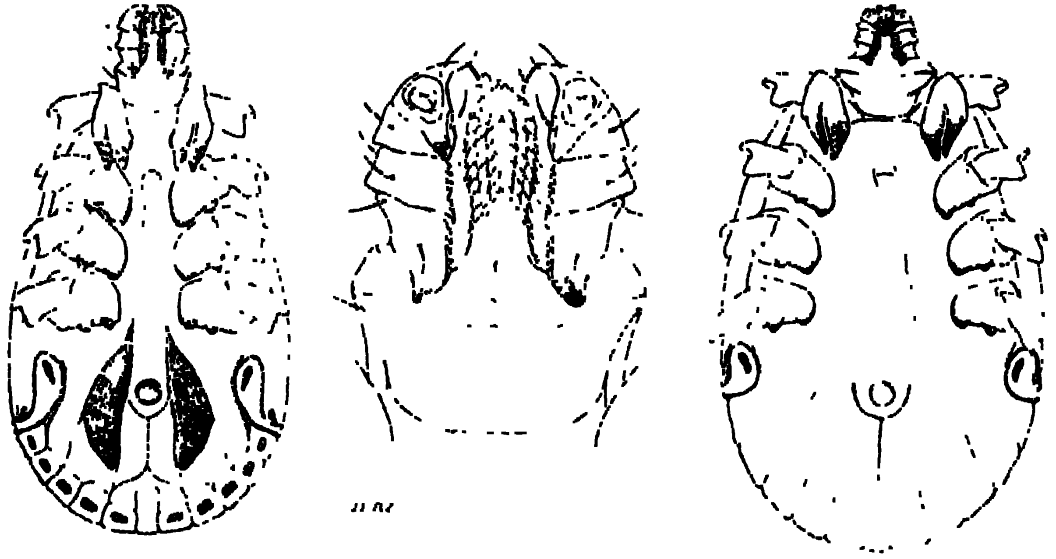
This species is widespread through Southern Europe, and is also known in Africa, West Indies, and Malaga, as a sheep, horse, cattle, and dog tick.

Morphology. Male, scutum half as long as wide; narrow anteriorly, with many punctations. Eleven festoons. Size 4·5 by 3 millimetres.

Female, when newly hatched, flat; when distended with blood, ovoid. Scutum oval, eyes about the middle of the length. Tegument with numerous punctations dorsally when young.

Life-History.—The female lays the eggs on grass, and these develop into larvæ, which attack a sheep, and moult on it in about eight days, forming nymphæ, which grow for twenty-one days, fall off on to the ground, moult, and become adults, which again infest sheep.

Pathogenicity.—It spreads *Piroplasma ovis*, which causes 'heart-water' in sheep, the infection being carried from an adult female through the eggs to the adult ticks of the next generation, which alone are capable of transmitting the disease.



FIGS. 324-326.—*Eurhipicephalus pulchellus* GERSTÄCKER, 1873: VENTRAL ASPECT.

a, Male (× 10); *b*, mouth parts (more highly magnified); *c*, female (× 10).

Eurhipicephalus simus Koch, 1844.

Synonyms.—*Rhipicephalus senegalensis* Koch, 1844: *Rh. prætentatus* Gerstäcker, 1893.

This tick is found in various parts of Africa—viz., Egypt, late German East Africa, and the Cape. It has several varieties—*e.g.*, *E. simus erlangeri*, *E. simus hilgerti*, *E. simus shipleyi*. In South Africa it is called the black pitted tick, because of its punctations, and causes 'coast fever' by spreading *Theileria parva*. Male oval, rounded posteriorly; 4 by 2·2 millimetres. Scutum brown-red. Female oval, 6 by 3 millimetres.

Eurhipicephalus sanguineus Latreille, 1804.

Synonyms.—*Ixodes sanguineus* Latreille, 1804: *I. rufus* Koch, 1844

Synonym of Nymph.—*Phauloixodes rufus* Berlese, 1889.

This is the common dog tick, by which *Piroplasma canis* is spread, which it acquires as an adult, and transmits in the succeeding nymphal and adult stages. It also spreads *Hæmogregarina canis*. It is practically cosmopolitan.

The female has an elliptical body, wider in front than behind: 11 by 7 millimetres, reddish-brown in colour. Scutum very small; integument nearly or completely without hairs: The mandibles have an internal apophysis with three teeth, arranged one internally and two externally; and an external apophysis with three teeth, arranged in series.

The male is 3·35 by 1·55 millimetres, with a scutum covering the dorsal surface, except at the sides and back. External apophysis with only two teeth.

Eurhipicephalus evertsi Neumann, 1897.

This is the red-leg tick, which spreads *Nuttallia equi*, and is found in Europe, Africa, and Asia. The life-history resembles *Eurhipicephalus appendiculatus* in the changes of host by larva and nymph. The infection is acquired in the nymphal stage, and transmitted by the adult. Size: male, 5 to 6 by 3 to 4 millimetres; female, 14 by 9 millimetres.

Margaropus Karsch, 1879.

Synonyms.—*Boophilus* Curtice, 1891, *Rhipicephalus* Neumann, 1897.

Rhipicephalinæ with eyes, though often indistinct: base and capitulum broader than long. Palpi short and broad; second and third segment thicker in the middle, and forming a sharp angle externally. Posterior margin of the first coxa slightly bidentate: stigmal plate round. Body without marginal festoons; anal groove absent. Male with two pairs of anal plates.

Type. *Margaropus annulatus* Say, 1821.

Only three or, according to Neumann, two species, of which two species (*M. annulatus*, *M. decoloratus*) may be one, the third being *M. lounsburyi* Neumann, 1907.

Margaropus annulatus Say, 1821.

Synonyms.—*Ixodes annulatus* Say, 1821; *Hæmaphysalis rosea* Koch, 1844; *Ixodes bovis* Riley, 1869; *Margaropus winthemi* Karsch, 1879; *Boophilus bovis* Curtice, 1880; and several others.

Female with elliptical body, as wide in front as behind. Scutum very small. Eyes small. Dorsal surface, with two antero-posterior grooves, interrupted towards their middle. Ventral surface with small sexual aperture and sexual furrows. Stigmata oval. Capitulum very short. Internal apophysis of mandible conical; the external with three teeth. Hypostome broad. Palpi very short. Legs short (*vide* Fig. 313).

Male with body oval, 2·15 by 2·35 millimetres, narrow anteriorly; widest opposite stigmata. Scutum brown-red, covering the whole dorsal surface with large punctata. Sexual orifice large, a little in front of the level of the second pair of legs. Festoons hardly marked. Two pairs of clypeal shields. Internal apophysis of the mandibles with bifid point: the external has two teeth. Coxa of first leg with a blunt anterior process and bifid posteriorly.

This tick has a very wide geographical distribution, being found in North and South America, the West Indies, Africa, Europe, Japan, and Australia: but the different countries show certain variations in the tick, and hence the species receive a little change in the name.

Life-History.—*Margaropus annulatus* begins its life with the egg on the ground, from which the larva emerges, and, gaining access to the host, undergoes its development into nymph and adult without the changes of host described in *Eurhipicephalus*.

When the adult female has gorged with blood, she drops off the host and lays her eggs.

Pathogenicity.—It is the spreader of *Piroplasma bigeminum*, the cause of Texas or red-water fever in cattle. The adult female acquires the *Piroplasma* and passes it on to the larva, which infects the host. It is also the carrier of *Spiroschaudinnia theileri*.

Varieties.—The names of the varieties are: (1) *M. dugesi* Mégnin, 1880, in North Africa; (2) *M. microphilus* Canestrini, 1887, in South America; (3) *M. australis* Fuller, 1899, in Australia, Asia, Africa; (4) *M. calcaratus* Birula, 1895, in the Caucasus; (5) *M. caudatus* Neumann, 1901, in Japan; (6) *M. argentinus* Neumann, 1901, in Buenos Ayres.

Margaropus decoloratus Koch, 1844.

This is looked upon as a variety of *Margaropus annulatus* Say by some authors. It is the blue tick of South Africa.

Morphology.—The clypeal plates in the male end in sharp points, and a caudal appendage is present. The hypostome has six rows of teeth.

Life-History.—It lives from the larval stage to the adult on the same host. The adult, when fully fed, drops off and lays the eggs on the ground.

Pathogenicity.—It is a spreader of *Piroplasma bigeminum*.

Rhipicentor Nuttall and Warburton, 1908.

Rhipicephalinæ with eyes, inornate, with festoons. Basis capituli hexagonal dorsally, and having very prominent lateral angles with short palps. Coxa I. bifid in both sexes. The male resembles *Eurhipicephalus* dorsally and *Dermacentor* ventrally. Coxa IV. is much the largest. There are no ventral shields or plates. Spiracles subtriangular or comma shaped.

Type.—*Rhipicentor bicornis* Nuttall and Warburton, 1908.

Rhipicentor bicornis Nuttall and Warburton, 1908.

Synonym.—*Rhipicephalus gladiger* Neumann, 1908.

This is an African species living on the horse in the Congo and Central Africa. It attacks and can live on man. Another species is *Rh. vicinus* Nuttall, 1908.

Dermacentor Koch, 1844.

Rhipicephalinæ with eyes; base of capitulum rectangular, broader than long. Dorso-submedian porose plate present; palpi short and thick; stigmata comma-shaped. Male without anal shields. The coxa of the fourth leg much larger than those of the others. Scutum ornamented.

Type.—*Dermacentor reticulatus* Fabricius, 1794.

In 1910 Stiles classified the species of Dermacentor into four groups, according to the microscopical structure of the stigmal plates in the adult.

A Adults with four longitudinal rows of large denticles on each half of hypostome, stigmal plate nearly circular without dorso-lateral prolongation, goblets very large - *D nitens*.

B Adults with three longitudinal rows of large denticles on each half of hypostome, goblets small medium, or large.
  Dorso-lateral prolongation of stigmal plate absent *Salmoni group*.
  Dorso lateral prolongation of stigmal plate distinct.
    Goblets of medium size - *Andersoni group*.
    Goblets small - *Reticulatus group*.

The *Salmoni group* includes *D. albipictus* Packard, 1869; ***D. salmoni*** Stiles, 1910; and *D. nigrolineatus* Packard, 1869.

The *Andersoni group* includes *D. occidentalis* Marx, 1892; ***D. parumapertus*** Neumann, 1901; *D venustus* Marx 1897; ***D. andersoni*** Stiles, 1905.

The *Reticulatus group* includes *D. reticulatus* Fabricius, 1794; ***D. variabilis*** Say, 1821.

Remarks.—There has been the greatest confusion as to the tick which causes Rocky Mountain fever. This was called ***Dermacentor occidentalis*** because Stiles considered that *D. andersoni* Stiles, 1905, was identical with *D. occidentalis* Marx, 1892, but the two forms have since been shown by him to be quite distinct. Therefore in any reference to a tick causing Rocky Mountain fever, no matter what name is used, it is important to understand that ***D. andersoni*** Stiles, 1905, is the species really referred to.

Dermacentor reticulatus Fabricius, 1794.

Synonyms.—*Acarus reticulatus* Fabricius, 1794; ***Ixodes reticulatus*** Fabricius, 1805; *I. marmoratus* Risso, 1826; ***Dermacentor albicollis*** Koch, 1844; *D. pordalinus* Koch, 1844; *D. ferrugineus* Koch, 1844; *Hæmaphysalis marmorata* Berlese, 1887.

Dermacentor with coarsely punctate stigmal plate.

This tick gains its importance from the fact that for some time it was considered to be the cause of the spread of Rocky Mountain fever, which was really due to the nearly related *D. andersoni*, with which it was long confused. It probably does not occur in America. It is widely distributed through Europe and Asia.

Dermacentor occidentalis Marx, 1892.

This tick was received by Marx from Occidental in California, and was first described by Neumann It is found in the north-western portion of the United States from California to Montana.

Morphology.—Male Oval, narrow in front, broad behind; scutum variegated brown and white Anteriorly there is an elliptical area, the pseudoscutum, closely representing the form and colour of the female scutum, and limited by a white border, and possessing two lateral brown stripes, with a median brown stripe or spots between them. Behind this there are four brown stripes arranged in a curve, open anteriorly. Posterior to these usually five brown stripes; one central and two lateral. Between these areas the whole dorsum is speckled with brown punctations. The eleven festoons are somewhat quadrangular, each composed of a white area with one brown spot, and speckled with brown punctations. Ventral surface with the first coxa bidentate, and the others with a single spine. Fourth coxa very large; about twice as large as the third. Generative aperture on a level with the second pair of legs. Stigma comma-shaped; hypostome with three rows of teeth on each side. Palpi longer than hypostome. Size, 5 by 2·5 millimetres.

Young female: Oval depressed body, broader posteriorly than anteriorly; reddish-brown in colour; about the same size as the male—5 by 2·5 millimetres. Scutum very large, and marked like the anterior part of the male, extending as far back as the third pair of legs, with eyes in the anterior part of the lateral border. Dorsal surface of abdomen with a marginal groove beginning behind the eyes, and three longitudinal grooves running backwards, the two lateral beginning just behind the scutum, and the median about the centre of the body. Posterior margin with eleven festoons. Ventral surface with fine hairs. Genital aperture at the level of the second coxa genital grooves close together at first, but diverging laterally behind the fourth coxa, and ending between the second and third external festoons. Anus with short anomarginal groove. Stigma comma-shaped.

Capitulum with the posterior lateral angle prolonged into a sharp point. Porose areas circular. Internal apophysis of the mandible with strong posterior tooth; external with three successive teeth. First coxa bidentate, other three with spines. Replete female: Swollen body laterally constricted at the stigmata, of deep brown or slate colour; size, 16 by 10 millimetres.

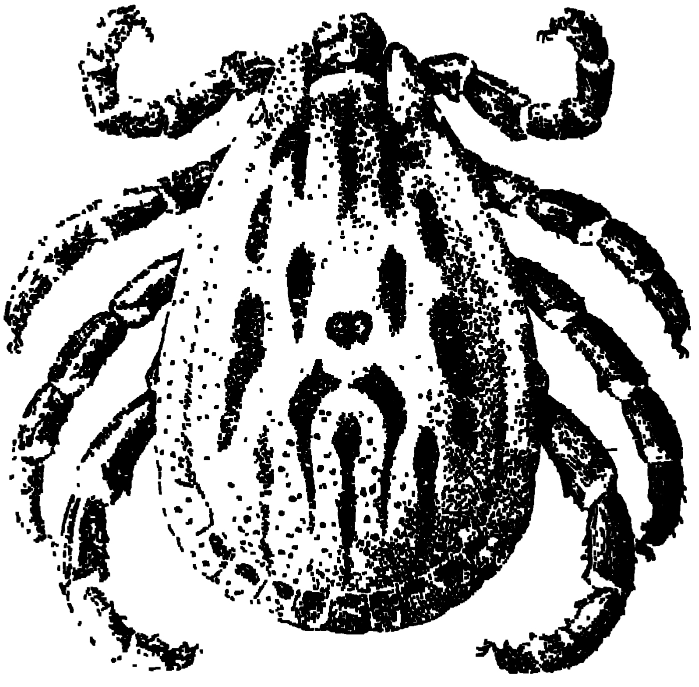


Fig. 347. *Dermacentor salmoni* Stiles, 1909: Male, Dorsal Aspect.

Life-History.—The egg hatches in seven to ten days, and produces a larva which feeds on some animal for several days, and then, becoming swollen and of a uniform slate-colour, drops off, and, becoming quiescent, moults and gives rise to the nymph. This nymph again attacks an animal, and when fed drops off, and in ten days moults and becomes the adult. The nymph however, can hibernate. If the adults do not obtain a host they die off quickly

Pathogenicity.—Nil.

Dermacentor andersoni Stiles, 1905.

Synonyms.—*Dermacentor occidentalis* of all writings on Rocky Mountain spotted fever until some time after 1910; *D. venustus* Marx (in part only); *D. andersoni* Kieffer, 1907.

Dermacentor with caudal margin nearly or quite semicircular. Colour, greyish to red or deep red-brown. Eyes not prominent. Scutum with whitish rust, and with large or small punctations.

Genital pore surrounded by hairs. Anal ring nearly circular. Stigmal plates with prominent dorso lateral prolongation, aperture and chamber large and elongate, goblets of medium size. Postero-lateral projections of plate small. Capitulum with short postero-lateral projections of base. External article with large recurved tooth, a smaller subapical, and a very small apical tooth. Hypostome with three rows of strong denticles. Palpi with lateral margin convex; first article with four or five bristles: third article rather triangular dorsally. Legs. outer spur of coxa I. longer than inner spur; trochanter I. with retrograde curved blade.

Male. Length, 4 by 2·5 millimetres broad. Body oval. Scutum covers dorsum except capitulum: deep reddish-brown, marked by four elongate spots arranged in semicircle; two elongated reniform spots behind these, one elongated median spot, and two shorter elongate submedian spots, and an indistinct forked spot.

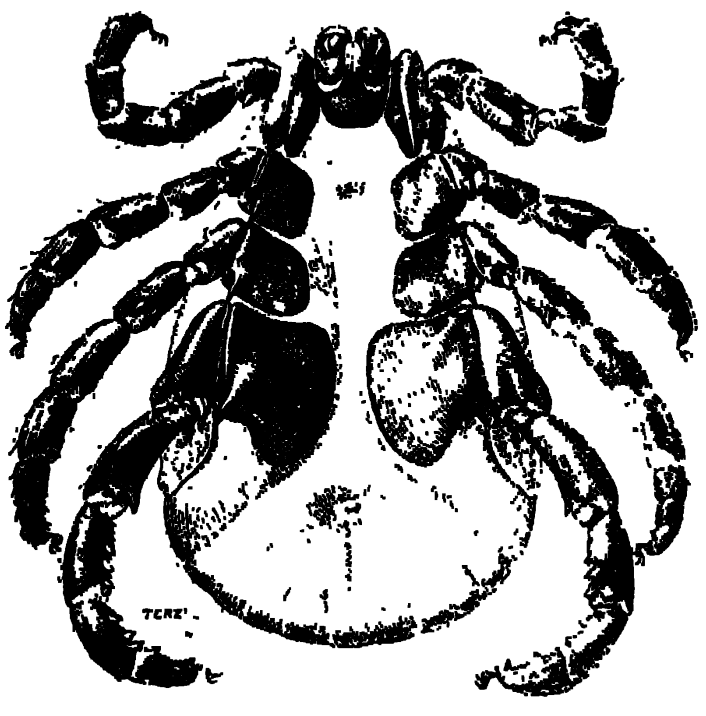

FIG. 328.—*Dermacentor salmoni* STILES, 1909: MALE, VENTRAL ASPECT

Female. Scutum, 1·56 to 1·62 millimetres in length by 1·9 millimetres broad; very conspicuous because of its whitish colour. Cervical grooves well developed. Venter with punctation and fine hairs. Genital grooves running parallel caudad.

Young Female. This is the form most commonly found. Length, 4·5 to 7 millimetres. Breadth, 2·3 to 2·6 millimetres. Body oval. Scutum covers about 0·43 of the length of the body. Eyes not very distinct. Vulva between coxæ II.

Replete Female. Length about 16 millimetres, and 6 millimetres to 9·5 millimetres thick. Eyes more distinct than in young female. Vulva may shift to level of first and second intercoxal space, and a radial groove may appear on each side between the anal and the genital grooves. Coxæ naturally farther apart than in young female owing to repletion.

Hexapode Larva.—0·656 millimetre in length by 0·316 millimetre in breadth, with the caudal end broader than anterior end.

Hosts.—Man, cattle, horses, dogs, rabbits, ground squirrels, and other squirrels.

Distribution.—Montana, Washington State, Colorado, and Idaho

Pathogenicity.—It is the carrier of the virus of Rocky Mountain fever, and also causes Tick Paralysis.

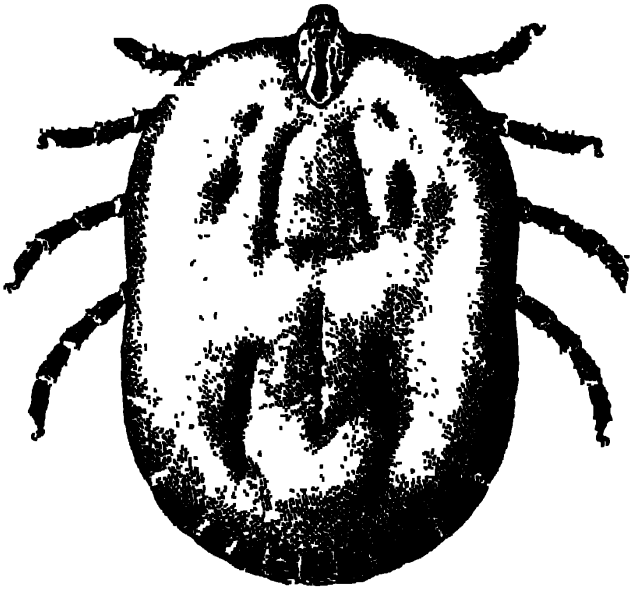

Fig. 329.—*Dermacentor salmoni* Stiles, 1900: Replete Female, Dorsal Aspect.

Hæmaphysalis Koch, 1844 (*vide* Figs. 316-319).

Rhipicephalinæ without eyes, with the base of the capitulum rectangular; twice as broad as long. Palpi triangular or crescentic. Stigmata circular or comma shaped. Anal shields absent. Tegument brownish.

Type. *Hæmaphysalis concinna* Koch, 1844.

Species.—The most important species are: *H. concinna*, *H. leachi*, *H. flavii*, *H. punctata*, the life history of the last named having been studied in detail by Nuttall, Cooper, and Robinson, while according to Stockmann it transmits *Piroplasma ovis*.

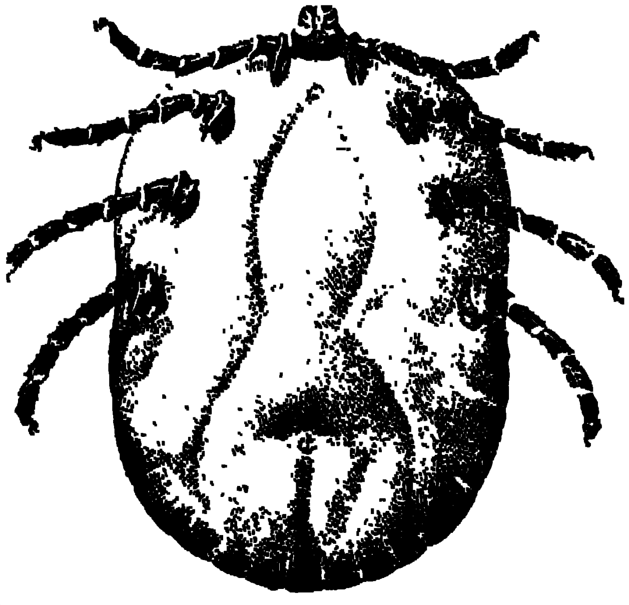

Fig. 330.—*Dermacentor salmoni* Stiles, 1909: Replete Female, Ventral Aspect.

Hæmaphysalis leachi
Audouin, 1827.

Synonyms.—*Ixodes leachi* Audouin, 1827; *Rhipistoma leachi* C. L. Koch, 1844; *Rhipicephalus ellipticum* C. L. Koch, 1844; *Rhipidostoma leachi* Karsch, 1878; *Hæmaphysalis leachi* Neumann, 1897.

This species is found in Africa, Sumatra, and New South Wales. It is the South African dog tick.

The male is 3 by 1·5 millimetres, with yellowish-red scutum, finely punctated dorsum, with eleven marginal festoons. Palpi longer than hypostome. Coxæ of all legs, with a short spine.

The replete female is 9 by 5 millimetres; scutum oval, larger than wide. Second segment of palpi long and spiny.

Life-History.—The larva, after feeding, drops off the dog, and moults. The nymph attacks another dog, feeds, drops off, and moults. The adult attacks a third dog, feeds, drops off, and lays eggs which develop larvæ.

Pathogenicity.—It is the spreader of *Piroplasma canis* among dogs, causing their biliary fever. Nuttall and Hadwen have shown that this canine piroplasmosis can be successfully treated by hypodermic injections of 6 c.c. of a 1 per cent. solution of trypanrot, or 4·5 to 5·5 c.c. of a saturated solution of trypanblau.

SUBFAMILY IXODINÆ.

The following diagnostic table, modified slightly from Salmon and Stiles, will indicate the genera:-

A. Eyes absent:—
  I. Pre-anal crescentic groove opens posteriorly:—
    (*a*) Palpi valvate—*Ixodes* (Fig. 331).
    (*b*) Palpi clavate—*Eschatocephalus*.
  II. Post-anal crescentic groove open anteriorly—*Aponomma*. (Fig. 333).
  III. Without anal groove in the female: one anal shield in the male—*Ceratixodes*.
B. Eyes present:—
  I. Anal plates absent—*Amblyomma* (Fig. 336).
  II. Anal plates present on males—*Hyalomma* (Fig. 339).

Ixodes Latreille, 1796.

Synonyms.—*Cynorhaestes* Hermann, 1804; *Crotonus* Duméril, 1822.

Ixodinæ without eyes, and with long palpi hollowed on the internal surface. Tarsi without terminal spurs. Pre-anal groove open posteriorly.

Male with scutum not covering the lateral and posterior margins: no festoons: stigmata oval. Ventral shields seven in number; one pregenital, one median, two epimeral, one anal, and two adanal.

Female with three dorsal longitudinal grooves and two longitudinal genital grooves ventral, and the anal crescentic groove already mentioned.

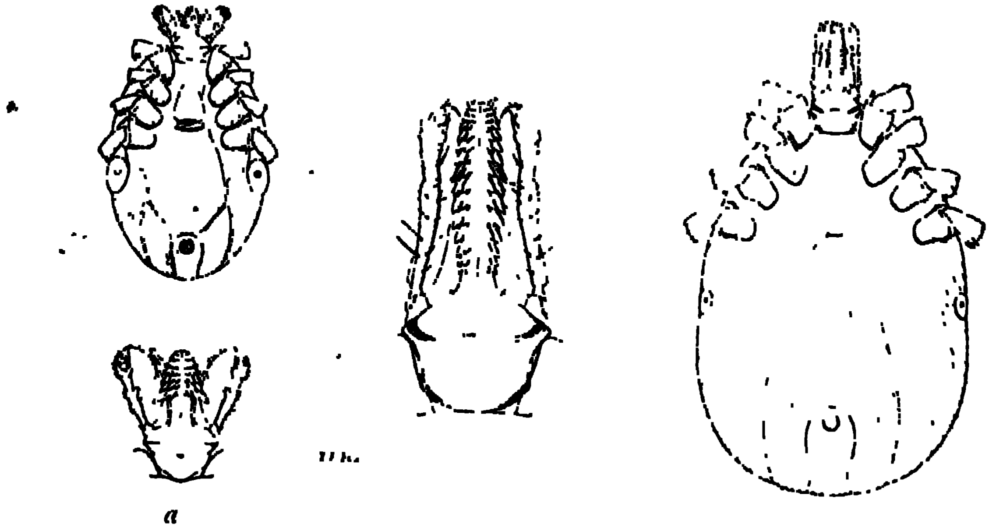
Type Species. *Ixodes ricinus* Linnæus, 1758.

Ixodes ricinus Linnæus, 1758.

Synonyms.—*Acarus reduvius* Linnæus, 1758; *A. ricinus* Linnæus, 1758.

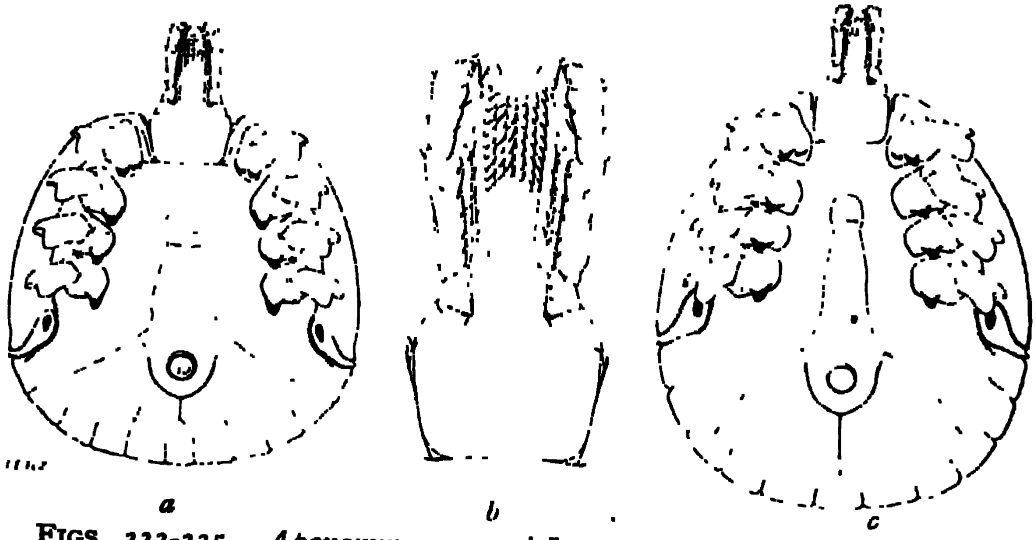
This is the castor-oil tick, and is found in Europe, North Africa, and North America on man, sheep, goats, cattle, horses, dogs, cats, rabbits, bats, birds, etc.

The male has an oval body, broader posteriorly, 2·5 by 1·5 millimetres. Scutum convex, deep red-brown. Genital pore on a plane with the third coxa. Pregenital and anal shields well marked. Capitulum long.



FIGS. 331-332.—*Ixodes pilosus* KOCH, 1844: VENTRAL ASPECT. *a*, Male (× 10) and mouth parts; *b*, mouth parts and female (× 10).

The female, when young, has a flat, oval body. Replete female is like a castor-oil bean, 10 to 11 by 6 to 7 millimetres, of ashy colour. Tegument covered with fine, short hairs. Dorsal surface with three well-marked posterior grooves and two anterior.



FIGS. 333-335.—*Aponomma gervaisi* LUCAS, 1847: VENTRAL ASPECT. *a*, Male (× 15); *b*, mouth parts (more highly magnified); *c*, female (× 15).

Genital pore at the level of the fourth coxæ. Genital grooves unite in front of the vulva. Well-marked pre-anal crescentic groove, open posteriorly. Stigmata whitish. Porose areas elongated transversely. Mandibles with two teeth on the internal apophysis, and external with five teeth.

Life-History.—The female lays about 1,000 eggs in about one to two weeks; the eggs take six weeks to hatch into a larva, which remain one week on the first host and then four weeks on the earth before it becomes a nymph. This stage requires one week on the second host and eight weeks on the earth before it becomes the adult, which seeks the third host, copulates, sucks blood, and drops off to lay eggs.

Pathogenicity.—It acquires *Piroplasma bigeminum* from infected cattle in the adult stage, and spreads it to fresh cattle in the larval and nymphal stages.

Ixodes hexagonus Leach, 1815.

Synonyms.—*Ixodes autumnalis* Leach, 1815; *I. erinacei* Audouin, 1832; *I. reduvius* Audouin, 1832; *I. sexpunctatus* Koch, 1847.

This is the European dog tick.

Pathogenicity.—According to Blanchard, the tick can transmit *Piroplasma canis* Piana and Galli Valerio, 1895.

Eschatocephalus Frauenfeld, 1853.

Synonyms.—*Sarconissus* Kolenati, 1857; *Hæmalastor* Neumann, 1889.

Ixodinæ without eyes, and with a long rostrum. Palpi pyriform in the male and claviform in the female. Pre-anal groove opening posteriorly. Stigmata circular. Legs long.

Male with dorsal and ventral irregular chitinous thickenings.

Female with very fine parallel grooves.

Type Species.—*E. vespertilionis* C. L. Koch, 1844.

There are over seven species found on bats and in caves.

Aponomma Neumann, 1899.

Synonym.—*Ophiodes* Murray, 1877.

Ixodinæ without eyes, and with the base of capitulum usually pentagonal, with dorso-lateral border very short; palpi long. Post-anal groove. Ventral sexual grooves.

Male nearly as broad as long, with a scutum marked with green spots covering the whole dorsal surface.

Female scutum shorter than broad.

Type Species.—*Aponomma gervaisi* Lucas, 1847.

These ticks are found chiefly on reptiles, but are also found on other animals.

Ceratixodes Neumann, 1904.

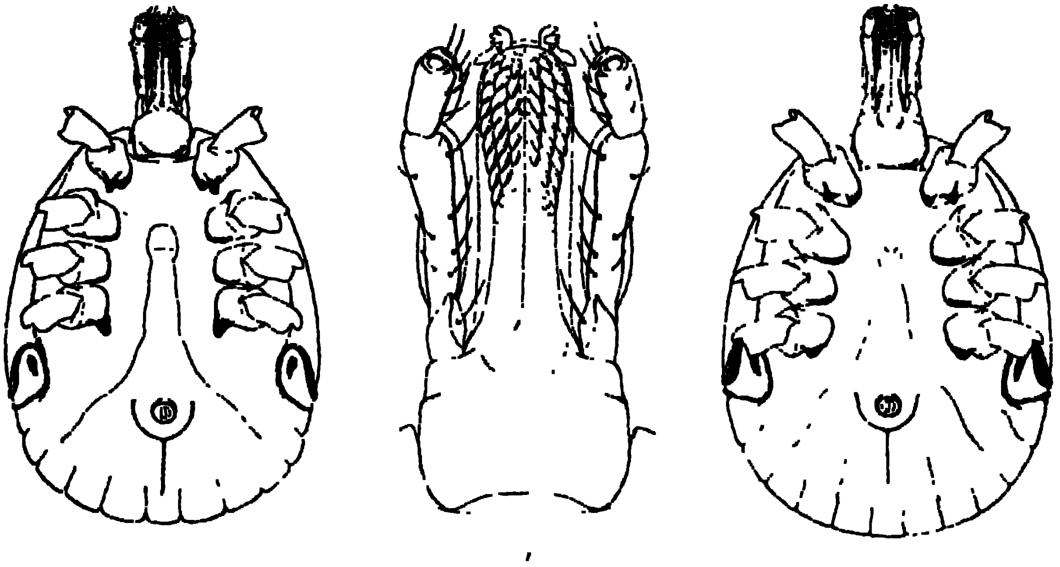
Ixodinæ with long palpi, without eyes, and without anal groove in female. Stigmata circular. One anal and two adanal shields in the male.

Type Species.—*Ceratixodes putus* Cambridge, 1879. It lives on sea-birds, and is found on cliffs, while *C. signatus* Banks, 1908, is known in North America.

Amblyomma Koch, 1844.

Ixodinæ with flat eyes; rostrum long, with valvate palpi. Anal groove semicircular, opening anteriorly. No median ano-marginal groove; no anal plates in the male. Stigmata triangular. Nearly always eleven festoons.

Type Species.—*Amblyomma cajennense* Koch, 1844.



FIGS. 336-338.—*Amblyomma hebræum* C. L. Koch, 1844: VENTRAL ASPECT. *a*, Male (× 7); *b*, mouth parts (more highly magnified); *c*, female (× 7).

Amblyomma hebræum C. L. Koch, 1844.

Synonyms.—*A. annulipes* C. L. Koch, 1844; *Ixodes poortmani* Lucas, 1850; *A. hassalli* Marx and Neumann, 1899.

This tick is found in Africa, especially in Cape Colony, where it is called the 'bont' or variegated tick, and is the spreader of 'heart water' in sheep and goats.

Morphology.—Male (*vide* Fig. 336) with sulphur-yellow-coloured scutum, variegated with brown, and finely punctated and marked with longitudinal grooves. Marginal festoons light-coloured except the two extreme festoons. Female with brown and white scutum, as broad as long; body of a fully replete female, 24 by 15 millimetres.

Life-History.—The usual life-history for Ixodidæ.

Pathogenicity.—Transmits 'heart-water' in sheep

Hyalomma Koch, 1844.

Ixodinæ with eyes, rostrum long, palpi valvate, anal groove semicircular, opening forwards, uniting sexual grooves, and followed by a median ano-marginal groove. Male with two pairs of ventral shields, two adanal and two lateral. Female with triangular stigmata.

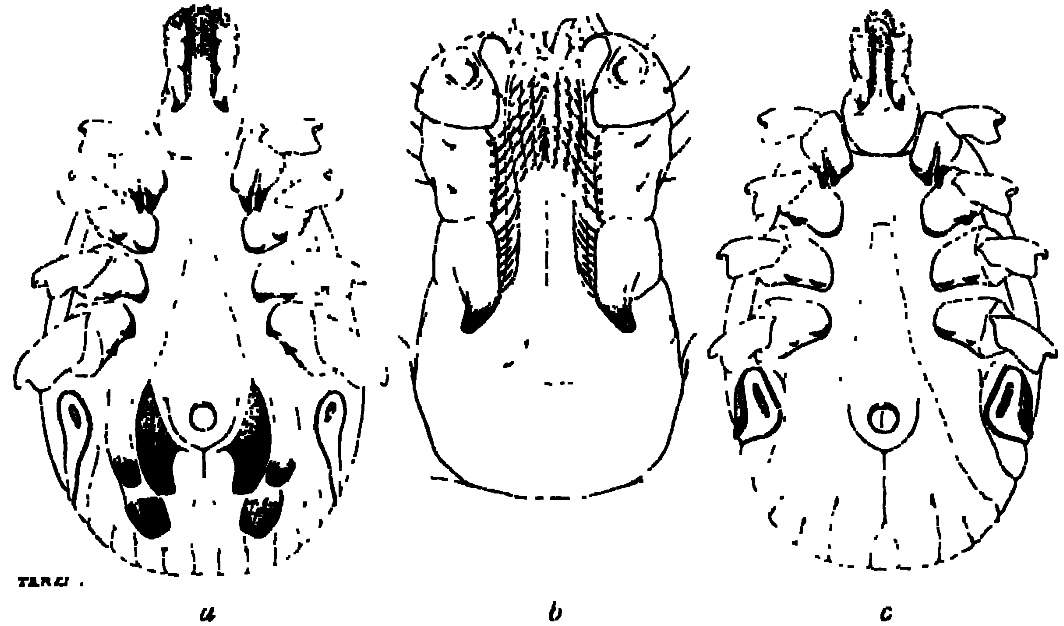
Type Species.—*Hyalomma ægyptium* Linnæus, 1758.

Only a few species:—*H. ægyptium*, *H. crassitarsus*, *H. affine*, *H. syriacum*, *H. rhipicephaloides*, *H. hippopotamense*, *H. monstrosum*.

Hyalomma ægyptium Linnæus, 1758.

Synonyms.—*Acarus ægyptus* L., 1758; *Ixodes camelinus* Fischer, 1823.

This tick is found in Africa, particularly in Egypt and South Africa; in Asia, particularly in Southern India; in Europe, especially in France and Italy. The adults attack cattle, especially sheep and goats, and also at times man. The larvæ and nymphæ are supposed to attack birds, not cattle.



Figs. 339-341.—*Hyalomma ægyptium* Linnæus, 1758 (× 8): Ventral Aspect *a*, Male (× 8); *b*, mouth parts (more highly magnified); *c*, female (× 8).

The male is almost black, with a pale marginal stripe, with a small, triangular, often white, median festoon.

The female is brown, with light blue stripes. Scutum, which as a rule is as broad as long, possesses numerous punctations, and is indentated behind the eyes.

Life-History.—This appears to require further investigation.

Pathogenicity.—Can transmit *Piroplasma bovis* to oxen.

SUBORDER IV. PROSTIGMATA.

The suborder Prostigmata contains two superfamilies, which are of importance in medicine.

Superfamily A: Trombidoidea.—Prostigmata in which the last joint of the palpi is bent down towards the penultimate joint, which usually ends in a claw. Body often with many hairs.

Superfamily B: Eupodoidea.—Prostigmata with simple palpi, in which the last joint of the palpi is not bent down towards the penultimate joint. Body with few hairs.

SUPERFAMILY A: TROMBIDOIDEA.

The Trombidoidea include the following families, which are of importance in medicine:—(1) Trombididæ; (2) Tetranychidæ; (3) Cheyletidæ.

FAMILY TROMBIDIDÆ.

Trombidoidea with soft skins, and chelate mandibles adapted for biting.

There are two important genera which may be differentiated as follows:—

A. Distal segment of palp with single claw—*Trombidium*.
B. Distal segment of palp with two claws—*Microtrombidium*.

Trombidium Latreille, 1795.

The larvæ of this genus are the harvest-mites, and are widely distributed. *Leptus americanus* Riley and *L. irritans* Riley are American species, being found in the United States and Mexico. *Trombidium tlalsahuate* Lemaire, 1867, is the *Tlalsahuate* of Mexico. The zoological names of the 'pou d'agouti' of Guiana, the 'niaibi' of New Granada, the 'colorado' of Cuba, the 'mouqui' of Para, the 'bête rouge' of Martinique and Honduras, are not known. It must be confessed that there is a great deal of uncertainty about the genus and species of these larvæ, and the subject evidently requires revision.

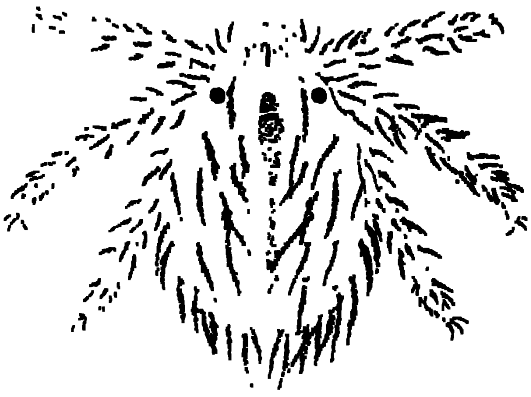


FIG. 312. *Microtrombidium akamushi* BRUMPT, 1910
(After Tanaka from *Centralb. fur Bakteriologie Par und Inf.*)

Morphology.—They are six-legged larvæ with prominent claws on the tips of their legs, provided with a powerful hypostome, which they drive through the skin. Around this hypostome the tissues of the host are supposed to form a tube.

Life-History.—Only the larvæ appear to be parasitic; the adults apparently are not.

Pathogenicity.—They cause itching, redness, and swelling of the affected part, which, if scratched, may become eczematous, and even at times suppurate.

Treatment.—Sulphur ointment kills them.

Genus **Microtrombidium** Haller, 1882.

Definition.—Trombididæ in which the distal segment of the palpus terminates with two stout claws.

Remarks.—These mites are quite common. Thus *Microtrombidium autumnalis* Shaw, 1790, is the harvest bug of England, and is commonly found in the South of England during August and September. It is also common in France during the hot and dry months. Bruyant raised a nymph in 1910 which was thought at first to be *M. pusillum* Hermann, but this is now thought to be doubtful. It is also found in Germany. It generally attacks small mammals such as dogs and cats. *Acarus batatus* Linnæus of Surinam perhaps belongs here. *M. wichmanni* Oudemans is found in New Guinea and Celebes.

Microtrombidium akamushi Brumpt, 1910.

Synonyms.—*Akamushi* (red mite); *Kedani* (hairy mite); *Shashitsu* (sand mite); *Shimamushi* (island mite); *Tsutsugamushi* (dangerous mite); *Yōchūbyō*.

Definition.—*Microtrombidium* of various characters, probably covering several distinct species, with and without all dorsal hairs of the palp feathered. Hair on galea of maxilla always strongly feathered. Hairs on dorsum of palp not feathered, except that on the tibia. Tarsal claw trifurcate. Last tarsus without long fine tactile hair.

Remarks.—The form shown in Fig. 342 may be a distinct species from *M. akamushi*, because all the dorsal hairs on the palp are feathered. This may be called *Microtrombidium brumpti* Hirst, 1915.

These are the mites which cause Japanese river fever, called *tsutsugamushi fever*.

Morphology.—The larva is orange red in colour, 0·16-0·24 millimetre in length, by 0·10-0·21 millimetre in breadth. The palpi are leg-like, and the body and legs are very hirsute.

The *scutum* is oblong, not wide, with straight posterior margin and usually seven hairs. The pseudostigmata are nearer the posterior than the anterior margin.

Eyes are well developed.

Dorsal hairs are 2, 8, 6, 8-10, 8, with a few posterior hairs.

The first coxa has two hairs. The hair on the galea of the maxilla is strongly feathered, while those on the dorsal surface of the palp are plain, except the one on the tibia, which is feathered. Tarsus with seven feathered hairs and a blunt rod-like hair. Legs slender and moderately long, with strongly feathered hairs.

Life-History.—*The akamushi* does not attack insects nor spiders, but will attach itself to man and to small mammals—monkey, dog, cat, rat, mouse, rabbit, and guinea-pig.

The mite remains on its host for three to four days, during which it swells up and turns pale. It then drops off and finds shelter under the ground, where a metamorphosis takes place in some five to six days, during which a nymph forms under the larval skin, and from which it escapes.

The newly hatched nymph, 0·4-0·57 × 0·25-0·285 mm., is a minute eight-legged creature, which, though it crawls about, is neither parasitic nor predaceous, but it feeds upon the juice of potatoes, melons, and other vegetables. After some growth the nymphs seek shelter under the earth and become pupæ.

The pupa is formed from the elongated body of the nymph, inside which the adult form develops, and which in a few days emerges.

The imago is at first without sexual organs, which begin to develop. Meanwhile the adult grows and undergoes more than one ecdysis, and in about ten weeks arrives at sexual maturity.

The eggs are laid singly in earth, but oviposition has not been observed, and the earliest egg known is the deutovum, 0·21-0·24 × 0·17-0·22 mm., inside which the chorion, having split the pale vitelline membrane, could be seen containing the red akamushi, which hatched out after three weeks' incubation.

Microtrombidium wichmanni Oudemans, 1905

Its larva attacks man and animals in Celebes.

Microtrombidium vandersandei Oudemans, 1905.

Synonym.—*Microtrombidium* Van der Sander.

The larva of this Trombidium occurs in New Guinea, and attacks man and animals. Its local name is 'Gonone.'

Metatrombidium Oudemans, 1909.

Metatrombidium poriceps Heim and Oudemans, 1904, has been found on fowls, dogs, and men.

FAMILY TETRANYCHIDÆ.

Trombidoidea with first and second pairs of legs without spines; skin with few shields; palpi not much thickened on base, moving vertically; eyes usually present. First pair of legs do not end in long hairs. Coxæ more or less in two groups. Body with fewer longer hairs. No dorsal groove; often spinning threads; tarsi never swollen. Mandibles styliform.

Genus Tetranychus Dufour.

Definition.—Tetranychidæ without cephalothoracic tubercles. Few legs, slightly longer than body, which is not twice as long as broad. Legs slender. Integument not tessellated dorsally. Palpi ending in a distinct thumb.

Tetranychus molestissimus Weyenbergh, 1886.

This mite is found in the Argentine and Uruguay. It is small and of red colour, living in a web on the interior surface of the leaves of *Xanthium macrocarpum*. From December to February it attacks mammals and man, thrusting its hypostome into the skin and causing severe itching. Another species—*T. telarius* (var. *russeolus*) L., 1758—may attack human beings.

FAMILY CHEYLETIDÆ.

Trombidoidea without spinous processes on the legs; skin with few if any shields; palpi much thickened at the base, moving laterally; last joint often with two pectinate bristles without eyes. First leg ending in several long hairs.

Cheyletus Latreille, 1796.

These are very small mites, distinguished by having enormous palpi, with pectinate bristles. *Cheyletus eruditus* has been described in the external auditory meatus of a man.

Acaropsis Moquin-Tandon, 1863.

Acaropsis mericourti Laboulbène has been found in the human external auditory meatus.

SUPERFAMILY B. EUPOPOIDEA.

FAMILY BDELLIDÆ.

No specialized seta on cephalothorax; integument not chitinized or leathery; palpi composed of four or five segments; cephalothorax large and clearly separated from abdomen; palpi large, geniculate, and bearing distally long tactile bristles; mandibles chelate

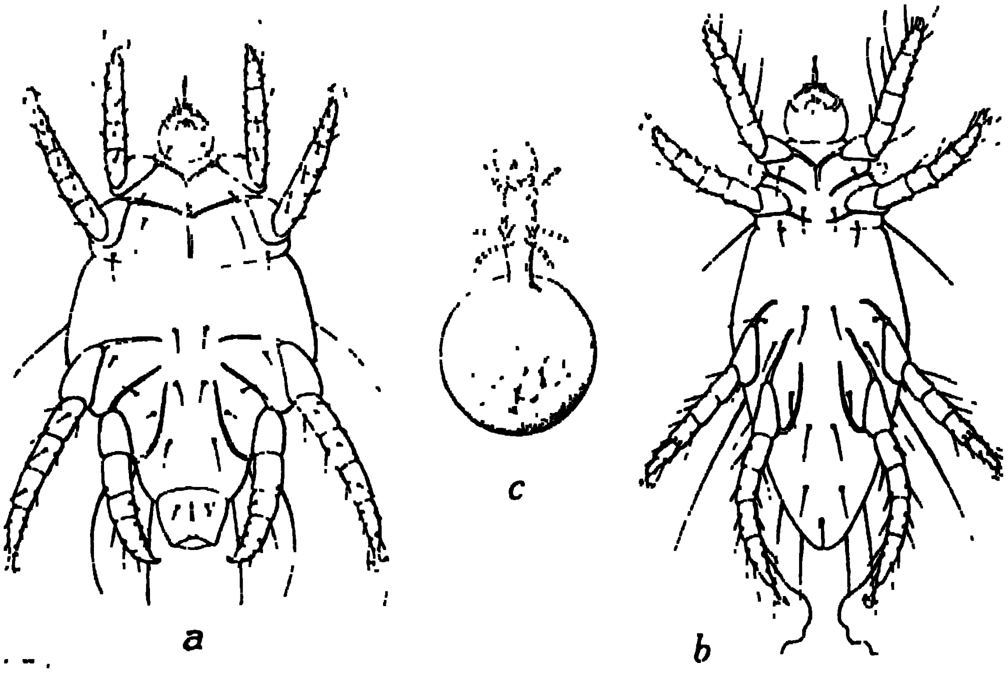
Tydeus molestus Moniez, 1889.

This mite was imported into Belgium in Peruvian guano, and caused much trouble to man and beast.

FAMILY TARSONEMIDÆ.

With marked sexual dimorphism and tracheæ. No ventral suckers.

Tarsonemus hominis Dahl found in cancerous tissues in man, is probably an accidental contamination of the preserving fluids.



FIGS. 343-345. *Pediculoides ventricosus* NEWPORT.
a, Male (× 350); *b*, female (× 220); *c*, distended female (× 60).

Genus Pediculoides Targioni-Tozzetti.

Pediculoides ventricosus Newport, 1850.

Synonyms.—*Heteropus ventricosus* Newport, 1850; *Acarus tritici* Lagrèze-Fossot and Montané, 1851; *Physogaster larvarum* Lichtenstein, 1868; *Pediculoides tritici* Targioni-Tozzetti, 1878; *Sphærogyna ventricosa* Laboulbène and Mégnin, 1885; *Tarsonemus monounguiculosus*.

This mite causes severe itching and urticarial eruptions on the breast, arms, face, neck, and shoulders of persons handling corn and barley, which contains it, in India, Algeria, and Europe.

Morphology.—Males are oval, 0·12 by 0·08 millimetre, with six pairs of dorsal hairs and a lyre-shaped lamella.

Female cylindrical, 0·2 by 0·07 millimetre; becomes much distended posteriorly when gravid.

Life-History.—They live on the stalks of cereals, and feed on animal and vegetal juices. The adult hatches directly from the egg.

Pathogenicity.—They cause diffuse erythema, urticaria, and itching.

Nephrophages Miyake and Scriba, 1893.

Nephrophages sanguinarius Miyake and Scriba, 1893. It is a very doubtful parasite of man; it was found in bloody urine passed by a man in Japan.

SUBORDER V. ASTIGMATA.

This suborder includes the superfamily Sarcoptoidea.

SUPERFAMILY SARCOPTOIDEA.

Astigmata with small three-pointed palpi adhering for some distance to the hypostome, with usually ventral suckers. Two families concern us (1) Tyroglyphidæ, (2) Sarcoptidæ

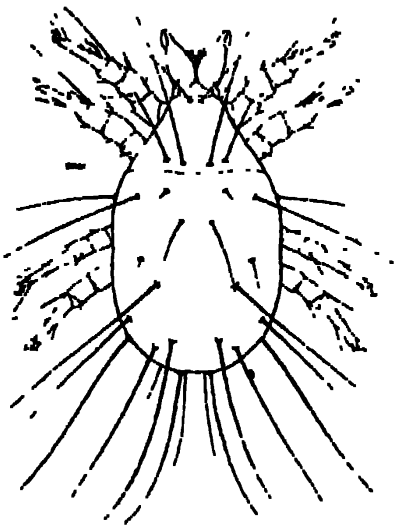


Fig. 346.—*Tyroglyphus longior* var. *castellanii* Hirst 1912: Dorsal Aspect.

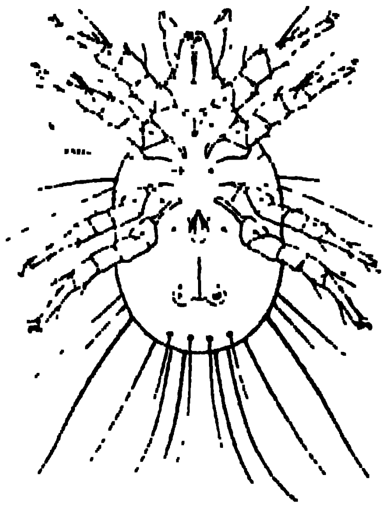

Fig. 347. *Tyroglyphus longior* var. *castellanii* Hirst 1912: Ventral Aspect.

Family 1: Tyroglyphidæ.

Very small mites without eyes; only accidental parasites being found in flour, sugar, cheese, etc.

Tyroglyphus Latreille, 1796.—With smooth dorsum; cephalothorax with four long bristles and no stout spines on tarsi; with claws and suckers. *Aleurobius farinæ* (De Geer) in corn may get into the skin They are the cause of so-called vanillismus. According to Theobald, Linnæus reported a case of dysentery as being due to this species (*Acarus dysenteriæ*).

Tyroglyphus siro Linnæus, 1758, is supposed to be the cause of vanillismus, and *T. longior* Gervais, 1844, is found accidentally in fæces, urine, or pus

T. longior var. *castellanii* Hirst, 1912, was found by Castellani in copra and on people affected by copra itch in Ceylon. In this variety, in contrast to *T. longior*, there is no pair of short hairs on the ventral surface, behind the anal suckers.

Glyciphagus Hering, 1838.—With dorsum covered with hairs

G. prunorum Hermann (synonym, *G. domesticus* de Geer, 1808) is the cause of grocer's itch.

Rhizoglyphus Claparède, 1869—*R. parasiticus* Dalgetty, 1901.—With short legs, armed with spines. Tarsi end in a claw. Live on plants.

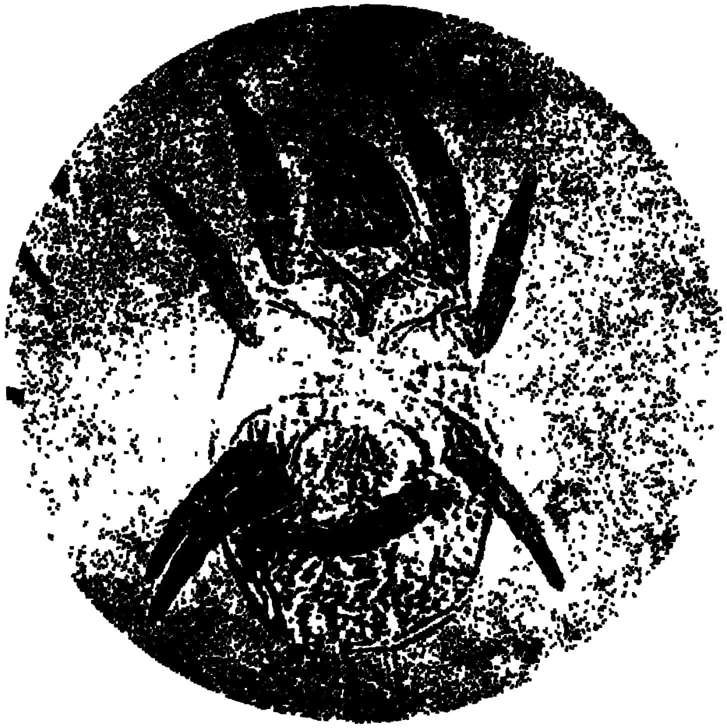

FIG. 348.—*Rhizoglyphus parasiticus* DALGETTY, 1901.
(From a photograph by J. J. Bell.)

This is the species which causes trouble in the feet of Indian coolies. Bell described a large circular, superficial sore on the sole of the foot, caused by many of these parasites invading the skin (see Chapter XCVI.).

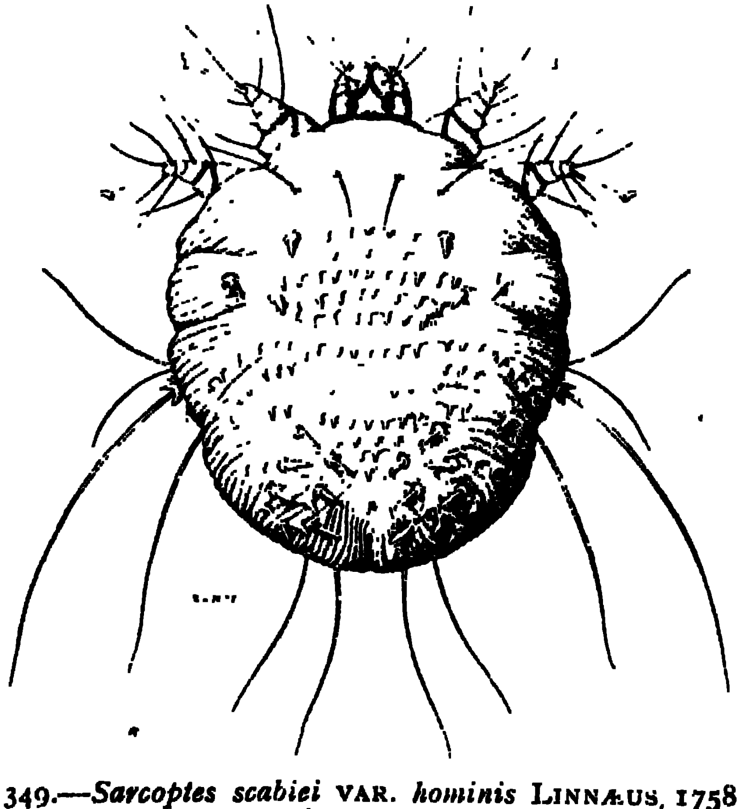

FIG. 349.—***Sarcoptes scabiei*** VAR. ***hominis*** LINNÆUS, 1758: FEMALE
(× 125.)

Histiogaster Berlese, 1883—*H. spermaticus* Trouessart, 1900.—This mite, which feeds on vegetables, appears to have been introduced into a patient by means of a catheter, and to have formed a cyst in the testis in a man in India.

Carpoglyphus Robin, 1869.—*C. alienus* Banks has been found in purulent urine passed by a man. Probably it was a contamination.

FAMILY 2: SARCOPTIDÆ.

Sarcoptoidea without genital suckers, without clinging apparatus, with transverse vulva. Lines in skin.

Sarcoptes Latreille, 1806.—Sarcoptidæ with round or slightly oval bodies; posterior two pairs of legs concealed beneath the body; tarsi end in simple long pedicles with ambulatory suckers.

Sarcoptes scabiei var. hominis Linnæus, 1758.—Female lives in furrows in the epidermis, in which it lays its eggs. Posterior legs end in spines. Males occur on the surface and die after copulation. Posterior legs end in suckers. Six-legged larva hatches in four to eight days.

Sarcoptes minor Furstenberg, 1861.—Usually a parasite of cats; has been found on man.

Sarcoptidæ as Internal Parasites. Sarcoptidæ have been described by Newstead and Todd as internal parasites in monkeys. An Acarid-like parasite was found by Castellani in the omentum of a negro in Uganda. This parasite somewhat resembled *Cytoleichus sarcoptoides* Heguin, which lives in the air sacs, and at times the liver and kidneys, of fowls.

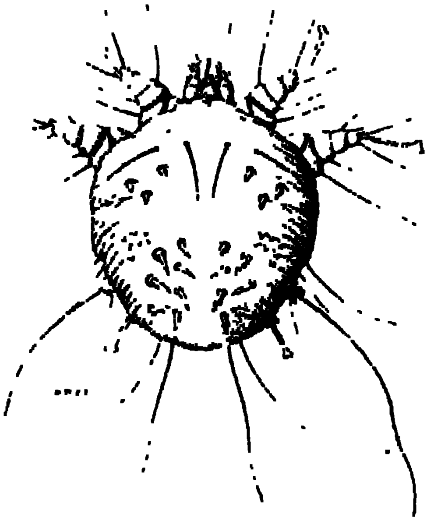

FIG. 350.—*Sarcoptes scabiei* VAR. *hominis* LINNÆUS, 1758: MALE. (× 125.)

Notœdres Railliet, 1893—*N. cati* Railliet, 1893.—Cause of the itch in the cat, and transmissible to man.

Cytoleichus sarcoptoides Mégnin.—Synonym *Cytodites nudus* (Vizioli, 1868), in fowls in the Sudan.

Cytoleichus hominis Hirst, 1917. Found by Castellani, in 1902, embedded in the fat of the omentum of a negro in Uganda.

Chorioptes bovis Gerlach and **Psoroptes equi** Gervais are stated by Zürn and Hirst to attack man.

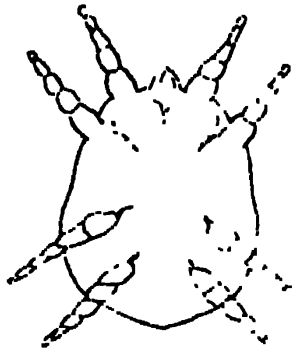

FIG. 351.—*Cytoleichus hominis* HIRST, 1917.

SUBORDER VI. VERMIFORMIA.

Very minute Acarina, with abdomen elongated and annulated without tracheæ and with epimeres on the legs.

This suborder contains only one family.

FAMILY DEMODICIDÆ.

Vermiformia with eight legs, living on animals. This family includes only one genus—*Demodex* Owen, 1843.

Demodex Owen, 1843.

With the family characters. This genus has been recently revised by Hirst. The species of *Demodex* live in the sebaceous glands and hair-follicles of mammals and man. The mouth consists of a rostrum, which is arranged for sucking. The palpi are three-jointed, and pressed to the under surface of the rostrum. The legs are eight in number, short, and consist of three segments with small terminal ungues. The abdomen is tapering, striated dorsally and ventrally, and rounded at the tip. The anus is situated at the anterior end of the abdomen

Demodex folliculorum Simon, 1842.

Synonyms.—*Acarus folliculorum* Simon, 1842; *D. folliculorum* Owen, 1843; *Macrogaster platypus* Miescher, 1843; *Simonea folliculorum* P. Gervais, 1844; *Steatozoon folliculorum* Wilson, 1847.

This parasite was first discovered by G. Simon, of Berlin, in 1842, in the contents of pustules of *Acne sebacea*.

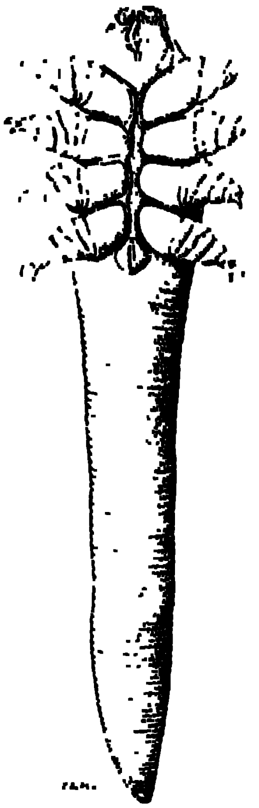

FIG. 352.—*Demodex folliculorum* Simon 1842. (× 150) (Partly after Berlese.)

About the same time Henle had found them in hair-follicles in the external auditory meatus, and Topping a variety in the dog. Two other species are known: *D. phylloides* Cook in pigs and *D. bovis* Stiles in cattle. *D. folliculorum hominis* is cosmopolitan, living in the sebaceous follicles of the face.

Male measures 300 μ by 40 μ, and the female 380 μ by 45 μ.

Life-History.—The eggs are 60 to 90 μ in length by 20 to 50 μ in breadth, and heart-shaped or fusiform. The egg hatches out a six-legged larva, which develops into an eight-legged nymph, from which the adult appears.

Pathogenicity.—Usually said to be nil, but a few authorities suspect the parasites to produce acne-like eruptions, and Borrel considers they play a part in the spread of cancer and leprosy.

ARACHNIDÆ INCERTÆ SEDIS.

LINGUATULIDA.

Parasitic Arachnoidea with ringed, elongated, vermiform bodies, possessing two pairs of hooks in the neighbourhood of the jawless mouth.

Remarks.—The *Linguatulida* have been found parasitic in man both in the adult and larval conditions, but the adult is much rarer than the larva. They have been found in Europe and Africa, and reported from the West Indies, but this was in a negro from West Africa. It is not impossible that they will be found to be far from uncommon parasites when the medical history of the West Coast of Africa is better known. When dealing with cases showing obscure abdominal or pulmonary symptoms in that part of the world, the medical man should remember these parasites.

Morphology.—The body is white in colour and vermiform in appearance, and, indeed, they were long mistaken for worms.

It is elongated, flattened, or cylindrical, and marked by a variable number of rings, and is usually divisible into two regions—an anterior broader portion called the cephalothorax, and a posterior, more attenuated, called the abdomen. It is covered with a chitinous cuticle pierced by pores, called stigmata, which have nothing to do with respiration, being merely the orifices of epidermal glands.

The mouth is situated anteriorly, and is either terminal or subterminal, with a chitinous ring. Two pairs of chitinous hooks, retractile into grooves, are situate on either side of the mouth, and are looked upon by Stiles as antennæ and palpi. There are no legs. The anus is terminal at the posterior end of the abdomen, with the female aperture situate just in front. The male generative pore is on the ventral surface, near the anterior end of the abdomen. The sexes are distinct. The mouth leads into a simple straight alimentary canal, which ends in the anus. There are no circulatory or respiratory organs. The nervous system consists of a ventral mass and a circumœsophageal commissure.

Life-History.—The female produces eggs, which, escaping from the definitive host, pass into the intermediary host, and there hatch out a four-legged larva, not unlike an embyro *Acarus*. This embryo undergoes complete metamorphosis, and forms a nymph resembling the adult, which does not, as a rule, mature, until it reaches its definitive host again.

Genera. —*Linguatula* Frölich, 1789; *Porocephalus* Humboldt, 1811; *Reighardia* Ward, 1899; and *Raillietiella* Sambon, 1909; but only the first two contain species parasitic in man.

Linguatula Frolich, 1789.

Linguatulida with depressed body, rounded dorsum, and crenate margins. Body cavity forming diverticuli into the lateral parts of the rings.

Species.—*Linguatula serrata* Frölich, 1879.

Linguatula serrata Frölich, 1789.

Synonyms. —*Tænia rhinaria* Pilger, 1802; *Polystoma tænioides* Rudolphi, 1810; *Linguatula tænioides* Lambinet, 1816; *Pentastoma tænioides* Rudolphi, 1819. **Nymph.**—*Pentastoma denticulatum*.

The adult lives in the nasal cavity and frontal sinus of the dog, wolf, fox, and rarely in the horse, mule, sheep, goat, and man in Europe; while the larva exists in sheep, oxen, horses, rarely in cats and dogs. Its real host appears to be the dog, especially sheep-dogs.

Habitat.—Europe, especially Central France.

Morphology.—The male is white in colour, 18 to 20 millimetres in length, and 3 millimetres broad. The female is greyish-white or brownish, owing to the contained ova.

Life-History.—The eggs, which are ovoid, 90 by 70 μ, are laid in the nasal cavities of the dog, and expelled by sneezing. If they fall on grass, they may enter the alimentary canal of a herbivorous animal, in whose intestine the embryo hatches. This embryo measures 130 by 60 μ, and possesses two pairs of legs and an anterior perforating apparatus composed of a stylet and two hooks.

It now bores its way into the liver, lungs, or some other organ, and in about eight weeks becomes encysted, losing all its appendages and measuring 275 by 180 μ.

A succession of ecdyses results in the formation of the nymph, which resembles the adult, except that it possesses numerous chitinous spicules on its skin, and by the sixth to the seventh month is about 6 to 8 millimetres in length.

These nymphæ now wander about the host, and are supposed to reach the bronchi, and thus to leave the herbivorous host and reach the dog either by the nose or mouth, in the nasal cavities of which they moult and become sexually mature, copulating about the sixth to seventh week after infection.

Pathogenicity.—Both the larva and the adult may be found in man, the former in the lung, rarely in the liver, spleen, or intestinal wall. The latter has but rarely been met with, and then appears to be due to embryos wandering into the nose and developing directly. Hitherto it has only been found in man in Europe and Central America.

Porocephalus Humboldt, 1811.

Linguatulida with cylindrical body and continuous cœlom.

Type Species.—*Porocephalus armillatus* Wyman, 1847.

Species.—There are about twenty known species, of which *P. armillatus* and *P. moniliformis* are known to occur in man, and will be described below, but Sambon suspects that *P. crotali*, *P. clavatus*, *P. stilesi*, and *P. najæ* will probably also be found in man as scientific work in parasitology extends.

Pathogenicity.—They cause porocephalosis in man and animals.

Porocephalus armillatus Wyman, 1847.

Synonyms—Adult.—*Linguatulida armillata* Wyman, 1847; *Pentastomum polyzonum* Harley, 1856; *Porocephalus moniliformis* Neumann, 1899, *pro parte*. **Nymph.** *Pentastomum diesingi* Beneden, 1849; *P. euryzonum* Diesing, 1850; *P. leonis* Weddell, 1863; *P. constrictum* von Siebold, 1852; *P. protelis* Hoyle, 1883; *Linguatulida constricta* Küchenmeister, 1855.

Porocephalus with cylindrical body, slightly flattened on its anterior face, and surrounded by about sixteen to twenty-two distinct rings, separated from one another by a wide interval. The body tapers from the middle backwards.

Remarks.—The larva of this parasite was discovered by Pruner in the liver of two negroes in Cairo in 1847, and subsequently by Bilharz, Fenger, Kearney, Crawford, Marchoux, Chalmers, and others; while the adult was discovered by Wyman in 1848 in the lungs of the African python. The adult was discovered by Savage in *Python sebæ* and described by Wyman in 1845. Sambon has recently studied both adult and larva.

The adult lives in African pythons and snakes (*Python sebæ*, *P. regius*, *Bitis nasicornis*, and *B. arietans*). The larval forms usually occur in *Proteles cristatus*, *Cynocephalus maimon*, and other monkeys; in *Erinaceus æthiopicus*, the African hedgehog; and in *Felis leo*, the lion.

Morphology.—Female 9 to 12 centimétres in length and 5 to 9 millimetres in breadth, with eighteen to twenty-two rings, each 1 to 2 millimetres in width. The cephalothorax extends from the anterior end of the body to the first body-ring, which is often very indistinct. Dorsally this region is convex, while ventrally it is concave, and carries the mouth, in front of which there are two papillæ, and on either side of which there are two hooks. Genital opening about 1 millimetre in front of the anus, which is terminal. Male 3 to 4·5 centimetres in length and 3 to 4 millimetres in breadth, with sixteen to seventeen rings. Genital opening in the middle of the ventral surface at the anterior end of the abdomen.

FIG. 353.—*Porocephalus armillatus* WYMAN: MALE, NATURAL SIZE.

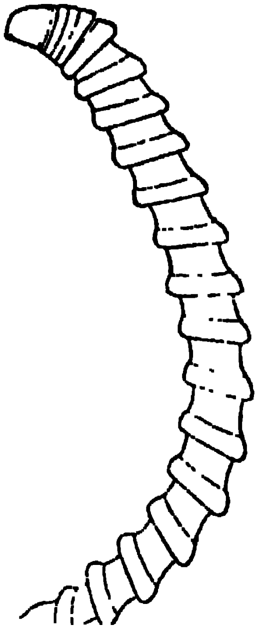

FIG. 354.—*Porocephalus armillatus* WYMAN: FEMALE, NATURAL SIZE.

(After Sambon.)

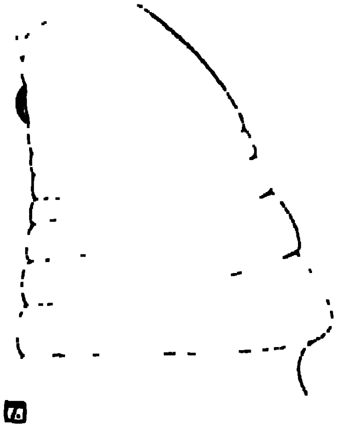

FIG. 355.—LATERAL ASPECT OF THE CEPHALOTHORAX OF *Porocephalus armillatus* WYMAN. (× 5.)

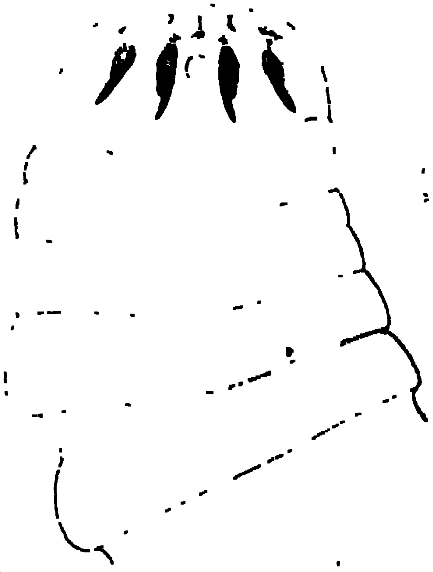

FIG. 356.—VENTRAL ASPECT OF THE CEPHALOTHORAX OF *Porocephalus armillatus* WYMAN. (× 5.)

(After Sambon.)

Life-History.—Probably this resembles that of *Linguatula serrata*, with the difference of hosts. In man the nymphæ are found not merely encysted in the lungs and liver, but moving freely through the peritoneal cavity and in the small intestine. Sambon considers that the eggs pass from the snake into water, and thence into animals and man while drinking, and become larvæ and nymphæ, which later gain access to the snake when the host is killed and eaten.

FIG. 357.—POSTERIOR END OF *Porocephalus armillatus* WYMAN. (× 5.) (After Sambon.)

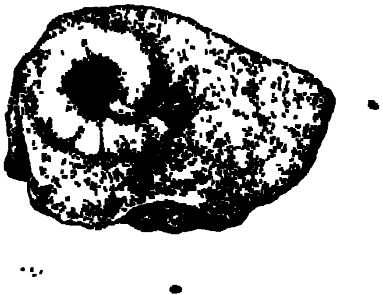

FIG. 358.—NYMPH OF *Porocephalus armillatus* WYMAN, ENCYSTED IN THE LIVER. (After Sambon, from our West African case.)

Pathogenicity.—This will be described later (Chapter LXXXIII.).

Porocephalus moniliformis Diesing, 1836.

Synonyms.—Adult.—*Pentastoma moniliforme* Diesing, 1835; *P. moniliforme* Leuckart, 1860; *Linguatula moniliforme* Mégnin, 1880; *Porocephalus moniliformis* Stiles, 1893. **Nymph.**—*Pentastomum tornatum* Creplin, 1849, *pro parte*; *P. aonycis* Macalister, 1874; *Porocephalus armillatus* Stiles, *pro parte*.

Porocephalus with twenty-six to thirty-one rings.

Remarks.—This parasite, which was discovered by Czermak in the lung of *Python molurus* Linnæus in 1828, and was first described by Diesing in 1835, has been carefully studied by Sambon, who remarks that it so strikingly resembles *P. armillatus* in general appearance and structure that at first sight it may be easily mistaken for it.

Morphology.—It is more slender, tapers more caudad; with twenty-six rings in the male and twenty-eight to thirty-one rings in the female. In fresh specimens it is bright lemon yellow in colour, with genital opening on the mid-ventral surface of the first body-ring in the male, and on the mid-ventral surface of the terminal body-cone 1 millimetre in front of the anus in the female. The anus is terminal.

Life-History.—The life-history is unknown.

Hosts.—The hosts of the adult are *Python molurus* Linnæus (the Indian python), *Python reticulatus* Schneider (the reticulated python), in which it lives in the lungs; while the hosts of the nymph are man, monkeys, tigers, leopards (?), civets, otters, and dogs (?).

Distribution.—India, Indo China, Southern China, the Philippines, Sumatra, Java.

Pathogenicity.—So far only two cases have been recorded in man—one at Djambi in Sumatra in 1906, when a nymph was found encysted beneath the serous coat of the small intestine of a Djambi native who died of dysentery, and the other was found in the liver of a native Filippino who died of tuberculosis. The liver in this latter case showed signs of atrophic cirrhosis.

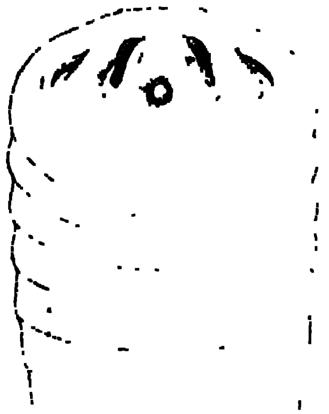

FIG. 359.—VENTRAL ASPECT OF THE CEPHALOTHORAX OF *Porocephalus moniliformis* DIESING, 1836. (× 5.)

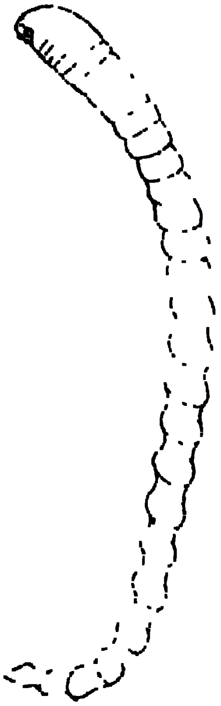

FIG. 360.—*Porocephalus moniliformis* DIESING, 1836: FEMALE, NATURAL SIZE.

(After Sambon.)

Species imperfectly described in Man.

In addition to the well-known cases of porocephalosis due to *Porocephalus armillatus* and *P. moniliformis*, there are the following cases to be discussed—viz., Welch's parasite, Osler's parasite, and Flint's parasite. Osler's parasite is considered to be doubtful, as it was passed *per urethram*, and might, according to Sambon, have been a sparganum.

Welch's Parasite.

In the *Lancet* of November 16, 1872, F. H. Welch had an article on 'The Presence of an Encysted Echinorhynchus in Man.' This parasite was damaged in extraction, and his drawing was not very instructive, but was sufficient to convince Cobbold, R. Blanchard, and Sambon that it represented a Linguatulid, and it shows two sets of hooks. The last-named observer comes to the conclusion that it may be either a very early nymph of *Porocephalus moniliformis* (provided with caducous accessory hooks), or it may be *P. najæ* Leuckart, 1860 (which is found in the abdominal muscles and peritoneum of the cobra), or *P. crociduræ* Parona, 1890 (found in *Crocidura fuliginosa*, a musk-shrew), or it may be a new species.

Porocephalus najæ Leuckart, 1860.

Synonym.—*P. najæ sputatricis* Leuckart, 1860.

Morphology.—Body imperfectly cylindrical, with about fifty rings. Length, 4·5 millimetres long by 0·6 millimetre broad.

Distribution.—Found in cysts in the abdominal muscles and peritoneum of the cobra.

Flint's Parasite.

Flint described the parasite at a meeting of the New York Pathological Society on December 12, 1876, as occurring in a man from Albany, Gentry County, Montana. This man had cavities in his lungs, and coughed up 75 to 100 parasites, which could crawl about the floor and could live for ten days in a bottle: moreover, they could resist freezing.

With regard to these parasites, which at the time were considered to be *Porocephalus armillatus* (*i.e.*, *Pentastomum constrictum*), Sambon points out that, if genuine Linguatulida, they can hardly belong to an African species, as the case occurred in America, and therefore he is inclined to believe that they must belong to *P. crotali* Humboldt, 1808, which are found as adults in *Crotalus adamanteus* Beauvois, *C. horridus* Linnæus, and *C. terrificus* Laurent, while the nymphæ have been found in *Marmosa murina* Linnæus, the murine opossum.

Porocephalus crotali Humboldt, 1808.

Synonyms.—*Echinorhynchus crotali* Humboldt, 1808: *Distoma crotali* Humboldt, 1808: *Distoma crotali durissi* Rudolphi, 1809: *Porocephalus crotali* Humboldt, 1811: *Polystoma proboscideum* Rudolphi, 1814: *Pentastoma proboscideum* Rudolphi, 1819; *Linguatula proboscidea* van Beneden, 1849, *pro parte*: *Porocephalus humboldti* Mayer, 1852: *Linguatula quadriuncinata* Mayer, 1852; *Porocephalus moniliformis* Mégnin, 1880, *pro parte*. **Nymph.**—*Pentastoma subcylindricum* Diesing, 1836.

Remarks.—This porocephalus was discovered by Humboldt in the lungs of the tropical rattlesnake.

Morphology.—When fresh, it is of a bright yellowish colour, with elongate, incurved, cylindrical body, somewhat flattened ventrally and club-shaped anteriorly, and is transversely encircled by over eighty flat bands. It is said to have an ovoid-shaped mouth on a line with the hooks, and two prominent papillæ.

Distribution.—It is thought to be coextensive in its distribution with the genus *Crotalus*—*i.e.*, the United States, Mexico, and Brazil.

Pathogenicity.—Possibly it is the cause of one form of porocephalosis in man.

CLASS IV. CRUSTACEA LAMARCK, 1815.

Aquatic Arthropoda which breathe by means of gills.

Crustaceans can hardly be considered as human parasites, for they have very rarely occurred as such—*e.g.*, *Caligus curtus* in the cornea, and *Gammarus pulex* in the stomach.

ORDER COPEPODA Latreille, 1831.

It must, however, be remembered that the Copepoda are of importance, because a species of *Cyclops* has been found to be the intermediary host of *Dracunculus medinensis* the guinea-worm. An excellent paper on the species found on the Gold Coast is contributed by Graham to vol. i. of the 'Annals of Tropical Medicine and Parasitology.' The Cyclops live in fresh water in any ditch, pond, or well

Prophylaxis.—It is recommended to treat a well with sufficient quicklime to render the water suddenly hot in order to kill these crustaceans. The well must, of course, be closed for some time after this proceeding, until the percentage of lime has diminished to reasonable proportions. A simpler remedy is to boil all water before drinking It has been also suggested to add 1 pound of caustic soda to 180 gallons of water 0·07 per cent. for the same purpose. Leiper's recommendation is, however, the best, and this is to raise the temperature of the well water to 65° C by blowing in steam, as he finds that all Cyclops die if the water is raised to 65° C. He calculates that it requires 87 gallons of water as steam to raise 1,000 gallons of water from 15° to 65° C., and that this requires 1 pound of coal or its equivalent in oil per gallon of water, and that for every square foot of grate 15 pounds of coal can be burnt per hour, so that if the grate is 1 square foot it will require 5·8 hours to raise 87 gallons of water as steam *i.e.*, 12 square feet of grate give 90 gallons of water as steam in half an hour.

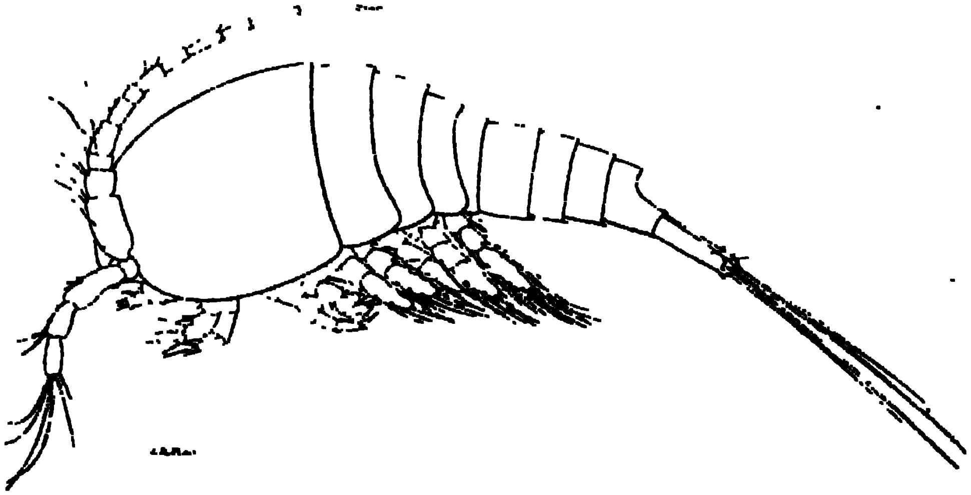

FIG. 301. CYCLOPS SP. (?).

CLASS V. CHILOPODA LATREILLE, 1837.

Arthropoda with three prosthomeres. The first post-oral somite is the mandibular; the second and third post-oral somites carry the maxillæ, while the fourth has its appendages converted into very large powerful jaws, which are provided with poison-glands. The remaining somites carry single-clawed

walking-legs, one pair to each somite. Body anomomeristic, showing from 17 to 175 somites behind that which carries the poison glands. They breathe by tracheæ, and the genital ducts open on the penultimate somites.

Family 1: Scolopendridæ.
Family 2: Lithobiidæ.
Family 3: Scutigeridæ.

Family 1: Scolopendridæ Leach, 1812.

Chilopoda with antennæ, possessing few joints, and with few ocelli.

Geophilus carpophagus Leach, *G. electricus* Linnæus, *G. cephalicus* Wood, *G. similis* Leach, have been found as accidental parasites about nineteen times in the nasal cavities and their neighbouring sinuses in man in Europe. *G. electricus* Linnæus has been found in the alimentary canal about four times.

Family 2. Lithobiidæ Newport 1844.

Chilopoda with many-jointed antennæ, numerous ocelli.

Lithobius forficatus L. and *L. melanops* have been found in the nasal cavities in three cases in man.

Family 3. Scutigeridæ Gervais, 1837.

Chilopoda with antennæ at least as long as the body and faceted eyes instead of ocelli.

Scutigera coleoptrata has been found in the alimentary canal.

Other species found in the alimentary canal are: *Chætechelyne vesuviana* Newport (found also in the nasal cavities), *Himantarium gervaisi*, *Stigmatogaster subterraneus*.

Pathogenicity.— In the nose these parasites cause inflammation with, at times, no flow of mucus, and at others a large discharge of it, associated with headache, which is generally more or less continuous, but may show remissions. In addition to these local symptoms general symptoms such as convulsions, anginiform attacks, dyspnœa, etc., may be induced through irritation of the fifth nerve. There is no evidence that these parasites cause any of the symptoms by their venom. They are generally expelled in attacks of sneezing, or spontaneously. The best methods of making them leave the nostrils are applications of snuff, eau de Cologne, or turpentine; but in some instances it will be necessary to open a sinus—*e.g.*, the frontal sinus—by surgical means in order to remove the parasite.

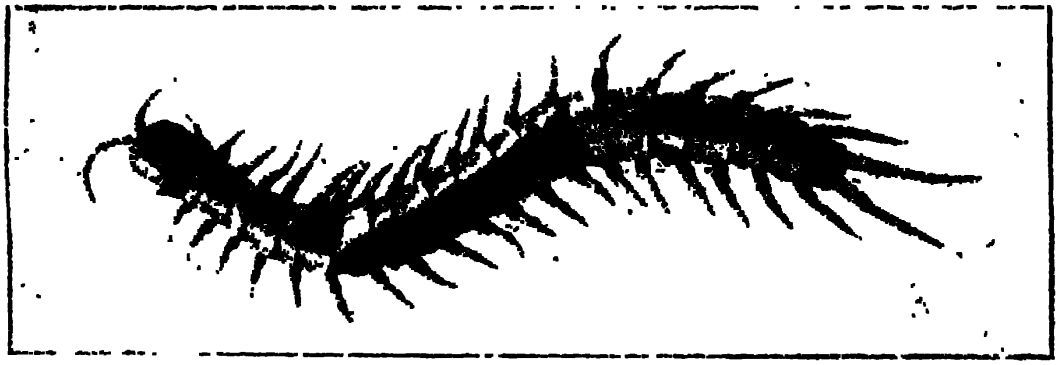

Fig. 302.—Scolopendra Species (?)
(This is a very common species in Ceylon.)

In the alimentary canal the symptoms will give rise to the suspicion of helminthiasis. They are—pain in the abdomen, cramp, nausea, vomiting, and reflex nervous symptoms.

Treatment does not appear very satisfactory.

CHAPTER XXIX

THE HEXAPODA

Synonym—Remarks—Morphology—Internal anatomy—Life-history—Habits—Enemies—Pathogenicity—Collection—Classification—References.

Synonym.—*Insecta.*—Arthropoda breathing by means of tracheæ, with antennæ on the head, three pairs of legs, and usually two pairs of wings on the thorax, which is composed of three segments. Abdomen with generally nine apparent segments.

Remarks.—The Hexapoda, or insects, are known to be of the utmost importance in the spread of disease, for the researches of Manson, Ross, Grassi, and others have shown that they are agents in the propagation of the parasites of filariasis, malaria, and other diseases.

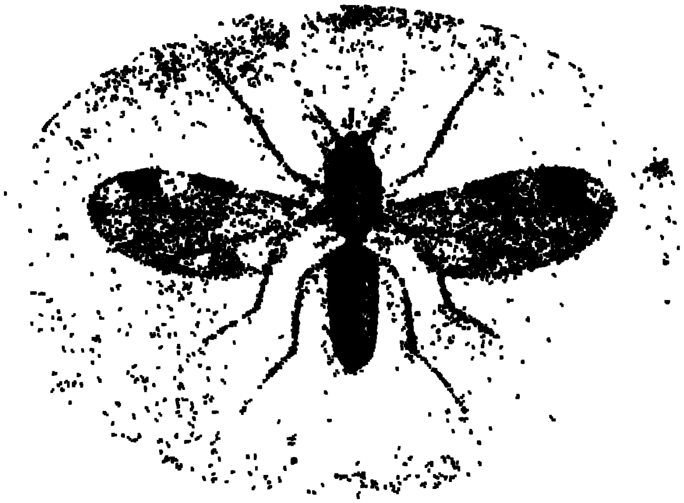

FIG. 363.—*Culicoides brucei*, A TYPICAL DIPTEROUS INSECT. (From a photograph by J. J. Bell.)

Morphology.—The body is distinctly divided into head, thorax, and abdomen. The head is composed of the fusion of about six segments, which are the ocular, antennal, intercalary (probably homologous with the second antennal segment of the Crustacea), mandibular, maxillary, and labial; but whether the hypopharynx represents a seventh segment or not is doubtful. The head carries, in addition to the eyes, four pairs of appendages, one for each somite or segment, except the intercalary segment, which is pre-mandibular. These appendages are the antennæ, the mandibles, the maxillæ, to which are attached palpi called the maxillary palps, and a second pair of maxillæ usually fused to form the lower lip or labium, which generally carries a pair of labial palps.

The exoskeleton of the head is composed of sclerites—that is to say, more densely chitinized regions of the integument—which are: (1) The clypeus; (2) the epicranium; (3) the gula.

The clypeus is the sclerite situate on the anterior portion of the dorsal surface, and carrying the labrum; in flies it is often called the face.

The epicranium is the larger part of the head, and may be subdivided into an anterior frons and a posterior occiput. The genæ form the sides of the head, meeting the epicranium and the gula at the occipital foramen.

The gula is the sclerite in the median ventral line which carries the basal part of the labium called the submentum. There is no exoskeleton at the posterior part of the head ventral to the occipital region, which thus forms a foramen in the hard tissues called the occipital foramen, through which the soft structures of the head communicate with those of the thorax.

The antennæ appear to be sensory organs, and the mandibles to vary in structure according as to whether the mouth is to be used for biting or sucking. In the former case they are broad and strong, while in the latter they are styliform. The first pair of maxillæ, similarly, may be broad, strong organs or styliform organs.

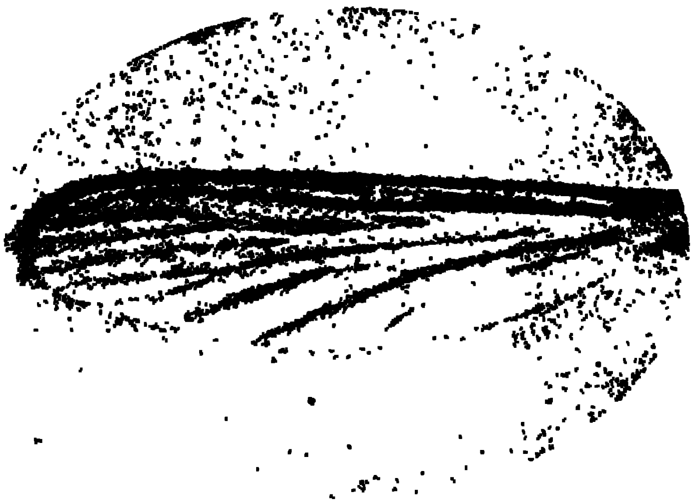

FIG. 304. WING OF A MOSQUITO TO ILLUSTRATE THE VENATION. (From a photograph by [illegible] Bell.)

In addition to these appendages the mouth shows an upper lip or labrum, which is simply a sclerite attached to the cephalic shield, and may have a median projection from its internal surface called the epipharynx, while the labium has a similar one called the hypopharynx. Thus the mouth parts of an insect may be very complicated, with labrum and epipharynx, mandibles, maxillæ, and maxillary palps, labium, and hypopharynx.

The thorax is joined to the head by a neck, and is subdivided into three segments—prothorax, mesothorax, and metathorax. These somites are by no means simple horny rings, but have their chitinous exoskeleton split up into hard pieces joined together by soft material. The hard pieces are a dorsal plate called 'the notum' a ventral plate called 'the sternum,' and lateral plates called 'pleura.' Further the terms, 'pro,' 'meso,' and 'meta,' are applied to these, indicating the region to which they belong—'pronotum,' 'mesonotum,' and 'metanotum'; 'pro-,' 'meso-,' and 'metasternum'—while each pleuron is divided into an anterior episternum and a posterior epimeron. According to Audouin, a typical thoracic segment should have a notum composed of præscutum, scutum, scutellum, and post-scutellum, but all these parts are seldom seen.

Each somite of the thorax carries a pair of jointed walking-legs, in which the segments or articles are named coxa, trochanter, femur, tibia, and tarsus (consisting of several joints, the first joint of which is sometimes called the metatarsus); some authorities have caused much confusion by calling the first tarsal joint the metatarsus, and the real second tarsal joint the first tarsal joint, and so on. The last tarsal joint is terminated by claws or ungues, between which other appendages called empodia and pulvilli are to be found, as will be explained later.

Typically, the mesothorax and the metathorax should each carry a pair of wings. These are transparent and strengthened by nervures, ribs, or veins, which are chitinous canals containing blood-spaces, nerves, and tracheæ. The areas between the nervures are called cells. The wings, however, become much modified in the different orders, and may be entirely absent. The arrangement of the nervures in the wing is called the 'venation,' and has been restudied by Comstock and Needham, who find that the primitive type is composed of two main tracheal branches, an anterior and a posterior. The anterior breaks up at the base of the wing into four longitudinal branches—the costa, subcosta, radius, and media—while the posterior has also four branches, of which the first is called the cubitus, and may be subdivided into two; and the other three are simple and are called the anal veins—first, second, and third. The costal vein is unbranched, and runs along the anterior margin of the wing. The subcostal vein typically divides into two branches, the radial vein into five branches, and the median into four

This primitive type is altered by atrophy or coalescence, leading to the reduction of the veins. The latter may take place from the base towards the tip, or from the tip towards the base of the wing, called outward and inward coalescence respectively. The wing cells may be named as follows.—

1. Costal Cell between the Costa and the Subcosta
2. Mediastinal, between the Subcosta and the Radius
3. Marginal, between Radius 1 and Radius 2.
4. First Submarginal, between Radius 2 and Radius 3.
5. Second Submarginal between Radius 3 and Radius 4
6. Third Submarginal, between Radius 4 and Radius 5
7. First Posterior, between Radius 5 and Media 1
8. Second Posterior between Media 1 and Media 2.
9. Third Posterior, between Media 2 and Media 3.
10. Fourth Posterior, between Media 3 and Media 4.
11. Fifth Posterior, between Media 4 and Media 5.
12. Sixth Posterior between Media 5 and Cubitus 1.
13. Seventh Posterior, between Cubitus 1 and Cubitus 2
14. First Anal, between Cubitus 2 and Anal 1
15. Second Anal between Anal 1 and Anal 2
16. Axillary between Anal 2 and Anal 3.
17. Spurious Cell, behind Anal 3

But all these cells are not present in any one given type of wing, owing to coalescence of the nervures, and hence the arrangement of the cells is different. Besides this, the venation is complicated by the presence of transverse veins, as will be explained later; moreover, wings may be absent, as in the lice.

The abdomen usually consists of ten somites, without appendages, composed of dorsal and ventral plates connected together and to preceding and succeeding segments by soft membranes. The posterior segments are often modified with reference to reproduction, possessing claspers in the male, and ovipositors in the female. The anal opening is on the last abdominal segment, and the reproductive aperture on the penultimate segment.

Internal Anatomy.—The mouth lies between the labrum above and the labium below, and leads into an oral cavity.

The salivary glands in most of the genera which we have to consider are well developed, and are, as a rule, not connected with the mouth, but open into a common duct which communicates with a groove or canal on the hypopharynx, and so opens near the tip of the proboscis

From the mouth a pharynx leads through an œsophagus, with a dilatation called the crop, into a proventriculus or masticatory stomach, which latter communicates with the mesenteron or chylific ventricle, whose juncture with the intestine is defined by the openings of the cæcal Malpighian tubules. This is an important landmark, defining where the stomach ends and the intestine begins. The intestine is subdivided into small intestine, colon or large intestine, and rectum. The last-mentioned may possess rectal glands, while anal glands may open into the rectum just in front of the anus, and are useful to the insect by forming the secretion which gives rise to repulsive odours.

With regard to the proventriculus, it should really be a powerful muscular organ lined with chitin, and possessing teeth, bristles, etc., but in the Diptera it will be found to be much degenerated. The Malpighian tubules, which number from four to six, are excretory in function. The alimentary canal possesses longitudinal and transverse muscular coats and a lining of epithelial cells.

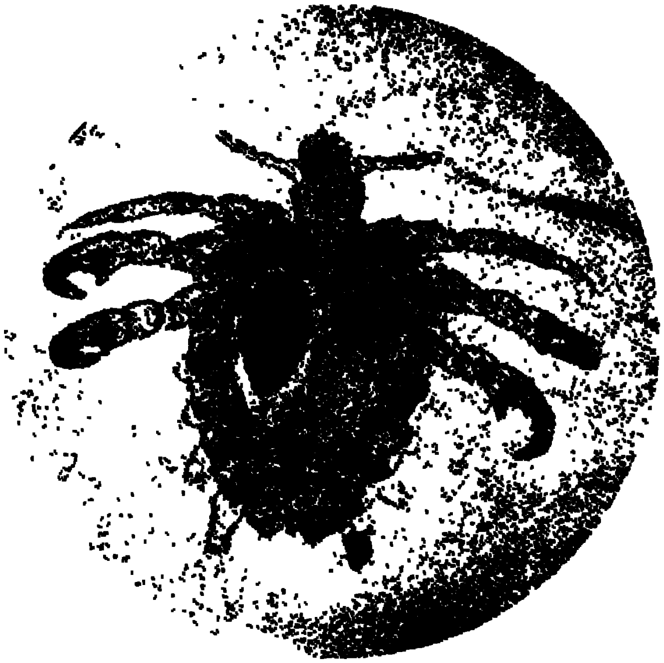

FIG. 305.—*Phthirius pubis* LINNÆUS, 1758, TO ILLUSTRATE AN INSECT WITHOUT WINGS.
(From a photograph by J. J. Bell.)

The stigmata or openings of the respiratory system are situate on the membranes, on the side of the body in the thorax and abdomen, and are very varied in number. They are never to be found on the head or on the last abdominal segment. From the stigmata the tracheæ, or air-tubes, ramify all over the body. These tracheæ are kept open by spiral thickenings of the chitinous lining membrane.

The fat-bodies are lobulated masses packed beneath the skin and between the organs, and are supposed not merely to represent reserve material, but to be of great importance in metabolism.

The circulatory system consists of a dorsal longitudinal vessel divided into chambers, which pulsate, and an anterior aorta, from which blood flows freely into the cœlom or body cavity. From this it returns to the heart by two lateral vessels and one dorsal and one ventral vessel. The blood is colourless, and contains amœboid cells.

As already mentioned, some insects possess poison glands.

The nervous system and sense organs will not be described here, as they are not of importance in tropical medicine.

The male reproductive organs consist of testes, vasa deferentia, ductus ejaculatorius, and an external copulatory organ. The female reproductive organs are two ovaries, which consist of a series of egg-tubes, and oviducts, which are united together to form the single oviduct, the lower portion of which is a vagina. This receives the cement glands and the sebaceous glands, which provide the secretion for gluing the eggs together, and the receptaculum seminis, beneath which is the bursa copulatrix, which is sometimes separated from the vagina.

Life-History.—This is very varied. In general terms the spermatozoa, bound into bundles of spermatophores, are introduced by the external copulatory organ, which, when protruded, is surrounded by the claspers in the form of a sheath, into the bursa copulatrix. The ovum, starting from the terminal portion of the ovarian tube, obtains, as it passes downwards, its food-yolk and its shell or membrane, the chorion, which has a small gap, the micropyle. On arrival at the junction of the oviduct and the spermatheca, or receptaculum seminis, the spermatozoa enter via the micropyle, and fertilize the egg. These eggs may be strung together, as they are laid, into masses by means of the sebaceous secretion mentioned above. The egg may develop directly into the adult, but this is only in the lowest forms. Usually the egg develops into a larva, which becomes a nymph or pupa, and thus into an adult, often called the 'imago.' This series of changes is called a metamorphosis. The pupa may present three forms:

1. *The free pupa*, with appendages free.
2. *The obtect pupa*, with appendages and body bound together.
3. *The coarctate pupa*, in which the pupa is contained in a puparium formed from the larval skin.

The larva is a most vigorous feeder, but the pupa does not take nourishment as a rule, though there are marked exceptions, especially among the Rhynchota and Siphunculata.

Habits.—We are mainly concerned with the predatory or blood-sucking insects. As a rule, only the female sucks blood, which, apparently, it does with a view of obtaining rich nourishment for its eggs. It is this habit which makes these insects of importance in tropical medicine, because not merely does it cause irritation by the introduction of secretions from the insects' salivary glands and mouth (alimentary canal), but also leads to the introduction into the victim of the germs of disease. Again, as we shall see later, larvæ are apt to become parasitic in man and animals, and in this way cause disease.

Enemies.—Insects and their larvæ have many enemies in birds, reptiles, fish, and other insects. Cannibalism is also met with, especially among mosquito larvæ.

Pathogenicity.—The principal disease-spreading insects are the Diptera—for example, the *Anophelinæ* disseminate malaria, the genus *Stegomyia* yellow fever, and the genus *Culex* filariasis, and perhaps dengue fever. Some species of *Glossina* are responsible for the African trypanosomiases, while they and other flies spread the animal trypanosomiases.

In addition, the common house-fly is an important factor in the dissemination of typhoid and perhaps dysentery in tropical countries. Fleas are now known to be the spreaders of plague, and bugs perhaps of some of the relapsing fevers. This is a sufficient list of ills to commend insects and their habits to the serious notice of the medical practitioner of the tropics.

How to Collect Blood-Sucking Flies.—Mr. Austen, of the British Museum (Natural History), has informed us that he will be pleased to send anyone, on application, a pamphlet giving full directions as to the collection and preservation of blood-sucking flies.

Classification.—The Hexapoda are classified into the following orders:—

1. Aptera.
2. Neuroptera.
3. Orthoptera.
4. Mallophaga.
5. Thysanoptera.
6. Hemiptera.
7. Anoplura.
8. Diptera.
9. Lepidoptera.
10. Hymenoptera.
11. Siphonaptera.
12. Coleoptera.

But the only orders which contain species important as spreaders of disease or as human parasites are—

1. Anoplura.
2. Mallophaga.
3. Hemiptera.
4. Diptera.
5. Siphonaptera.
6. Coleoptera.

CHAPTER XXX

MALLOPHAGA AND ANOPLURA (LICE)

General remarks—Mallophaga—Anoplura—Pediculidæ—Pediculinæ—Hæmatopinidæ—References.

GENERAL REMARKS

THE *wingless* insects which occur as ectoparasites on mammals belong as a rule to the *Mallophaga* and the *Anoplura*, when they are generally called 'lice,' or to the *Siphonaptera*, when they are called fleas, while some few belong to the *Pupipara*.

The Mallophaga (biting lice) and Anoplura (sucking lice), however, differ from the Siphonaptera (fleas), in that in the former the whole of the life-history is spent upon the vertebrate host, while in the latter the larvæ live in soil or in protected areas in houses. Moreover, the fleas can change from one host species to another, while the lice have an extraordinary limitation, as they may spend generations on individual hosts, and generally only change from one host to another of the same species by actual contact, and as a rule die in a few days if separated from a host or if a host dies.

This limitation to one given species of host has been ably demonstrated by Kellogg, who has pointed out that it explains many of the curious features of their evolution.

Kellogg and Mjoberg believe that the Mallophaga and the Anoplura are fairly closely related to one another. They think that it is possible that the Mallophaga are the more primitive, especially as no Anoplura are known on marsupials, while Mallophaga are present, which they think points to the possibility of these mammals being older than the sucking lice, especially as the known genera of two-clawed Mallophaga found on mammals are limited to marsupials, while the two-clawed condition is common to the Hexapoda generally, while all the Anoplura found on mammals are one-clawed.

It is possible that the ancestors of the Mallophaga may have been related to the ancestors of the book louse (*Atropos divinatoria*), which belongs to the Psocidæ, a family of the Neuroptera, there being perhaps a common psocid-mallophagan ancestor, from which, by process of evolution, the Psocidæ and the Mallophaga, and later the Anoplura, were evolved. The difference in the mouth parts of the Mallophaga and Anoplura is looked upon as being adoptive rather than palegenetic in character.

The relationship of the Psocidæ to the Mallophaga lies in the common external and internal characters, as well as in their habits, and more especially in a very curious pharyngeal sclerite, which is thought to be a modified hypopharynx, which is found in both these groups and nowhere else in the Hexapoda.

Once started on their evolution, the Mallophaga have been influenced mainly by the fact that they live in a sort of 'island isolation' on given species. This condition of life, which is exactly similar for many different species, is suitable for the production of many varieties of one and the same species, and hence the description of a given species has to be of a very flexible character, but it is opposed to the production of those more distinctive differences which are utilized to make genera and families.

Hence, although in these orders the varieties and species may be many, the genera and families are but few in number. Thus, for example, in the *Mallophaga* there are about 1,500 known species grouped into 27 genera, 4 families, and 2 suborders.

The important difference between the Mallophaga and the Anoplura is that the former have a masticatory mouth, while the latter have a sucking mouth.

ORDER MALLOPHAGA Nitzsch, 1818.

Synonyms. *Mandibulata* De Geer, 1778, *Ricinidæ*.

Nomenclature. The name Mallophaga is derived from μαλλός, wool, and φαγειν, to eat.

Definition. Hexapoda usually of small size, wingless, provided with biting mouth parts and with simple incomplete metamorphosis. Habitat, epizoic parasites on birds and mammals.

Historical.—The first descriptions and illustrations of these animals are to be found in Redi's 'Esperienze intorno alla Generazione degl' Insetti,' published in Florence in 1668, where the illustration on Plate 2, called 'Pollino de Piccion Grosso,' is the same as Linnæus' *Pediculus columbæ*, or pigeon louse, and Nitzsch's *Lipeurus baculus*, a name by which it is still known, while the figure termed 'Pollino dell' Arzevola o Lonquetola' on Plate 12 is the same as Nitzsch's *Trinoton luridum*, the duck louse. Linnæus classified all these bird lice under the generic term of 'Pediculus,' from which they were separated by De Geer, in 1778, under the term 'Ricinus,' because their masticatory mouth, enabling them to eat pieces of skin, hairs, and feathers, distinguished them from the blood-sucking species, for which the name 'Pediculus' was retained.

The name 'Ricinus' was changed into 'Nirmus' by Hermann in 1804, while the whole of the species known at the time were classified and named by Nitzsch in 1818, since which date our knowledge of these parasites has been increased by Denny in 1842, Giebel in 1874, Piaget in 1880 and 1885, Taschenberg in 1882, Kellogg in 1908, 1913, and 1914, as well as by many other observers whose papers may be found in the *Bulletin of Entomological Research* and in the *Annals and Magazine of Natural History*. To all these works the reader is referred for a fuller knowledge of these interesting parasites than that which can be given in the present work.

Morphology. The Mallophaga vary in size from 1·5 to 10 mm., and from 1-2 mm. in breadth, but the majority are small, about 2·5 millimetres in length. The body is strongly chitinized, smooth, wingless, and flattened dorso-ventrally. The mouth parts are of the biting type, with well-developed mandibles, and in some species the labial palps are easily seen. The eyes are represented by a single pair of ocelli placed at the lateral margins of the head. The antennæ are 3-5 segmented, and may be concealed in a groove, or the ventral aspect of the cheeks, or may be exposed.

The prothorax is distinct, but the meso- and meta-thoraces are sometimes united, and may also be with difficulty differentiated from the abdominal segments. The legs are flattened, long, and strong, and end in one or two claws.

The body varies in colour, being whitish, pale brownish, or dark brown in colour, and marked by darker spots and bands, which are caused by chitinization.

The pharyngeal sclerite may be present or absent, as may be the accompanying glands; the crop may be simple or have a sac-like diverticulum. Ingluvial glands may be present or absent, and the testes may number four to six and the egg tubes three to five.

Life-History.—Owing to the fact that these parasites die in a few hours to seven days if removed from the body of the host, and also in a few days if the host which they do not leave is killed or dies, the life-story of not a single species has so far been completely worked out. It is, however, known that the eggs are fastened to the hairs or feathers of the host, and that the young when hatched are like the parents, but smaller, paler, and without characteristic skin markings; they attain their adult characters without metamorphosis.

They run freely about the host, feed upon hairs and feathers, and very rarely upon dried blood, and usually pass from bird to bird or animal to animal by contact, being rarely found away from the host, which they probably slightly irritate, because birds are seen to be constantly cleaning their feathers. They have been found to be parasitic on about 100 species of mammals, representing 48 genera, 24 families, and 5 orders, and 1,100 bird species, or 33 orders of birds out of a total of 35 orders.

Classification. The principal factor which has influenced the evolution of this curious group of animals is isolation, each host being, according to Kellogg, like a small island, so that each species is made up of many dislocated small groups, and this is why each species has to be given a very flexible description, and why many varieties might be made from one species. This condition of life is opposed to producing larger variations which might be used to make genera and families, and the life conditions of many of the species are very similar. Hence varietal specific distinctions are many, and generic and family few.

Hence some 1,500 species are known which can be divided into two suborders, each 4 families and 27 genera. The mammalia-infesting families are only two in number, the Gyropidæ and Trichodechitidæ, characterized by having two-clawed members, and each of those families by only one genus. The bird-infesting families are also two in number, and have respectively 15 and 10 genera.

The following table gives the differentiation of the suborders' families:—

SUBORDER 1: ISCHNOCERA Kellogg, 1896.

Antennæ exposed, filiform, three- or five-segmented; no maxillary palpi, mandibles vertical, crop with sac-like diverticula; ingluvial glands present, testes four, egg tubes five.

A. Antennæ three-jointed, tarsi one claw. Habitat, mammals—*Trichodectidæ.*

B. Antennæ five-jointed, tarsi two claws. Habitat, birds—*Philopteridæ.*

SUBORDER 2. AMBYCERA Kellogg, 1896

Antennæ concealed, clavate or capitate, four-segmented, maxillary palpi present, mandibles horizontal, crop single; ingluvial glands absent, testes six, egg tubes three to five.

A. Tarsi with one claw. Habitat, mammals—*Gyropidæ.*

B. Tarsi with two claws. Habitat, birds—*Liotheidæ.*

The genera parasitic on mammals may be recognized as follows:—

SUBORDER ISCHNOCERA Kellogg, 1896

Family Trichodectidæ Burmeister 1835

This family contains only one genus, *Trichodectes* Nitzsch, 1818, which is parasitic on mammals and has tarsi with only one claw.

SUBORDER AMBYCERA Kellogg 1896.

Family Gyropidæ Burmeister, 1835.

This family contains only one genus, *Gyropus* Nitzsch, 1818, parasitic on mammals and with tarsi armed with only one claw.

ORDER ANOPLURA Leach, 1815.

Synonyms.—*Pediculina* Burmeister, 1835; *Siphunculata* Meinert, 1891; *Pseudorhynchota* Cholodkowsky, 1903; *Lipognatha* Börner, 1904; *Ellipoptera* Shipley, 1904.

Definition.—Hexapoda with labrum and labium joined together to form a rostrum or proboscis, which is armed with recurved hooklets, and contains a hollow extensile sucker formed by the mandibles and maxillæ. Eyes without facets. Antennæ five-jointed. Thorax with little traces of segmentation. Wings absent. Legs with hook-like terminal joints, suitable for clinging. Last abdominal segment rounded in male, notched in female. Metamorphosis incomplete. Habitat, epizoic on mammals.

Historical. The sucking lice were known to the ancients, for Aristotle was acquainted with the pubic louse, while references can be found in the works of Theophrastus, Dioscurides, Galen, and Pliny.

The more modern writers are Moffat, 1634, Camerarius, 1652, Redi, 1668, Leeuwenhoek, 1697, and Swammerdamm in 1737, several of whom give excellent figures of these parasites.

In 1758 Linnæus, in his 'Systema Naturæ,' gathered a heterogeneous collection of species, including some of Mallophaga and Anoplura, in his genus Pediculus; and in 1815 Leach gave the more commonly used name to the order, which included the Mallophaga as well as the sucking lice.

We have already seen how the species of Mallophaga were separated from this composite genus Pediculus, and it now remains to point out that Leach in 1815 created the genera *Phthirius* for *Pediculus pubis* and *Hæmatopinus* for *Pediculus vituli*, *P. asini*, and *P. suis*.

Later important investigations were made by Nitzsch, 1818, Burmeister, 1835, Denny, 1842, Giebel 1874, Piaget, 1880, and especially by Enderlein in his 'Lause Studien,' published in 1904, and by Della Torre in 1908.

We have seen that Mjoberg and Kellogg consider that the Anoplura are derived from ancestors common to them and the Mallophaga, being separated by the alterations induced by sucking blood.

Morphology.—The anatomy will be dealt with under the heading Pediculidæ, and need not detain us here, except to invite attention to the characters of the mouth parts, which are so modified as to form a sucking mouth, while the pharynx performs the rôle of a sucking pump.

Classification. The order is divided into four families, some of which are capable of being subdivided into subfamilies. The number of genera is 15, and the known species are about 100, which are all parasitic on mammals.

The following table, taken from Della Torre, enables the families to be differentiated:—

A. Head not prolonged into a nozzle-like projection. Antennæ three to five segments. Tibia with a thumb-like process. Tibia and tarsus very short and thick. Legs clinging in character.

  I. Body flattened. Mesothorax and three to eight abdominal segments, with stigmata. Antenna three to five segments. Tibia with thumb-like process.

(*a*) Head broader than thorax. Eyes large pigmented. Pharynx short and broad. Proboscis short and pressed against thorax—*Pediculidæ* Leach, 1815.

(*b*) Eyes very small or absent. Pharynx long and narrow. Proboscis very long—*Hæmatopinidæ* Enderlein, 1904.

II. Body thick and heavy. Mesothorax, metathorax, and two to eight abdominal segments, with stigmata. Eyes absent. Back part of the head widened backwards. Antennæ four to five segments. Tibia with short strong thumb-like process. Thick short spines on the body. Female gonopodia elongated and narrow—*Echinophthiridæ* Enderlein, 1904.

B. Head prolonged into a nozzle-like projection, at the anterior end of which lies the mouth opening. Antennæ five segments. Tibia without thumb-like process. Tibia and tarsus very long and thin. Legs not clinging in character—*Hæmatomyzidæ* Enderlein, 1904.

FAMILY I: PEDICULIDÆ Leach, 1815.

Definition.—Anoplura with flattened body, and head not prolonged anteriorly into a nozzle-like projection, with large prominent, pigmented eyes, three to five jointed antennæ, and short proboscis. Pharynx short and broad. Paroglossæ (fulturæ) very strong and broad, with broad arms. Stigmata on mesothorax and third to eighth abdominal segments. Legs suitable for clinging. Tibia and tarsus thick. Tibia with a thumb-like process.

Remarks.—The Pediculidæ are found all over the world, on man as well as on animals. They cause much irritation by their bites, which may become infected, causing impetigo. Apart from this, however, they have recently been suspected of spreading blood-parasites—*e.g.*, *Trypanosoma lewisi* and *Hæmogregarina gerbilli*—which are believed to undergo development in them; and, in addition, they contain parasites peculiar to themselves—*e.g.*, *Herpetomonas pediculi*.

Morphology.—The head is usually clearly defined, but the thorax may or may not be so well defined from the abdomen. Eyes may be present or absent—a fact which appears to depend upon whether the host is nocturnal or not in its habits. The antennæ are usually five jointed. The mouth consists of a proboscis, composed of labrum and labium, which is armed with recurved booklets, and contains the maxillæ and mandibles, which take the form of a suctorial tube. The thoracic segments are fused together. The thorax may be as broad as the abdomen, or narrower. There are no wings. The legs have four segments, of which the terminal one carries a strongly curved claw. The abdomen has, if statements can be trusted, a various number of segments, differing in the different genera.

The last segment in the female has a slit-like opening guarded by two chitinous plates, while in the male there is in the same situation a horny papilla surrounded by spines.

Internal Anatomy.—Christophers and Newstead have studied the anatomy of *Hæmatopinus stephensi* Christophers and Newstead, 1906, parasitic on *Gerbillus indicus* (the Indian field-rat).[1]

The alimentary canal consists of a mouth followed by a chitinous pharyngeal pump into which the ducts of the salivary glands open, and an œsophagus which leads into the mid-gut. This second part of the canal consists of two portions of which the first appears to be a crop and the second a chylific ventricle. There are four Malpighian tubules. The intestine shows no differentiation into small and large. The rectum is globular, with a distended posterior portion containing the rectal papillæ. The fat-body is well developed. The female generative organs consist of two ovaries with oviducts. Each ovary consists of five to six follicular tubes. The two oviducts unite into a common duct, and there is a spermatheca. The male organs are testes, vasa deferentia, vesiculæ seminales, and penis.

Life-History.—The ova, which are attached to the hairs of the host, give rise larvæ, which closely resemble the adults

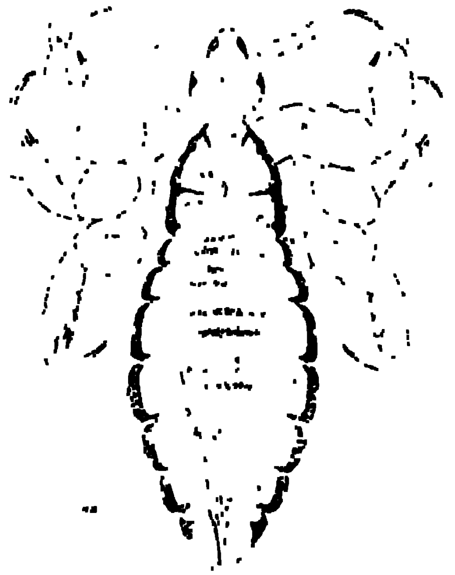

FIG. 306.—*Pediculus humanus* L.: MALE. (× 25.)

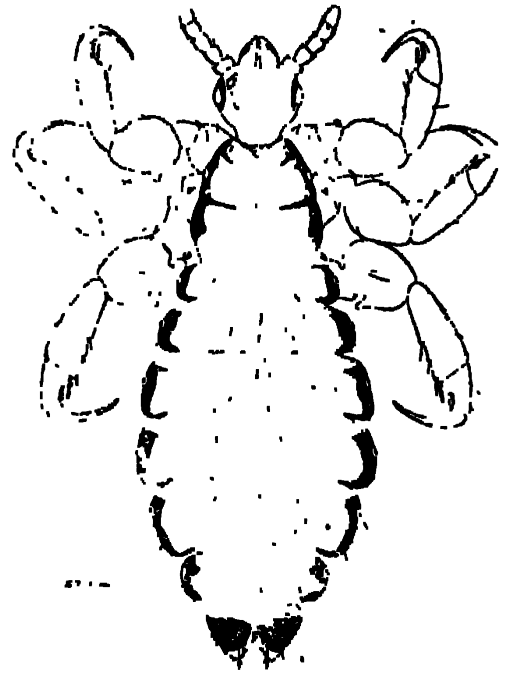

FIG. 307.—*Pediculus humanus* L.: FEMALE (× 25.)

Pathogenicity.—Lice are important carriers of disease, being vectors in certain forms of relapsing fever, in typhus, and in trench fever, etc.

Classification.—The Pediculidæ are subdivided into two subfamilies, which may be recognized as follows:—

A. *Pediculidæ* with five-jointed antennæ—*Pediculinæ*.
B. *Pediculidæ* with three-jointed antennæ—*Pedicinæ*.

SUBFAMILY A: PEDICULINÆ Enderlein, 1904.

Definition.—Pediculidæ with five-jointed antennæ.

Classification.—The Pediculinæ contain two genera, both of which are parasitic on man, and which may be differentiated as follows:—

(*a*) All legs strong, distinct neck, thorax narrower than abdomen—*Pediculus*.
(*b*) Forelegs long, slender, with three claws; no neck; thorax broader than abdomen—*Phthirius*.

Genus Pediculus Linnæus, 1758.

Definition.—Pediculinæ with distinct neck and thorax narrower than abdomen. Legs all strong with strong claws. Thumb-like projection of the tibia long, thin, and covered with bristles. Abdomen long and narrow, with segments not compressed together, and without lateral hook-like processes on the fifth to eighth segments. Two-jointed telson carries ventrally a pair of cone-like processes. Female gonopodia clamp-like and bent inwards.

Classification.—Only four species are at present assigned to the genus Pediculus:—

P. humanus Linnæus, 1758, found on man
P. corporis de Geer, 1778, found on man.
P. punctatus Rudow, 1869, found on *Bos grunniens*.
P. consobrinus Piaget, 1880, found on *Ateles pentadactylus*.

There is a doubt as to whether *P. punctatus* is really a pediculus, and *P. consobrinus* is said by Neumann to be indistinguishable from *P. humanus*, therefore the species are reduced to two:—

P. humanus Linnæus, 1758.
P. corporis de Geer, 1778

These are very alike, and have been thought to be only varieties of one another. Interbreeding seems to be possible. The following points may help to differentiate them

1. Found on the human head, with well-defined abdominal segments marked by a festooned lateral border—*P. humanus*.
2. Found in the clothing, larger than *P. humanus*, with broader thorax and lateral borders of abdomen less festooned, and segments not quite so distinctly indicated—*P. corporis*.

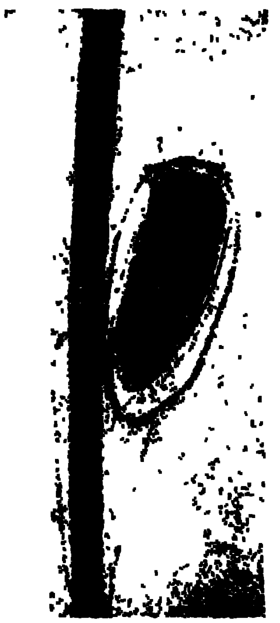

FIG. 308.—EGG OF *Pediculus humanus* LINNÆUS, 1758. ATTACHED TO A HAIR. (× 35 DIAMETERS.)

(From a photograph by J. J. Bell.)

Pediculus humanus Linnæus, 1758.

Synonyms.—*Pediculus humanus* var. 1 Linnæus, 1766: *P. humanus* var. *capitis* de Geer, 1778; *P. cervicalis* Leach, 1817; *P. capitis* Nitzsch, 1818; *P. humanus* Csiki, 1904; *P. nigritarum* Latreille.

Definition.—Pediculus often varying in colour somewhat according to the human race, on which it is parasitic, with thorax often narrowing distinctly anteriorly, well-defined abdominal segments marked by lateral festoons. Thumb-like projection on the tibia armed with a spine. Habitat, homo.

Remarks. This is the head louse, which is cosmopolitan in distribution, but varies in colour on the different races, as was pointed out by Murray, being very dark on African negroes and Tamils, and said to be yellow on Chinese and Japanese, and orange on Hottentots.

On Europeans it is light grey in colour. Daniels says that the pediculi of Chinese do not pass readily to Tamils, though in our experience the pediculi of native servants, Sinhalese and Tamils, will pass to Europeans.

These pediculi are extremely common in the tropics, and it is an every-day scene to witness natives busy at work killing them on their friends' heads.

Morphology.—The head louse is about 2 millimetres in length by 1 millimetre in breadth. The female is larger than the male, and exists in greater numbers. The head is triangular, the thorax broad with short legs, and the margins of the abdomen are dark.

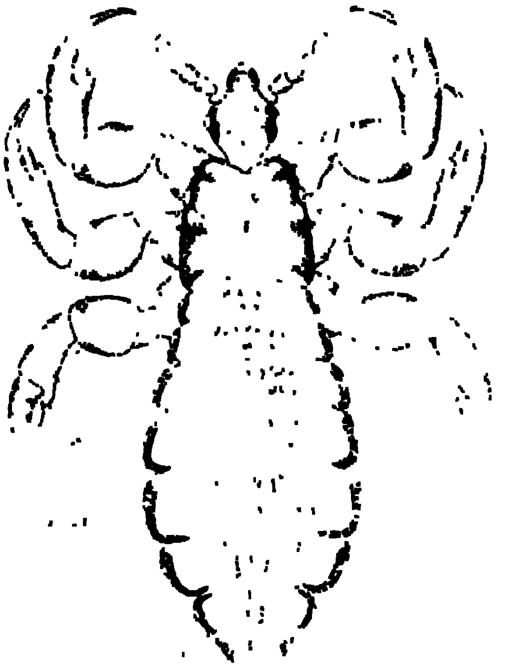

FIG. 369.—*Pediculus corporis* DE GEER: MALE (×25.)

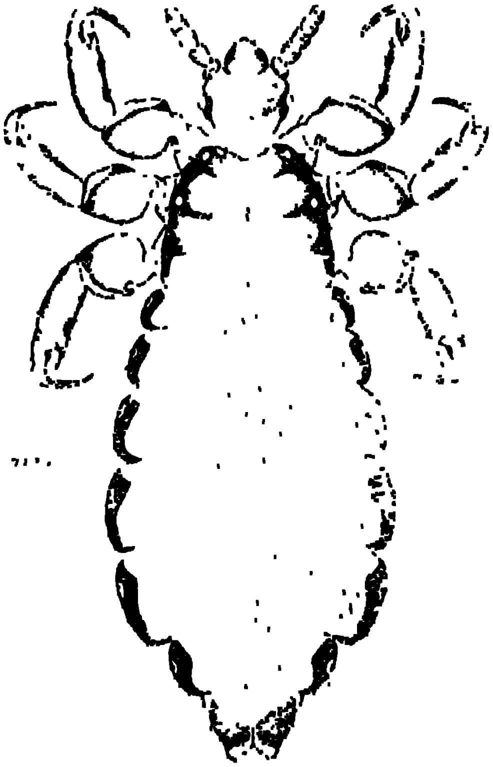

FIG. 370.—*Pediculus corporis* DE GEER: FEMALE (×25.)

Male.—The posterior somite is rounded off and prominent, with a circular opening dorsally which is the common aperture of the genital and alimentary canal. The penis is simple, wedge-shaped, and is usually seen protruding dorsally.

Female.—The last abdominal segment is deeply notched at the apex, where the anus is situated. The vagina opens on the ventral surface.

Life-History.—The female lays fifty to sixty eggs, which are attached firmly to the hairs by the secretion of the cement gland. In about six days these eggs hatch. The young pediculi become fully developed in fourteen to twenty days.

Pathogenicity.—It can carry typhus and produce a form of impetigo.

Treatment.—White precipitate ointment or common paraffin oil may be used.

Pediculus corporis de Geer, 1778.

Synonyms.—*P. humanus* Linnæus, 1758; *P. humanus* var. 2 Linnæus, 1766: *P. humanus* var. *corporis* de Geer, 1778; *P. vestimenti* Nitzsch, 1818; *P. corporis* Csiki, 1904.

Definition.—Pediculus usually dirty-white in colour, thorax only slightly narrowed anteriorly, abdominal segments not very distinctly defined and not well festooned laterally. Thumb-like projection on the tibia without a spine. Habitat, homo.

Remarks.—This louse lives in the folds and seams of the clothes.

Morphology.—It is larger than *P. humanus*, and has an oval, elongated head, with large antennæ. The thorax is more segmented than in *P. humanus*, and the legs more developed, with larger claws.

Life-History.—It lays seventy to eighty eggs, measuring 0·7 to 0·9 millimetre, in the seams of the clothing, which hatch in three to four days, and become mature in fifteen to eighteen days.

Pathogenicity. It is a carrier of typhus fever, trench fever, and certain forms of relapsing fever.

Treatment. Boil or steam the clothes in a sterilizer at 212° F.

Genus Phthirius Leach, 1815.

Pediculidæ with the anterior legs weak, armed with large short claws; abdomen broad and short, with first to fifth segment so strongly compressed that the stigmata appear to be in one segment. Fifth to eighth segments with lateral tooth-like process, of which the two last are long. Habitat, homo.

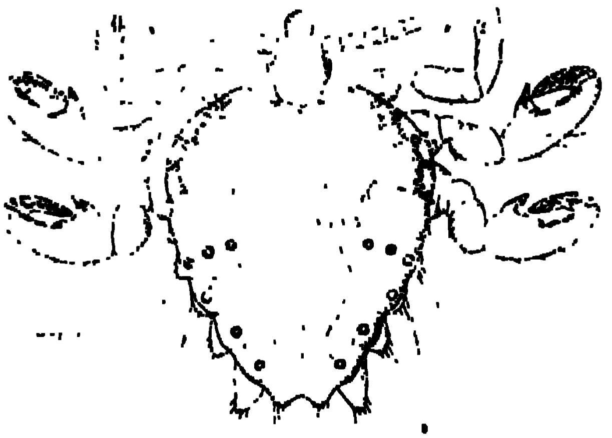

Fig. 371.—*Phthirius pubis* Linnæus: Female. (× 25.)

Phthirius pubis Linnæus, 1758.

Synonyms.—*Pediculus pubis* Linnæus, 1758; *P. inguinalis* Reichard, 1759; *Phthirius inguinalis* Leach, 1815; *P. tabescentium* Alt, 1818; *P. pubis* Küchenmeister, 1855.

Remarks.—*P. pubis* is the pubic or crab-louse, and is more common on men than on women. It usually infests the pubic hairs, but may also be found on the eyelashes and on the eyebrows.

Morphology.—The body in general is flat and broad, with a rounded head bearing antennæ with five segments, and two small eyes. There is a neck. The broad, flat thorax is merged into the abdomen, and carries three pairs of legs, of which the anterior pair is slender, and possesses a straight claw suitable for walking, and the two posterior pairs have claws suitable for clinging.

The female measures 1·2 to 2 millimetres in length by 1·5 millimetres in breadth. The male is half the size of the female.

Life-History.—The female lays ten to fifteen eggs, which it attaches to hairs. These hatch in seven days, and the resulting pediculi become mature in about two weeks.

Pathogenicity.- It produces often a dermatitis, with itching and a greyish discoloration of the skin, said by Dugnet to be caused by a pigment produced by the parasite. Erasmus Wilson says that reddish deposits may be seen on the hairs, due to the fæcal matter of the parasite.

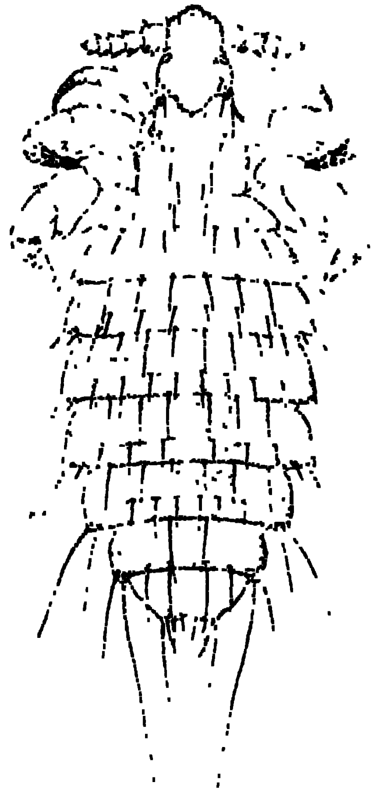

FIG. 372.—*Polyplax spinulosa* BURMEISTER: FEMALE.

Treatment.--White precipitate ointment or some other mercurial preparation.

SUBFAMILY B: PEDICININÆ
Enderlein, 1904.

Definition. Pediculidæ with three-jointed antennæ.

Remarks. Only one genus, *Pedicinus* Gervais, 1844, is known, and there are three known species found on monkeys—viz., *P. eurygaster* Burmeister, 1835 (synonym, *P. microps* Nitzsch and Giebel, 1864), found on *Pithecus sinicus* (Linnæus, 1771); *P. longiceps* Piaget, 1880, found on *Lasiopyga mona* (Schreber, 1775); and *P. piageti* Strobelt, 1881 on *Pithecus brevicaudus* (Elliot, 1909).

FAMILY 2: HÆMATOPINIDÆ
Enderlein, 1904.

Definition. Anoplura with head broadest behind, and not prolonged anteriorly into a nozzle-like projection. Eyes rudimentary or absent. Antennæ three to five segments. Proboscis very long. Pharynx long and narrow. Paraglossæ very small. Mesothorax and third to eighth abdominal segments with stigmata. Row of hairs on each abdominal tergite and sternite. Legs suitable for clinging. Tibia and tarsus very short and thick. Tibia with a thumb-like projection. Pretarsal sclerite sometimes present.

Classification.- Enderlein has divided the family into three subfamilies, which may be recognized as follows:--

A. Antennæ with five segments:-
  I. Eyes rudimentary, situate on the extremity of a forwardly directed fork-like lateral process from the posterior aspect of the head. Mandibles well developed. Forelegs larger and stronger than other legs. Pretarsal sclerite present—*Hæmatopininæ*.
  II. Eyes and eye process absent, mandibles rudimentary. Forelegs smaller than other legs. Pretarsal sclerite absent—*Linognathinæ*.
B. Antennæ with three segments—*Euhæmatopininæ*.

SUBFAMILY HÆMATOPININÆ Enderlein, 1904.

This subfamily contains only the genus *Hæmatopinus* Leach, 1817, with some twenty known species, of which the type *H. suis* (Linnæus, 1758) Leach, 1817, is found on *Sus scrofa* Linnæus; other species are found on equines, bovines, camels, antelopes, deer, conies, and monkeys.

SUBFAMILY LINOGNATHINÆ Enderlein, 1904.

This subfamily contains five genera, which may be recognized as follows:—

- A. Abdomen with strongly chitinized tergites, sternites, and pleurites. Tergites and sternites partly subdivided. Pleurites extended backwards and outwards, making sides of abdomen segmented. Hind legs stronger than middle legs. Claw of hind leg short and much compressed, and fittable into tarsus.
  - I. Abdomen elongated; 1-7 sternites and 2-7 tergites, divided into two plates lying one behind the other. Each plate with a transverse row of strong long hairs. Pleura without serrated process on the inner side. Stigmata small—*Polyplax* Enderlein, 1904.
  - II. Abdomen more or less elongated. Pleura two to six, provided with a dorsal and ventral long knife like pointed process. Four to seven tergites and sternites, composed of three secondary segments, each with a transverse row of long broad scale like hairs, third tergite and sternite composed of two rings each. Anterior ring is broader than posterior—*Hoplopleura* Enderlein, 1904.
- B. Abdomen without sclerites, with smooth border. Hind legs same size as middle leg:—
  - I. Each sternite and tergite of the abdomen with two or three transverse rows of very long closely set hairs—*Linognathus* Enderlein, 1904.
  - II. Each sternite and tergite of the abdomen with one transverse row of hairs:—
    - (*a*) Stigmata large, and those on the abdomen raised like tubercles and standing out above the hinder border of that segment—*Solenopotes* Enderlein, 1904.
    - (*b*) Stigmata very small, and not raised as tubercles—*Hæmodipsus* Enderlein, 1904.

The genus Polyplax contains a rapidly increasing number of species. The one illustrated in Fig. 372 is *P. spinulosa* (Burmeister, 1839), which is found on *Epimys norvegicus* Erxleben, 1777, in Europe.

SUBFAMILY C: EUHÆMATOPININÆ Enderlein, 1904.

This subfamily has two genera with one species, and this can be recognized as follows:—

- A. Hind legs with femur and tibia armed with projecting rectangular, stalked, sheath like appendages—*Euhæmatopinus* Osborn, 1896.
  Species: *E. abnormis* Osborn, 1896, on *Scalops aquaticus* in North America.
- B. Hind legs normal—*Hæmatopinoides* Osborn, 1891.
  Species: *H. squamosus* Osborn, 1891, on *Geomys bursarius* in North America.

REMAINING FAMILIES.

The family *Echinopthiriidæ* Enderlein, 1904, contains three genera—viz., *Antarctophthirius* Enderlein, 1904—with two species, *Echinophthirius* Giebel, 1871, with three species, and *Lepidothirius* Enderlein, 1904 with only *L. macrorhini* Enderlein, 1904.

The family *Hæmatomyzidæ* Enderlein, 1904, contains one genus, *Hæmatomyzus* Piaget, 1869, and one species, *H. elephantis*, on the Ceylon elephant

CHAPTER XXXI

HEMIPTERA

Hemiptera — Gymnocerata — Clinocoridæ — Reduviidæ — Hydrometridæ — Aradidæ — Reference.

ORDER HEMIPTERA Linnæus, 1742.

Synonyms. —*Rhyngota* Fabricius: *Rhynchota* Burmeister.

Definition. Hexapoda with four wings, the front pair being either membranous or half horny and half membranous, but both pairs may be wanting in the parasitic species. Mouth suctorial. Metamorphosis complete.

Remarks. —The Hemiptera include the cochineal insect, *Coccus cacti*; the Aphidæ, plant-lice; and, in particular, the cicadas, whose shrill notes wake the quiet of an African forest. The anterior wings are called hemelytra, and usually consist of three portions:

1. The clavus—the hard, coriaceous portion next to the scutellum.
2. The corium—hard, coriaceous portion occupying the whole of the area between the clavus and the membrane.
3. The membrane—apical portion.

The posterior pair are the true wings.

In the Clinocoridæ the corium is divided into three portions:—

1. Internal—corium proper.
2. External and basal—embolium.
3. External and apical—cuneus.

Classification. —The order is divided into two suborders:—

SUBORDER I.: HOMOPTERA.—With both pairs of wings membranaceous.

SUBORDER II.: HETEROPTERA.—With the front pair of wings half horny.

The first will not be considered here.

HETEROPTERA.

This suborder has two series:—

Series 1, *Gymnocerata* Fieber.—Antennæ conspicuous.

Series 2, *Cryptocerata* Fieber.—Antennæ hidden.

GYMNOCERATA Fieber.

The families of importance to us are:—

Clinocoridæ.
Reduviidæ Stephens.
Aradidæ.
Hydrometridæ.

These families can be diagnosed, according to Distant, in the following manner:—

- A. Species not aquatic; abdomen not clothed beneath with a silvery, velvety pubescence; scutellum not reaching to the base of the membrane nor to the middle of the abdomen.
  - (1) Mesopleuræ and metapleuræ composed of one piece; hemelytra without cuneus.
    - (*a*) Tarsi three jointed. Rostrum short, stout, bent at the base, so that in repose it does not lie against under-surface of the head; ocelli behind eyes; hemelytra complete with distinct membrane—*Reduviidæ.*
    - (*b*) Tarsi two-jointed, anterior legs normal and inserted on the disc of the prosternum. Hemelytra neither reticulate nor cellular—*Aradidæ.*
  - (2) Mesopleuræ and metapleuræ composed of seven pieces; hemelytra with a cuneus and an embolium; ocelli absent—*Clinocoridæ.*
- B. Species aquatic or semi-aquatic; abdomen clothed beneath with a silvery velvety pubescence; antennæ four-jointed—*Hydrometridæ.*

Family Clinocoridæ.

Synonym.—*Acanthiadæ.*

Definition.—Gymnocerata without ocelli, with elytra so short that the abdomen is left uncovered. Tarsi three-jointed.

Remarks.—This family contains the bugs as so called in medical literature. There are eight genera—*Clinocoris* Petersonn, 1829; *Œciacus* Stal, 1873; *Loxaspis* Rothschild, 1912; *Cacodmus* Stal, 1873; *Aphrania* Champion, 1900; *Hæmatosiphon* Champion, 1900; *Bertilia* and *Leptocimex* Roubaud, 1913—and by some authorities these are gathered into two subfamilies, *Clinocorinæ* and *Hæmatosiphoninæ*, with about twenty species in all, of which twelve are parasitic on bats.

CLINOCORINÆ.

Clinocoris Petersonn, 1829.

Synonyms.—*Cimex* Linnæus, 1758; *Acanthias* Fabricius, 1803; *Klinophilos* Kirk, 1899.

Nomenclature.—*Koris* Aristotle; *Cimex* Pliny.

Definition.—Clinocoridæ with the anterior margin of the thorax strongly excavated and with prominent lateral angles.

Remarks.—There can be no doubt that originally bugs fed upon vegetable juices, and that it is only within geologically recent periods that they have taken to blood. Thus the field bug, *Lyctocoris campestris*, which is found under stacks of corn in Europe, may find its way into barns and stables, and will then attack horses and cattle, though under normal circumstances it would merely suck vegetal juices. The relationship to bats is interesting, as apparently the family is essentially a family of bat parasites.

Type Species.—*Clinocoris lectularius* (Linnæus, 1758).

Other Species.—*C. rotundatus* Signoret, 1852; *C. ciliatius* Eversmann, 1841; *C. pipistrelli* Jenyns, 1839 (spreads *Trypanosoma vespertilionis*); *C. columbarius* Jenyns, 1839; *C. fœdus* (vary rare): *C. dissimilis*; *C. improviso* (very rare); *C. pelosellus* (America); *C. peristeræ*.

C. boncti Brumpt, 1910, of our previous editions becomes *Leptocimex boncti* (Brumpt, 1910), and *C. inodorus* of previous editions becomes *Hæmatosiphon inodorum*, which is found on fowls and may enter dwellings.

Clinocoris lectularius Linnæus, 1758.

Synonyms.- *C. lectularius* Meriett, 1667; *Cimex lectularius* Linnæus, 1758; *Acanthia lectularius* Fabricius, 1794.

Definition.--Clinocoris with short, broad head, with two prominent eyes, but no ocelli; antennæ four-jointed, apical joints slender; elytra rudimentary and lie over the metathorax; prothorax semilunar, with extended anterior angles; abdomen uncovered, with seven segments and an eighth anal appendage: legs slender, anterior tibia twice as long, and posterior three times as long as the tarsi, which are three-jointed: proboscis flexed into a groove beneath the head and prothorax.

Historical.---The bed bug was well-known to the ancient peoples of Asia and also to the Romans, who called it *Cimex*. It seems to have come to Europe from the East, and to have reached Germany in the twelfth century, England about 1500, while Thomas Moffat says it was recognized in London in 1503--but then he was writing one hundred years after the event. Originally it was known as the wall-louse or chinch, and the term 'bed-bug' is apparently of recent origin. Both males and females suck blood, and are suspected of spreading Obermeyer's relapsing fever.

Morphology.—It is reddish-brown in colour, with short, broad head carrying two eyes, two antennæ composed of four segments, of which the first and second are stout, and the third and fourth slender. The mouth consists of a proboscis, which is composed of an upper part—the labrum—which is small, and a lower curved portion. This is large and jointed—the labium—inside which are four stylets, the two outer being the mandibles, and the two inner the maxillæ. There are no palpi. The prothorax is semilunar, with two rounded horns. The dorsum is raised in the median line. The mesothorax is triangular, with the apex posteriorly. The metathorax is covered dorsally by the elytra, which are two small chitinous plates belonging to the mesothorax, but consist of clavus, corium, empodium, cuneus, and membrane. The abdomen, which is rounded in shape, with seven segments and an eighth anal appendage, is broadest opposite the third segment. Posteriorly it is covered with round hairs. Length, 5 to 6 millimetres. Male smaller than female with penis flexed into a notch between seventh and eighth segments.

Internal Anatomy.—The mouth leads into the pharynx, beneath which is a syringe organ or salivary pump, into which the salivary glands open. The pharynx leads via the œsophagus into a large crop. There is the usual mid-gut, intestine, and rectum.

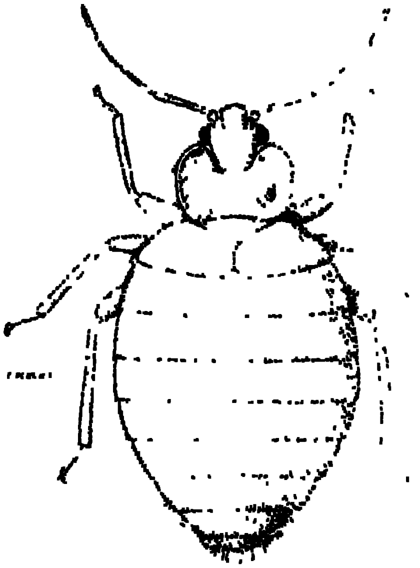

FIG. 373.—*Clinocoris lectularius* L.: MALE. (× 10)

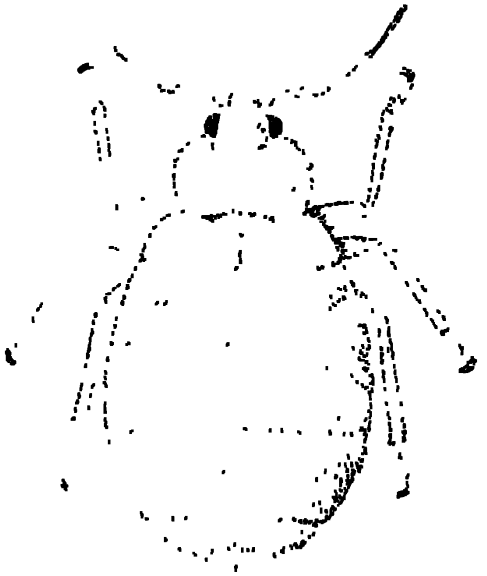

FIG. 374.—*Clinocoris lectularius* L.: FEMALE. (× 10)

Life-History.—They live in cracks in floors, walls, and furniture during the day, and issue forth at night to suck blood from human beings. They are capable of emigration from house to house. The female lays some fifty eggs three or four times a year. Complete development is said to require eleven weeks, but may be completed in as short a time as seven weeks.

The eggs, which are oval, 1·12 millimetres in length, and white in colour, take about seven to ten days to hatch. The larva grows slowly, moulting about five times, at intervals of about eight days, after which the wing-pad appears, showing that the adult stage is reached. They feed only upon blood.

Bionomics.—*Bite.*—In biting, they extend the proboscis, and feel about, testing the skin with the delicate hairs, then pierce it by the stylets, and inject saliva by the syringe, causing congestion of the area, when the blood runs up the grooves in the stylets by capillary attraction into the pharynx.

Smell.—The peculiar odour is due to the secretion of sac-like glands situated at the base of the abdomen, and opening on each side of the metasternum. The secretion is a clear, oily, volatile liquid, which is supposed to be protective in function.

Pathogenicity.—It is quite possible that they spread *Spiroschaudinnia recurrentis*, the cause of Obermeyer's relapsing fever. The effects of their venom have already been described.

Prophylaxis.—Bugs are by no means without their enemies, of which the most marked is the common red house-ant (*Monomorium pharaonis*), while another enemy is the common cockroach; but, despite these foes, bugs are extremely common in tropical hospitals.

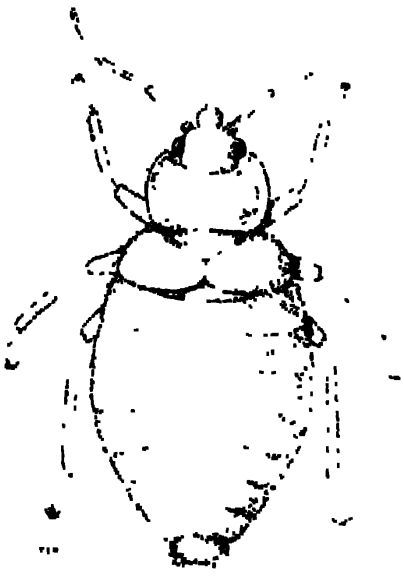

FIG. 375.—*Clinocoris rotundatus* Signoret: Male. (×10.)

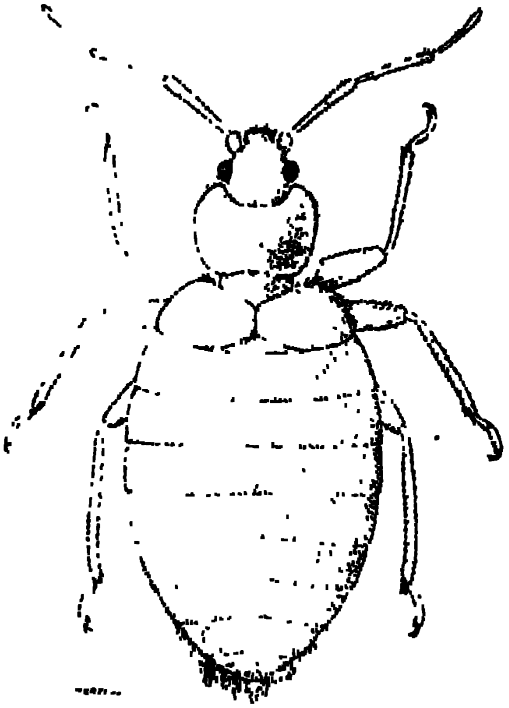

FIG. 376.—*Clinocoris rotundatus* Signoret: Female. (×10.)

The first step in prophylaxis is, of course, strict cleanliness, and the use of painted iron bedsteads which can be easily taken to pieces and washed. Another good means is to make use of mattresses and pillows covered with Willesden canvas, which can easily be washed. The mattress should be in sections, and not all in one piece, as otherwise it is difficult to manipulate. The most useful substances for killing bugs are acetic acid, camphor, and carbolic acid. Acetic acid poured into the joints of a bedstead is said to kill the bugs rapidly. Kerosene is often used, but does not appear to be very effective. Pyrethrum is also used. Apart from bedsteads, the whole room may be infected, in which case fumigation with sulphur is quite the best remedy, 4 ounces being burnt for each 1,000 cubic feet of space, and the room left closed for four or five hours, in order that the gas may act thoroughly.

Clinocoris rotundatus Signoret, 1852.

Synonyms. *Cimex rotundatus* Signoret, 1852: *Cimex macrocephalus* Fieber, 1861. This is the Indian bed-bug, which is found in India, Ceylon, Burma, Assam, and Malaya in Asia, and also in Sierra Leone, Mauritius, Réunion, St. Vincent, and Porto Rico.

Morphology.- *C. rotundatus* differs from *C. lectularius* by being darker in colour, with a shorter, narrower head, with a prothorax with rounded borders, and with a longer, narrower abdomen.

Pathogenicity.- According to Patton it spreads *Leishmania donovani*, the parasite of kala azar or tropical febrile splenomegaly

Clinocoris ciliatus Eversmann, 1841.

Synonym. *Cimex ciliatus* Eversmann, 1841.

This bug is found in Kasan, in Russia. It requires reinvestigation.

Morphology.- It is smaller than *C. lectularius*, yellowish-red in colour, and thickly covered with hairs. Length, 5·3 millimetres.

Pathogenicity.—Not known

Genus Œciacus Stal, 1873.

Clinocorida with the anterior margin of the thorax slightly excavated, and with only slightly projecting lateral angles.

Type Species.—*Œciacus hirundinis* Jenyns, 1839, also *Œciacus vicarius* in martin and swallow nests in North America.

Loxaspis Rothschild, 1912.

Clinocorida with anterior margin of thorax very narrow, scutellum transversely oblong, with posterior margin produced centrally into a point.

Type Species.- *L. mirandus* Rothschild, found on a bat in Uganda, and found in 1913 by Marshall on bats in Sennar, Anglo-Egyptian Sudan; also *L. seminitens* on bats in Java. *L. [illegible]* Roubaud 1913; on bats and bites man

Genus Cacodmus Stal, 1873.

C. villosus on Natal, Transvaal, and Nyassaland bats, *C. ignotus* on African bats; *C. indicus* on Indian bats

Genus Aphramia Champion 1900

Aphramia barys.

Genus Hæmatosiphon Champion, 1900.

H. inodorum, usually found on fowls, but may enter dwellings.

Genus Bertilia.

B. valdiviana under the bark of trees in Chili

Genus Leptocimex Roubaud, 1913.

L. boneti, synonym *Cimex boneti* Brumpt, 1901, found on man in the higher regions of the Ivory Coast and in Haute Guinée.

FAMILY ANTHOCORIDÆ.

Gymnocerata with embolium, membrane with one to four nerves, which arise at the tip and along the side of a triangular basal cell. Antennæ cylindrical.

Genera.- *Anthocoris* Fallén, 1829, and *Lyctocoris* Hahn, 1835.

Anthocoris Fallén, 1829.

Two species of importance—*A. kingi* Brumpt, 1910, in the Egyptian Sudan, and *A. congolensis* Brumpt, 1910, in the Belgian Congo

Lyctocoris Hahn, 1835.

Lyctocoris campestris Fabricius is said to attack man.

FAMILY REDUVIIDÆ.

Gymnocerata with long, narrow heads and distinct neck. Eyes large and prominent; proboscis short, thick, and curved; antennæ long, slender at the tip; legs long; elytra with three divisions when present; tarsus three-jointed.

The genera which will be noted here are: *Reduvius*, *Conorhinus*, *Lamus*, *Reduviolus*, *Rasahus*, *Melanolestes*, but *Harpactor*, *Eulyes*, *Arilus*, *Prionotus* also bite man and animals.

In addition, it may be mentioned that Wellman found *Phonergates bicoloripes* Stal, which is locally known as 'ochindundu,' in the act of sucking the juices of *Ornithodoros moubata*. It is well known that the Reduviidæ attack other insects and ticks. He also mentions that the same insect produces a more painful effect upon man than the bite of the tick *O. moubata*.

Reduvius Fabricius, 1803.

Body moderately elongate, head oblong, ante-ocular portion of head larger than post-ocular portion, eyes large, completely extending across the lateral parts of the head; rostrum with second joint much larger than first; pronotum transversely constricted before the middle anterior lobe with a strong central sulcus or fissure, which is broadly extended to the disc of the posterior lobe. Anterior much shorter than posterior lobe Scutellum with apical spines, legs moderately long and slender, anterior femora normal, interior tibiæ furrowed

Reduvius personatus Linnæus, 1758.

This is the wheel or masked bug found in Europe and the United States, and known for the severity of its bite; for it causes pain, swelling and irritation in the affected area which may last as long as a week.

Conorhinus Laporte, 1832.

Synonym.—*Triatoma* Wolf, 1802.

Reduviidæ with head long, porrect, and more or less distinctly impressed behind eyes; rostrum with first joint very much shorter than second; antennæ inserted on the sides of the head about midway between eyes and apex; ocelli placed very far apart; prosternum broadly sulcated; abdomen frequently with the disc flattened; posterior tibiæ longer than the femora.

The species of *Conorhinus* are mostly found in South America, and live on the blood of mammals and of insects, including bed-bugs. Some of the more important are: —*C. sanguisugus*, *C. rubrofasciatus* de Geer, *C. renggeri* Herrich-Schaeffer, *C. nigrovarius*, *C. protractus*, and *C. variegatus*.

Conorhinus sanguisugus Leconte, 1855.

This is the blood-sucking cone nose of America, which feeds upon the blood of insects, including bed-bugs, and of mammals, including man. The bite is

very severe, and causes much swelling and irritation. It is a night-flier, and has an odour like that produced by bugs.

Morphology.—It is a large dark brown insect, with pink markings and a flattened body and very narrow pointed head, with a strong, thick, long proboscis. The thorax is provided with wings

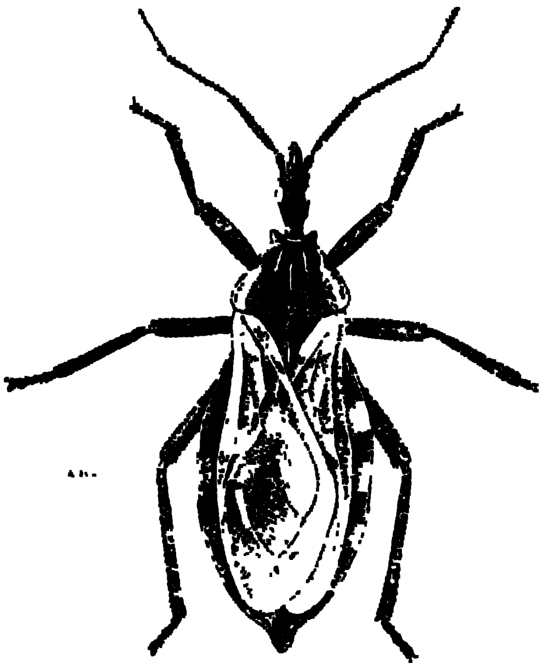

FIG. 377.—*Conorhinus sanguisuga* LECONTE, 1855: FEMALE. (× 2)

Life-History.—The eggs when first laid are white, but later change to yellow, and finally to pink. The larva hatches in about twenty days, and is very active. It moults twice and becomes the pupa, which also moults twice, the last stage showing wing pads. The pupa is also active.

Habits.—In addition to feeding upon blood, these insects may suck the juices of decomposing flesh.

Pathogenicity.—Its bite at times is followed by severe general symptoms, such as swelling in different parts of the body, nausea, etc., as well as local pain.

Remedy.—Sweet oil is advised as a remedy for the local pain.

Conorhinus rubrofasciatus de Geer. This is the Malay bug found in Africa (Sierra Leone and Madagascar), in Asia (Ceylon, India, Malaya, China, and the Philippine Islands). It is said to produce a very severe bite. *Conorhinus renggeri* Herrich-Schaeffer is the black bug of the Pampas. *Conorhinus nigrovarius* is the 'bichugue' of South America and bites severely. *Conorhinus protractus* is the big bed bug of Utah.

Lamus Stål, 1859.

Reduviidæ with the head much shorter than the thorax, with a conical preocular portion, with the basal segment of the rostrum longer than the apical. Antennæ, which are inserted a little in front of the eyes, are more than twice as long as the head, ocelli present. Scutellum unarmed; legs rather slender; anterior femora slightly thinner than the posterior and armed with spines.

Lamus megistus Burmeister.

Synonym.—*Conorhinus megistus* Burmeister; *Triatoma megista.*

Chagas has demonstrated that *Lamus megistus* is the carrier of *Trypanosoma cruzi*. This *Reduviid* attacks men and animals, and, owing to its habit of biting the face, is called 'Barbeiro' by the indigenous population.

Morphology.—*L. megistus* Burm. is a large black insect with numerous regularly arranged red markings, and differs from *C. rubrofasciatus* de Geer, which is closely allied to it, by the fact that

C. rubrofasciatus is of a dull dark brown colour with markings on the pronotum, and with dusky yellow or brick-red elytra and connexivum.

Pathogenicity.—It is the cause of South American trypanosomiasis.

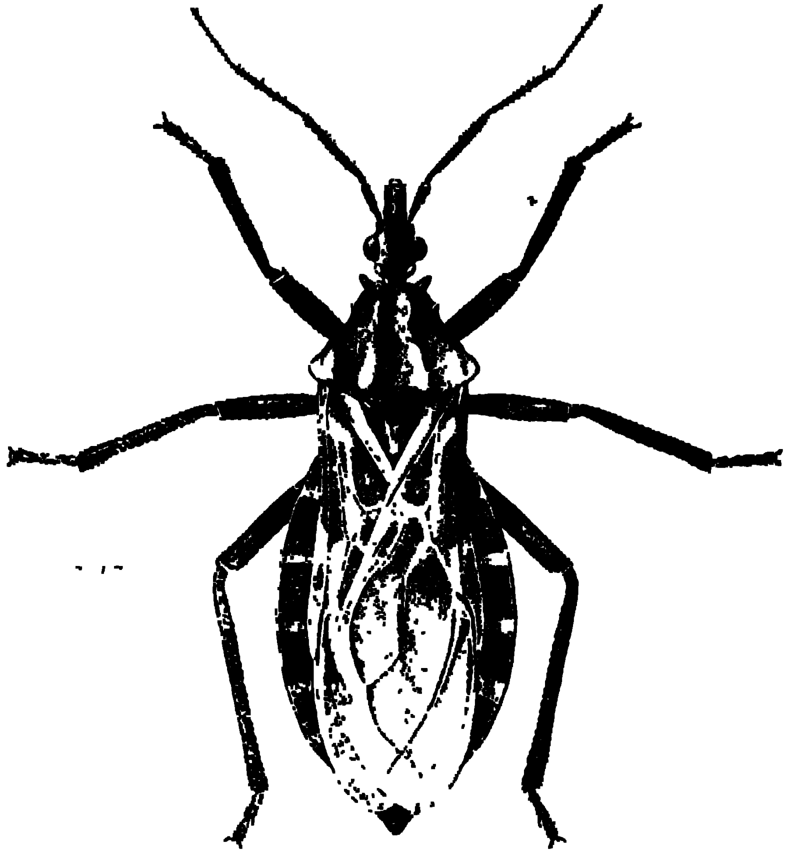

FIG. [illegible].—*Lamus megistus*, Burmeister, 1835.

Reduviolus Kirby, 1837.

Reduviolus subcoleoptratus Kirby, 1837, has once been recorded as a human blood-sucker in the United States.

Rasahus Amyot and Serville, 1843.

Rasahus biguttatus Say, 1831, is found in the houses in Cuba, Panama, and Para, where it really seeks the bed bug, but bites man also.

Melanolestes Stål, 1866.

Melanolestes morio Erichson, 1848. Found under stones during the day in Guiana, Mexico, and the United States of America. Bites man.

M. abdominalis Herrich-Schaeffer, 1848, in the same regions as *M. morio.*

FAMILY HYDROMETRIDÆ.

The Hydrometridæ, or water bugs, are interesting to the student of tropical medicine, because Patton has traced out the development of a Crithidia resembling *Leishmania donovani* in one of them, as has been described in the chapter on Protozoa, p. 567.

FAMILY ARADIDÆ.

Broad, very flat bugs, with four segments in the antenna and three in the proboscis. No cuneus. Tarsus two segments.

Dysodius lunatus Fabricius is the 'Pito' bug of South American houses, which bites severely.

CHAPTER XXXII

THE DIPTERA

CULICIDÆ AND THEIR ALLIED FAMILIES

Diptera: Morphology—Classification—Culicidæ—Corethridæ—Chironomidæ—Psychodidæ—Simulidæ—References.

DIPTERA.

Definition.—Hexapoda with two well-developed transparent wings and two rudimentary wings in the form of halteres. Mouth parts well developed, adapted for piercing and sucking or for suction. Mesonotum forms by far the larger portion of the thorax. Metamorphosis is complete.

Remarks.—The Diptera are by far the most important order of the Hexapoda as regards tropical medicine, for they include the blood-sucking flies, which are capable of carrying disease; also certain flies which cause disease by depositing their eggs in cavities or on the surface of the body, with the result that the larvæ enter the nose, and cause disease by gnawing away mucous membrane, cartilage, and even bone, or the alimentary canal, in which they may cause serious symptoms. Apart from these, it must be remembered that flies, particularly the common house fly, may mechanically, either externally or by its alimentary canal, carry and deposit germs on food, by which means human beings become infected with disease.

Morphology.—The most important points in the morphology of the Diptera in general may be briefly mentioned

Head.—The head in certain families shows an anterior depressed area, the lunula, bounded by an arched suture, which passes over the base of the antennæ This is the invaginated 'ptilinum,' or vesicle, by which the imago breaks its way out of the pupa. With regard to the antenna, it is of great importance whether it is many- or few-jointed. In the latter case it often carries an arista on the third joint, which may be looked upon as representing the remainder of the larger antennæ of other species

The mouth parts, though composed of the typical labrum, epipharynx maxillæ, mandibles, hypopharynx, and labium, will be found to be very different in the various species of biting flies. More especially are the labial palps altered in *Glossina* and *Stomoxys*, becoming armed with teeth and capable of making the hole in the skin which is necessary for the sucking of the blood.

Thorax. In many cases the thorax is largely composed of mesothorax, the pro- and meta-thoraces being much reduced The wings are of importance. Some genera possess a prolongation backwards, called the squama, which conceals the halter. The venation of the wing has a peculiar nomenclature, which will be more fully explained under the heading Culicidae, but which may here be compared with the typical arrangement of Comstock and Needham, from which it differs mainly by the form of coalescence called 'inward' which means that two veins have coalesced from the tip towards the base of the wing.

Typical Names		Dipterous Names
Costa		Costa.
Subcosta		Subcosta
Radius 1		First Longitudinal
Radius 2 Radius 3	Coalesced	Second Longitudinal.
Radius 4 Radius 5	Coalesced	Third Longitudinal
Media 1 Media 2 Media 3 Media 4	Coalesced more or less	Fourth Longitudinal.
Cubitus 1 Cubitus 2		Fifth Longitudinal.
Anal 1 Anal 2		Sixth Longitudinal
Anal 3		Seventh Longitudinal.

The above table shows the two ordinary systems of nomenclature for the chief veins of the Diptera at present in use. The terms in the right hand column are older than the other ones and are generally employed by English writers. In addition to the longitudinal veins there are several transverse veins, viz.:

1 The Humeral from the Costa to Subcosta.
2 The Radio-medial or anterior from the Radius to the Media.
The distal Medio-cubital or posterior from the Media to the Cubitus.
4 The proximal Medio-cubital or anterior Basal.
The Cubito-anal or posterior Basal.

The wing shows a costal cell, generally subdivided by the humeral vein, a subcostal, a marginal, a variable number of submarginal, a posterior, and an anal cell. The second anal vein is often wanting and represented by merely an infuscation. In addition there are generally an anterior or radial, a posterior medial and an anal or cubital basal cell. In the Culicidae the first submarginal and the second posterior cells are often called the fork cells. In the first posterior it is important to note whether it is closed, and does not reach the margin of the wing owing to the junction of the media with the radius, or open, or partially open and does reach the margin of the wing. A discal cell in the middle of the wing is present in some genera. It is bounded either by the media or by that vein and the cubitus.

The legs possess the usual number of segments, but with regard to the nomenclature of these segments there is a certain amount of confusion. The fifth tarsal segment carries two claws and usually two pulvilli or pads, while between them lies the empodium in the form of a bristle or third pad, which may be looked upon as a sixth tarsal or claw segment.

Abdomen. This has usually nine segments, which may be reduced by the fusion of segments, especially in connection with the male and female generative organs. The genitalia, especially the male, are of importance in classification, and will be mentioned in detail under the heading Culicidae.

The body is adorned by scales and hairs. The former have been made use of by Theobald to classify the Culicidae, while the latter may be strongly developed in places, and have been used in flies as a help in classification, and are of the utmost importance in fleas.

Flies are usually modest in colour, being often yellowish, brownish, or blackish, but some of the Culicidæ, e.g., *Megarhina*, are brilliantly coloured. The colours depend partly upon pigments and partly upon interference with or reflection of light.

Life-History. The female generally lays eggs; more rarely a larva is produced directly, as in *Glossina*. The eggs are laid in some material which will be useful to the larva—e.g., the eggs of Culicidæ in water and the eggs of Muscidæ often in decomposing matter. The larva is generally a very active, vigorously feeding little grub, which may or may not have a distinct head. The pupa may either remain in the old larval skin which forms the puparium (such a pupa, as seen in the Muscidæ, belongs to the coarctate type), or it may not be so enclosed, but the body and appendages being closely united, it forms the obtectate type. The imago escapes from its pupal skin by a T-shaped slit (Orthorrhapha), or by a circular opening (Cyclorrhapha).

Collection of Flies.—Mr. Austen has asked us to invite the reader's attention to certain remarks of his taken from the second report of the Wellcome Research Laboratories, which are as follows:—

1. Specimens of blood-sucking and other Diptera intended for determination should be in *the most perfect condition possible*.
2. Specimens collected by *natives* seldom fulfil this condition.
3. Flies should, if possible, always be transfixed by a pin through the thorax and pinned to a small piece of cardboard, and should be drawn up *near the head of the pin*, and not left close to the point.
4. If pinning is impossible, specimens are best placed *in three-cornered envelopes* of soft paper.
5. Flies should *never* be placed in contact with *dry cotton-wool*.
6. *A plug of soft paper* must always be pressed down on top of specimens placed in spirit, in order to fix them in the tube.
7. Several specimens *of each species* should be sent if identification is desired.
8. Specimens should always be *labelled*, with the name of locality, and date of capture, and notes of interest forwarded at the same time.

Classification.—The Diptera may be classified as follows, according to the characters of the pupa, larva, and antennæ.

SUBORDER I. ORTHORRHAPHA.

Definition. Diptera without lunula or ptilinum. Larva with a distinct head. Pupa obtectate. Imago escapes by T-shaped opening.

Section 1: Nematocera. Orthorrhapha with antennæ composed of more than six joints, with the joints, except the first two, similar, without arista. Palpi four- or five-jointed.

Families. Culicidæ, Corethridæ, Chironomidæ, Psychodidæ, Simuliidæ, Blepharoceridæ, etc.

Section 2: Brachycera.—Orthorrhapha with antennæ in which the joints differ from one another, with or without arista, which, when present, is usually terminal.

TRIBE I: *Brachycera homœodactyla*.—Orthorrhapha brachycera with three well developed pulvilli. Larva with a projecting posterior stigma.

Families.—Tabanidæ, Leptidæ.

TRIBE 2: *Brachycera heterodactyla.*—Orthorrhapha brachycera with two or three pulvilli. In the last case the middle is different from the two other pulvilli. Some species without pulvilli. Posterior stigma of the larva in front of the body-end.

Families.—Asilidæ, Empidæ.

SUBORDER II. CYCLORRHAPHA.

Definition.—Diptera with a lunula and usually a ptilinum. Antenna with always three joints and an arista. Palpi one-jointed. Mandibles absent. Maxillæ rudimentary. Discoidal cell bounded by the media and cubitus. Abdomen with seven segments at the most, often with less.

Section 1: Aschiza.—Cyclorrhapha with a clearly defined lunula, but a rudimentary ptilinum. Arista poorly developed.

Families.—Not of interest in tropical medicine.

Section 2: Schizophora.—Cyclorrhapha with lunula; at times absent, but the arched suture over the antennæ is well defined. Ptilinum usually well developed. Antennæ lie in separated hollows. Arista well developed.

TRIBES: *Muscidæ acalyptratæ* and *Muscidæ calyptratæ*.

SUBORDER III. PUPIPARA.

Definition.—Diptera with well-developed rudimentary or no wings; parasitic on vertebrates. The fully-developed larvæ are passed directly from the body of the imago without a free-living egg stage.

SUBORDER ORTHORRHAPHA.

SECTION NEMATOCERA.

FAMILY CULICIDÆ.

Definition.—*Orthorrhapha nematocera* with a long piercing proboscis, and a body more or less clothed with scales and hairs. Antennæ with whorls of hairs or plumes, which may be dense and long in the male, though scanty in the female. Wings with six to seven longitudinal veins, with scales and two distinct fork cells. The costa passes all round the wing, and carries scales, which form a fringe. Metamorphosis complete.

The Culicidæ include the flies which we call mosquitoes, a word which is derived from the Spanish, meaning little flies, and are the same as gallinippers in America. The genus *Culex* was formed by Linnæus in 1790 for the gnat *Culex pipiens*; the genus *Anopheles*, from a Greek word meaning harmful, by Meigen in 1818; the genus *Stegomyia* by Theobald in 1901. A great many other genera have also been described, but are not so important in tropical medicine as these three. Among the early workers in this field of research special prominence must be given to the names of Arribalzaga and Ficalbi.

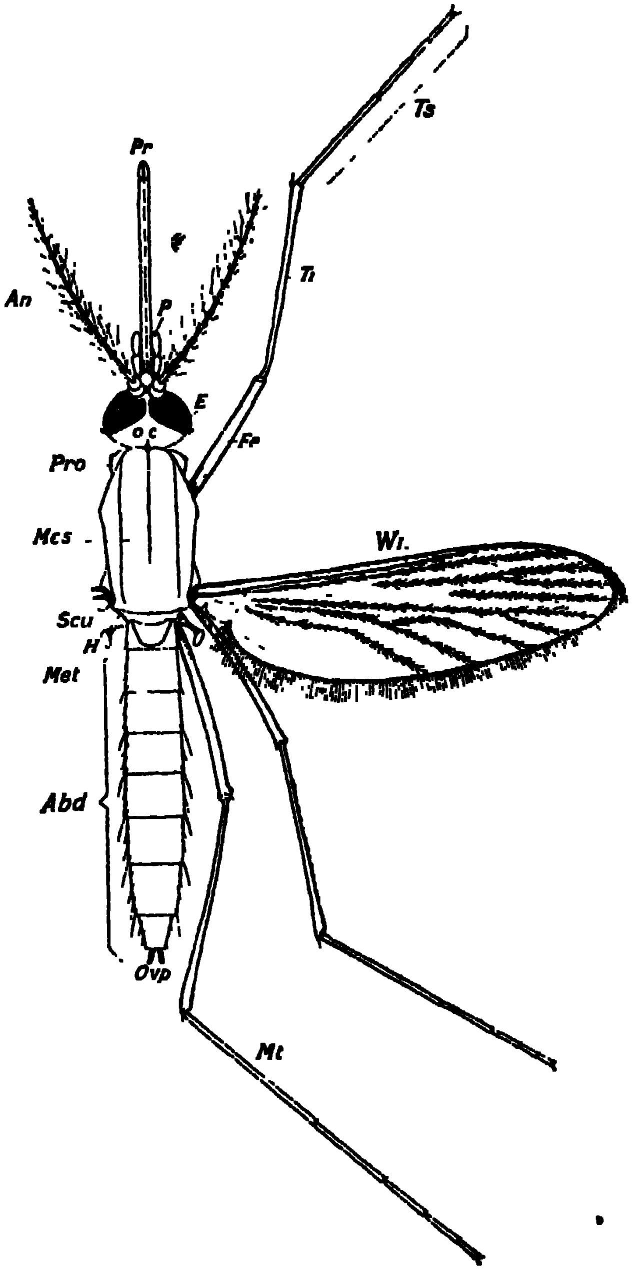

FIG. 379. DIAGRAM OF A MOSQUITO.

(After Theobald, from 'The Culicidæ of the World.')

Pr., proboscis; *P.*, palp; *An.* antenna; *E.*, eye, *Oc.*, occiput; *Pro.*, prothorax; *Mes.*, mesothorax; *Scu.*, scutellum, behind which is seen (*Met.*) the shield-like post-scutellum; *H.*, halter; *Abd.*, abdomen; *Ovp.*, ovipositor; *Wi.* wing; *Fe.*, femur; *Ti.*, tibia; *Mt.*, metatarsus; *Ts.*, tarsus: the line indicating the tarsus is made to include the metatarsus, which is sometimes regarded as the first tarsal joint.

In our description of the classification of the Culicidæ we have followed Theobald, but a simpler system is urgently required and may be evolved during the next few years, as there are already signs that such a system may be possible.

Careful dissections of *Anopheles* have been made by Nuttall and Shipley, and of *Culex* by Christophers, while the larva and pupa of *Anopheles* have been studied in detail by Imms.

As the *Anopheles* is, without doubt, of the greatest importance to medical men, its anatomy will be described.

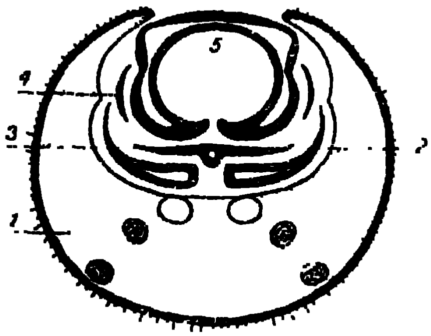

FIG. 350.—TRANSVERSE SECTION OF THE PROBOSCIS OF *Anopheles maculipennis* MEIGEN.

(After Nuttall and Shipley, from the *Journal of Hygiene*.)

1. Labium, 2, maxilla, 3, hypopharynx with salivary duct; 4, mandible, 5, labrum-epipharynx with the figure (5) placed in the blood tube.

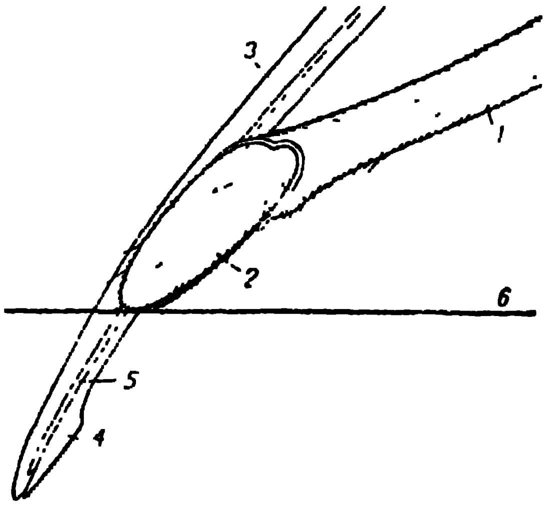

FIG. 351.—DISTAL END OF THE PROBOSCIS OF *Anopheles maculipennis* MEIGEN.

1, Labium; 2, labellæ; 3, labrum-epipharynx; 4, maxillæ, 5, mandibles; 6 skin line. (The labellæ should be divergent to the plane of the paper.)

Morphology. *Anopheles maculipennis* Meigen has been studied by Nuttall and Shipley, whose account is followed in the description given below.

The body of a mosquito is divided into (*a*) head, (*b*) thorax, (*c*) abdomen.

Head. The most conspicuous objects on the head are the two large reniform, often brilliantly coloured eyes, which lie on a piece of exoskeleton, called the 'epicranium,' which covers the whole head, except in the ventral median line where the gula can be seen. Dorsally the eyes nearly meet, being separated by a piece called the 'vertex,' in front of which is the frons, which carries a pair of antennæ, different in male and female. The male antenna has sixteen segments, of which the first segment is very small; the second is globular, and contains an auditory organ, the third is long, and the fourth to the fifteenth carry twenty-five to thirty hairs in whorls at the proximal end of each segment. The sixteenth segment is about half as long as the penultimate. So dense are the whorls of verticillate hairs in the male that the term 'plumose' is applied to the whole antenna. The base of the sixteenth segment carries six hairs, and the tip is rounded. The female antenna consists of fifteen segments. The first is very small, merely a ring of chitin; the second is deeply hollowed for the third segment, which is the longest. The proximal ends of the fourth to the fifteenth carry six large hairs. The tip of the fifteenth segment bears fine hairs. These few hairs produce quite a different appearance in the antennæ, which are called 'pilose.'

In front of the frons a sclerite called the 'clypeus,' belonging to the exo-

skeleton of the head, projects forwards, under cover of which the mouth appendages appear as a median proboscis and two lateral palpi.

These mouth parts are made up of the following (*vide* Fig. 22, p 224). -

1 Labrum, or upper lip, with which is combined the epipharynx to form the labrum epipharynx.
2. The mandibles.
3. The first pair of maxillæ, to which the palpi belong.
4 The hypopharynx.
5 The second pair of maxillæ, which have united together to form the lower lip or labium.

The labrum epipharynx commences at the head end as two separate chitinous structures: the more dorsal, continuous with the clypeus, is the labrum, and the more ventral, continuous with the chitinous lining of the mouth cavity, is the epipharynx, the part in the proboscis forms a deep groove, open ventrally. In the female its free end is sharp and pointed; in the male it is truncated

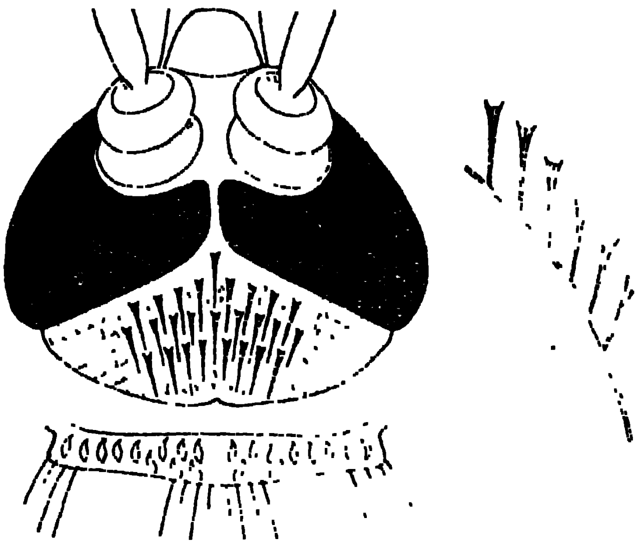

FIG. 25. THE OCCIPUT AND SCUTELLUM OF AN ANOPHELINE MOSQUITO TO SHOW THE SCALE CHARACTERS.

At the side is seen the lateral aspect of the ventral side.

(After Theobald, from 'The Culicidæ of the World.')

The mandibles are absent in the males, while in the female they appear as yellow delicate chitinous blades the base of which is attached to the sides of the labium and the apex is knife shaped with its edge serrated by thirty-one fine teeth (*vide* Fig. 23).

The first maxillæ are chitinous rods attached posteriorly to the side of the base of the labium, which is here swollen, and carries on its outer angle the palp It is continuous posteriorly with a chitinous bar, which runs backwards into the head and affords attachment to several muscles. The free extremity of the maxilla has thirteen teeth (*vide* Fig 24, p 225).

The maxillary palps project on either side of, and dorsal to, the proboscis. They are five-jointed, and covered with scales In the male the distal end of the third segment is broadened, and the whole fourth and fifth segments are broad and flat, giving a spatulate appearance to the tip. The length of these palpi varies in the different genera of the Culicidæ, as will be mentioned under the heading of Classification

The hypopharynx takes its origin just above the base of the labium in a solid mass of chitin, which is pierced by the salivary duct, which is a canal 3 to 50 μ in diameter. In the male the hypopharynx is fused with the labium

The second maxillæ are united together to form a lower lip, or labium, which is curved dorsally so as to form a deep groove in which the first maxillæ lie ventrally and laterally, with the hypopharynx situated dorsally and mesially, and the labrum epipharynx dorsally with the mandibles on either side. The distal end carries two short segments called 'labellæ,' which are movable on hinge joints. Between these labellæ there is a projection of the labium connected with them by a thin membrane (Dutton's membrane) which is stretched during the act of biting. Through this membrane filarial embryos escape from the interior of the labium. The labium itself is composed of a double cuticular wall carrying scales on its exterior, and enclosing internally a cavity containing muscles, etc., among which the filarial embryos can lie. There are, therefore, two tubes in the proboscis: the first, large, formed by the labrum-epipharynx and the hypopharynx, is the blood-tube, up which the blood is sucked into the pharynx; while the other, small, lying in the hypopharynx, is the salivary duct. The first is afferent, the second efferent.

Behind the eyes there is an area of the head called the 'occiput,' which carries different kinds of scales in different genera, as is seen by the following diagram (Fig. 383). These scales may be differentiated into narrow curved scales, upright forked scales, and flat scales, the presence and character of which have been made the means of classification. The upright forked and the curved scales occupy the middle area of the occiput, and alone are met with in this species, but quite different arrangements are met with in other genera. The extreme posterior area of the head is the nape. Below the eye laterally is the area of the head called the 'gena.' At the back of the head is the occipital foramen, through which the soft structures pass to the neck.

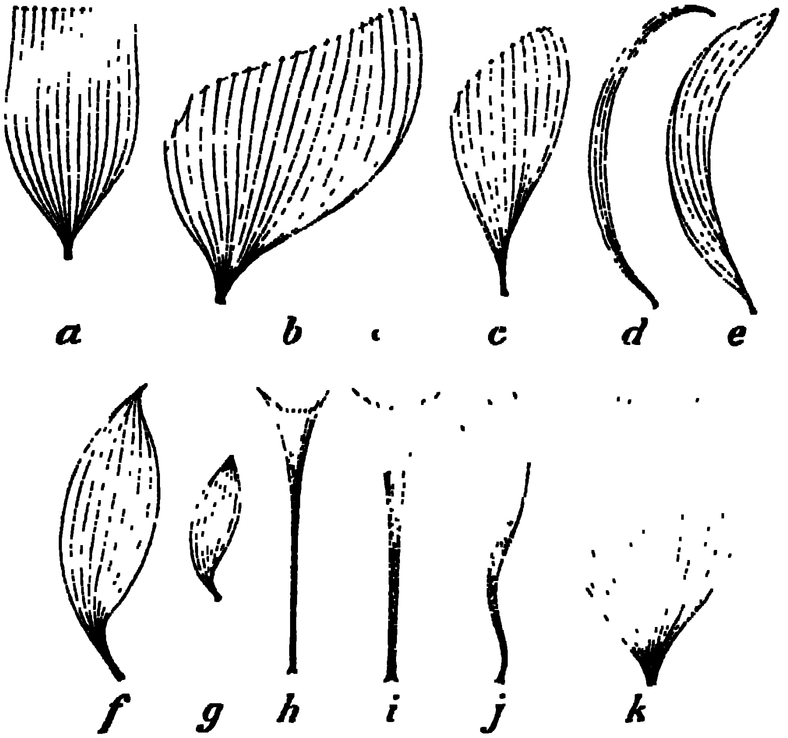

FIG. 383.—VARIOUS FORMS OF SCALES FOUND ON DIFFERENT PARTS OF A MOSQUITO.

(After Theobald, from 'The Culicidæ of the World')

a, Flat scale from abdomen; *b*, broad wing scale; *c* another broad wing scale; *d*, curved hair-like scale; *e*, narrow curved scale; *f*, flat spindle-shaped scale; *g*, small form of *f*; *h* and *i*, upright forked scales; *j* twisted upright scale; *k* inflated scale.

Neck.—The neck is the soft connection of the head with the thorax. It is strengthened with chitinous rods.

Thorax.—The thorax shows the usual three divisions into pro-, meso-, and meta-thorax, but of these the mesothorax is much the largest, and is often called 'the thorax'; in fact, the pro and meta-thorax are hard to see. It will be remembered that a typical thoracic segment should show dorsally a notum, composed of præscutum, scutum, scutellum, and post-scutellum; ventrally a sternum, and laterally a pleuron, consisting of episternum and epimerum.

On the posterior portion of each side of the neck may be seen a small sausage-shaped sclerite, called the patagium, in front of which is the neck sclerite while posteriorly there is another sclerite reaching as far as the first thoracic spiracle. Below these, and reaching to the coxa of the first leg, is still another sclerite. These four sclerites make up the prothorax. The patagium may represent a pronotum, the neck sclerite an episternite, and the posterior sclerite an epimerum, while the sclerite connected with the coxa of the first leg is undoubtedly a prosternum. This segment of the thorax carries the first pair of legs, and perhaps the first spiracle.

The interpretation of the parts of the prothorax presents considerable difficulty. Some authorities believe that there is no pronotum. The mesothorax is well developed, and presents dorsally a præscutum and scutum fused together, behind which is a trilobed area, the 'scutellum.' Behind this, again, is a shield shaped area, looked upon by some observers as a metanotum, but more probably representing the post-scutellum of the mesothorax. Laterally behind the first spiracle lies the episternum of the mesothorax, below and behind which is the mesosternum, wedged in between the second and third legs on each side. The two mesosterna are bound together by a chitinous bar.

Between the post-scutellum and the first abdominal segment lies the minute true metanotum. The metasternum is easily seen between the second and third pairs of legs and the episternum of that segment lies just dorsal to the third coxa, and contains the second thoracic spiracle as well as carrying the halter. The thorax is covered with hair-like curved scales, and its appendages are the legs and wings. There are three pairs of legs, one for each division of the thorax, which have the usual number of segments -- coxa, trochanter, femur, tibia, metatarsus and tarsus, the latter being four-jointed. The last joint of the tarsus carries the two claws or ungues, which may be toothed. In the first leg in the male the claw is single, and the first terminal tarsal segment is hollowed out. In the female all the legs terminate in a double hook, and the first tarsal segment is not hollow., The empodium, a median process projecting between the ungues is in *Anopheles maculipennis* reduced to a tuft of hairs. The arrangements of the ungues, however, vary very much in different genera and species.

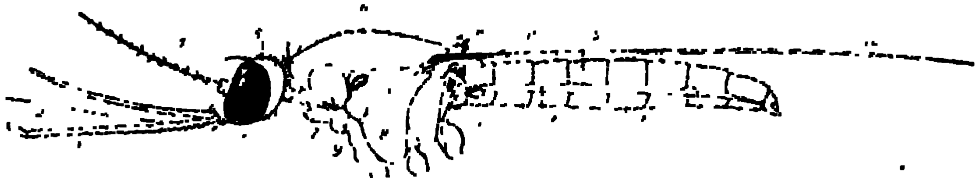

FIG. 384.--LATERAL VIEW OF *Anopheles maculipennis* MEIGEN.
(After Nuttall and Shipley, *Journal of Hygiene*.)

1, Labium; 2, labrum epipharynx; 3, palp; 4, antenna; 5, occiput; 6, mesothorax (præscutum and scutum); 7, prothorax; 8, mesosternum; 9, first thoracic spiracle; 10, metasternum; 11, second thoracic spiracle; 12, scutellum; 13, post-scutellum; 14, wing. 15, tergum; 16, pleural membrane; 17, sternum.

The wings arise by their bases from the side of the mesothorax, between the scutum and the episternum. The anterior border of the wing is straight and thick, while the posterior is curved and near the base is folded or indented twice to form squama and alula The area of the wing, bounded by the squama and alula, is broken up by a series of thickenings and ridges from which the nerves take their origin. The base of the wing has a socket which fits on to a knob on the episternum. The veins of the wings are: -

1. *The Costa.*

2. *The Subcosta*, which joins the Costa some distance from the apex of the wing.

3. *The Radius 1* (*First Longitudinal*).--Runs from base to apex of the wing.

4. *The Radius 2 + 3 (Second Longitudinal)*.—Commences in the middle of the wing, and shortly divides into two branches (Radius 2 + 3), enclosing a piece of the wing called the first submarginal cell.

5. *The Radius 4 + 5 (Third Longitudinal Vein)*. Commences in the middle of the wing and runs to the margin.

6. *The Media (Fourth Longitudinal Vein)*. Runs from the base of the wing to the margin, but forks (Media 1 + 2) to enclose the second posterior cell.

7. *The Cubitus (Fifth Longitudinal Vein)*. Runs from the base and forks (Cubitus 1 + 2) to enclose the third posterior cell.

8. *The Anal 1 + 2 (Sixth Longitudinal Vein)*. Runs a curved course from its margin.

In some mosquitoes there is a second anal vein (seventh longitudinal vein), but more often this is only indicated by a fold or incrassation. There may be a vena spuria or marking between the cubitus and the anal vein.

9. *Transverse or Cross Veins.*

- (*a*) The Humeral, between the Costa and Subcosta.
- (*b*) The Radial, between Radius 2 + 3 and Radius 4 + 5 (second + third longitudinal veins).
- (*c*) The Radio medial, between the Radius and Media (third + fourth longitudinal veins).
- (*d*) The Medio cubital, between the Media and the Cubitus (fourth + fifth longitudinal veins).

These veins mark out the following cells:

1. The Costal cell, between Costa and Subcosta, but subdivided by the humeral vein.
2. Subcostal (Mediastinal) cell, between Subcosta and Radius 1.
3. Marginal cell, between Radius 1 and Radius 2 + 3.
4. First Submarginal cell between Radius 2 + 3.
5. Second Submarginal cell between Radius 2 + 3 and Radius 4 + 5.
6. First Posterior cell, between Radius 4 + 5 and Media.
7. Second Posterior cell, between Media 1 + 2.
8. Third Posterior cell, between Media and Cubitus.
9. Fourth Posterior cell, between Cubitus 1 + 2.
10. Anal cell, between Cubitus and Anal 1.
11. Axillary cell, between Anal 1 + 2 and Anal 3, when present.
12. Spurious cell, behind Anal 3, when present.
13. Anterior Basal cell, bounded anteriorly by the Radius 1, posteriorly by the Media, and externally by the Radial transverse vein.
14. Posterior Basal cell, bounded anteriorly by the Media, and posteriorly by the Cubitus, and externally by the Medio cubital vein.

The wing has scales on all its veins, except the cross and the spurious veins, which are arranged in two ways: (1) Two rows of flat scales on each vein; (2) lateral scales along each vein.

Generally these scales in the Anophelinæ are lanceolate or long and narrow, but one genus, *Cycloleppteron*, has large inflated scales. It will be found that scales vary much in the different genera and species, the principal forms of which may be gathered from the following: The posterior margin of the wing carries a fringe consisting of scales arranged as follows: (1) Flat scales; (2) long lanceolate scales; (3) short lanceolate scales alternating with the long lanceolate scales.

Abdomen. There are eight segments in the abdomen, each of which consists of a dorsal plate, the tergum, and a ventral plate, the sternum, joined together by a pleural membrane on which lie the abdominal spiracles, said to number six or eight by different observers.

On the posterior end of the terminal segment are the external genital organs. In the male these consist of a pair of large basal lobes, each terminating in a clasp segment armed with a claw, thus forming the clasper. The arrangements of the male genitalia vary so much that they have been used as a method of classification. Therefore it is necessary to explain in a general way the terms used with regard to the various parts which may be found.

On the ventral surface of the basal lobe is the tubercle or lobe, called the claspette, while from their inner margin, near the base, a pair of claspers called harpagones, and more distally another pair, the harpes, project. Just at the junction of the two basal lobes are another pair of lobes—the setaceous lobes—which are believed to be the rudimentary ninth segment. The unci are absent in the Anophelinæ, but present as a pair of ventral processes in the Culicinæ. In the female there are the flap-like ovipositors.

The flat abdominal scales of the other Culicidæ are absent in the Anophelinæ, except in one genus.

Internal Anatomy.—A few points with regard to the internal anatomy of the mosquito may be mentioned.

ALIMENTARY CANAL.—The alimentary canal consists of: (1) Mouth; (2) buccal cavity; (3) pharynx, or pumping organ; (4) œsophagus and its pouches; (5) œsophageal valve, or proventriculus; (6) mid-gut; (7) ileum; (8) colon; (9) rectum; (10) anus (*vide* Fig. 385).

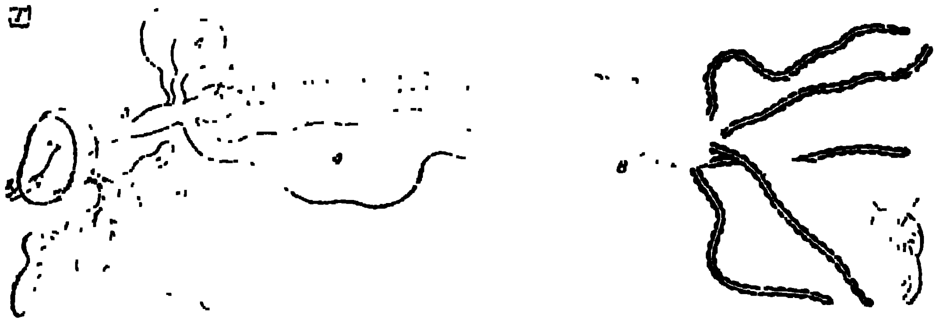

FIG. 385.—THE ALIMENTARY CANAL OF *Anopheles maculipennis* MEIGEN.
(After Nuttall and Shipley, *Journal of Hygiene*.)

1, Mouth and buccal cavity; 2, pharynx; 3, œsophagus; 4, dorsal and ventral œsophageal diverticula; 5, proventriculus; 6, salivary glands; 7, narrow portion of ventriculus; 8, so-called stomach; 9, Malpighian tubules; 10, intestine; 11, rectum; 12, anus.

1. *Mouth.*—The mouth is the place where the maxillæ, mandibles, labrum-epipharynx, hypopharynx, and palps fuse together.

2. *Buccal Cavity.*—This extends from the mouth to the valve between it and the pharynx, and is lined with chitin, and has an upward and backward direction until it approaches the pharynx, when it turns suddenly upward. There is a portion of its roof which possesses a thinner cuticle than the rest of the buccal cavity, and has been called the soft palate. This structure possesses two spines directed downwards into the lumen of the cavity, and has attached to it five pairs of palatal muscles. It is thought that as this membrane is wrinkled and has muscles attached to it, it may indicate that it is used for suctorial purposes. Posteriorly there is a valve between the buccal cavity and the pharynx, lying on a level just behind the posterior end of the clypeus. This prevents the return of fluids to the mouth during pumping. Annett and Dutton described a complicated sense organ at the junction of the buccal cavity and the pharynx, but this has not been confirmed.

3. *Pharynx.*—The pharynx extends from the posterior end of the buccal cavity to nearly the posterior end of the head, where it ends in the œsophagus. It is considerably larger in the female than in the male, because the former sucks blood, while the latter does not. The anterior portion is tubular, and passes through the nerve ring between the supra- and infra-œsophageal ganglia. The posterior portion is triangular, and has a chitinous wall arranged into three plates, one dorsal and two latero-ventral.

Posteriorly, near the œsophagus, the triradiate pharynx is surrounded by a sphincter muscle, and the chitin of this portion is marked by ridges, which end in very fine spines, making a comb-like appearance, and possibly acting as a strainer. The three chitinous plates have powerful muscles attached to them, of which the two posterior dorsal dilators run from the occiput to the dorsal plate, the two anterior dilators (two pairs in the female) taking their origin from the vertex are inserted also into the dorsal plate, and the five-paired latero-ventral dilators arising from the lateral posterior angle of the head pass upwards and a little forwards to the latero-ventral plates. When these muscles contract the triradiate pharynx becomes nearly circular, and when they relax the walls come together.

In this way the pharynx pumps the blood from the victim up the blood tube in the proboscis into the alimentary canal.

4. *Œsophagus.*—The short œsophagus runs from the pharynx to the œsophageal valve. Anteriorly it is narrow, but posteriorly it expands so much that this portion is sometimes called the crop. It is lined with thin chitin, and has many bands of muscles attached to it. Its posterior end lies on a level with the origin of the first pair of legs, and at this situation it gives off three pouches, two dorsal and one ventral. The large ventral pouch opens into the œsophagus by a single opening in the middle line, and extends backwards under the alimentary canal to the level of the fifth, sixth, or seventh abdominal segment, when fully distended. In shape it is fusiform. The two small latero-dorsally placed pouches open into the sides of the œsophagus. All these sacs are lined with thin chitin and have some slight musculature.

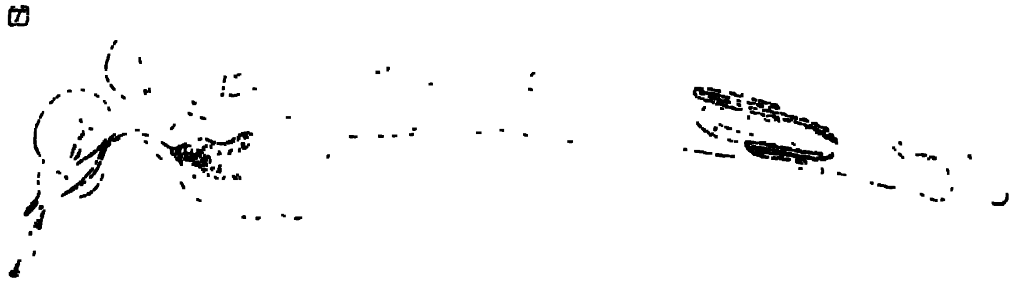

FIG. 386.—THE ALIMENTARY CANAL OF *Anopheles maculipennis* IN SITU.
(After Nuttall and Shipley, *Journal of Hygiene*.)

1, Proboscis, 2, buccal cavity, 3, pharynx, 4, œsophagus, 5, œsophageal pouches, 6, salivary glands, 7, proventriculus, 8 and 9, mid gut; 10, Malpighian tubes, 11, ileum, 12, colon, 13, rectum, 14, rectal papillæ; 15, anus.

5. *The Œsophageal Valve or Proventriculus.*—The œsophageal valve is an annular thickening of the intestinal wall, due partly to circular muscles, which are capable of closing the lumen of the gut when they contract, and partly to an invagination of the more anterior portion of the gut into the more posterior, thus forming a valve. Projecting from it are six small protuberances, more marked in the larva than in the adult insect. Christophers considers that this portion of the alimentary canal is the proventriculus of other insects. It is not lined with chitin.

6. *Mid Gut or Chylific Ventricle.*—The mid gut is a straight tube running from the œsophageal valve at the level of the first pair of legs to the posterior limit of the sixth abdominal segment; but this varies as to whether it is filled with food or not. It consists of two parts: an anterior narrow, and a posterior more distended, often called the 'stomach,' which begins on a level with the second abdominal segment, and is the receptacle for the food. The wall of the stomach is composed of the following layers:—

(1) A delicate internal cuticle.

(2) A single layer of large cylindrical or cubical epithelial cells with large nuclei; their condition varies with the state of distension of the stomach.

(3) An elastic basement membrane.

(4) Muscular fibres, circular and longitudinal, forming a loose network.

In this last layer there are numerous air-tubes or tracheæ, which probably help to keep the gut in position in the cœlom.

7-10. *Hind-Gut.*—This runs from the end of the mid-gut to the anus, being divided into the following regions:—

(1) A dorsally bent portion, the ileum, lined by flattened epithelium.
(2) A ventrally bent portion, the colon, lined by cubical epithelium.
(3) A dilated portion, the rectum, which has six large ovoid papillæ.

The rectum narrows just before the anus, which opens on the last segment of the body.

Malpighian Tubes.—There are five Malpighian tubes opening at the junction of the mid- and hind-gut.

Salivary Glands.—The salivary glands consist of two groups, each containing three acini, lying on each side of the body, in the anterior portion of the thorax, close against the prosternum, and extending almost as far back as the proventriculus. The ducts from each of these acini unite together to form a single duct on each side, which passes forwards through the neck into the head, where it unites beneath the subœsophageal ganglion, with its fellow of the opposite side, to form a common salivary duct. This duct passes forwards to end in the salivary pump, which is continuous with the salivary groove or canal of the hypopharynx. The duct of the salivary gland, therefore, is not in any way connected with the alimentary canal. These glands, which are much larger in the female than in the male, are composed of acini, surrounded by a basement membrane which is very delicate and structureless, and upon which rests a single layer of epithelial cells surrounding a central lumen. The whole acinus lies in a cleft in the fat-body.

Space does not permit of descriptions of the vascular, nervous and muscular systems being included.

Reproductive Organs. The female reproductive organs consist of ovaries, oviducts, and a common oviduct, a mucous gland and its duct, and a spermatheca and duct, while the male organs are testes and vasa deferentia, which after receiving the ducts of the receptacula seminis, run to an ejaculatory duct, which ends in a short penis.

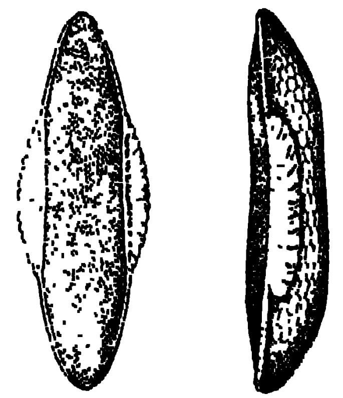

FIG. 387.—EGG OF *Anopheles maculipennis*.

(After Nuttall and Shipley.)

On the left the egg is seen from above, and on the right from the side.

Life-History. A mosquito passes through a complicated life cycle, consisting of an egg, a larval, and a pupal stage, the last-named giving rise to the perfect insect or imago.

Soon after a female insect is hatched it probably becomes fertilized, though some authorities believe that this does not take place until after the first meal of blood, which in any case precedes the oviposition, which takes place in the early morning.

The eggs, which number about one hundred, are laid upon the surface of the water, on which they may be seen arranged in stars, rows, or triangles.

The eggs of *A. maculipennis* are boat-shaped, about 0·5 to 1 millimetre in length, with a flat upper and convex lower surface, and with one end somewhat broader than the other. The head of the larva will be found at this broader anterior end. The upper surface is granular and reticulated, while the lower is smooth. On each side of the middle third the chitinous capsule is thrown into folds, called floats, while the margin projects as a chitinous frill.

The duration of the egg stage has not been well defined. Nuttall and Shipley give two to three days for *Anopheles maculipennis*, but it is probable that it is shorter in the tropics. The appearance and grouping of the eggs are quite different in the Culicinæ, as will be mentioned later.

The larva escaping from the blunt anterior end of the egg by the shifting off of a piece like a cap from the rest of the shell is seen to consist of head, neck, and abdomen.

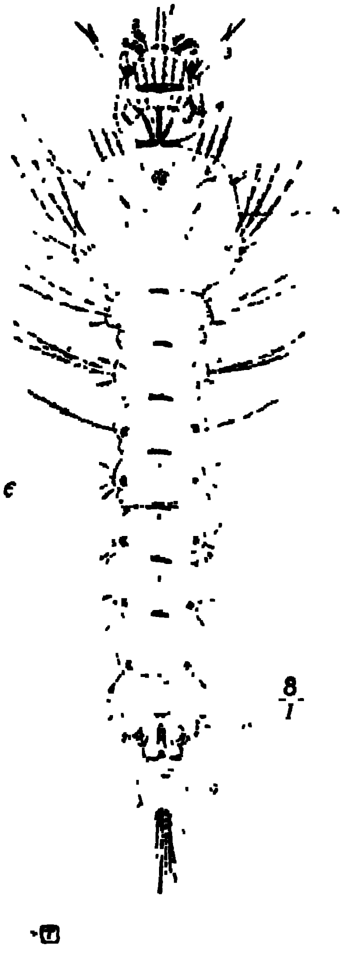

FIG. [illegible]. LARVA OF *Anopheles maculipennis*.

(After Nuttall and Shipley, *Journal of Hygiene*.)

1, Internal clypeal hairs; 2, external clypeal hairs; 3, antennæ; 4, head markings; 5, thorax; 6, abdomen; 7, palmate hair; 8, stigmatic aperture on last segment.

When first hatched the head is very black, but later on it becomes lighter in colour, and shows characteristic markings. At the back of the head there is a little notch, and from this a V-shaped dark line opens forwards, formed by two diverging bands of chitin, arranged along which are patches of pigment, which give rise to the characteristic markings. There are two large compound eyes, behind each of which lies a single eye-spot, or ocellus.

The antennæ are conspicuous rod-like bodies ending in two leaf-shaped appendages, between which is a branched hair, while another hair of specific importance arises from a papilla situated at the junction of the proximal and middle thirds.

Between the roots of the antennæ and projecting forwards there is a smooth shield-like area, the clypeus, which carries four or six hairs, which are also of specific importance. Two of these hairs (internal clypeal hairs) arise anteriorly near the middle line; external to these lie the external clypeal hairs, which arise from the outer angle of the clypeus, and behind them lie the posterior clypeal hairs. Sometimes there is a basal hair external to the antennæ.

The mouth parts consist of two large feeding-brushes, two maxillary palps, two mandibles, and on the ventral median line the under lip of Meinert, a conical chitinous structure, and a snout-like process covered with hairs projecting between the brushes.

The thorax is large, increasing in size as the larva grows older. It has numerous hairs, and sometimes a pair of the palmate hairs presently to be described.

There are nine segments in the abdomen, of which the eighth is characterized by possessing the openings of the tracheæ, and the ninth by possessing four large papillæ, and hair projecting downwards and backwards. The first two segments possess a pair of large feathered hairs on each side, the third a single hair on each side. The others do not possess these hairs. Certain of the abdominal segments have small fan-shaped hairs, called 'palmate hairs,' fixed by a short stalk on the outer side of the dorsum of the segment. Each of these consists of nineteen to twenty leaflets, which are capable of closing and opening upon the stalk like a fan. These hairs are rudimentary in the freshly hatched larva, but in the adult they are well marked, and have been used for purposes of classification, according to the variations in their number and position, and the characters of the leaflets and their terminal hairs, if present. These hairs are of use in helping to keep the larva in its horizontal position when it comes up to breathe on the surface of the water.

The stigmatic siphon is placed, as already mentioned, on the eighth segment, forming by means of raised, toothed, chitinous processes a quadrilateral space.

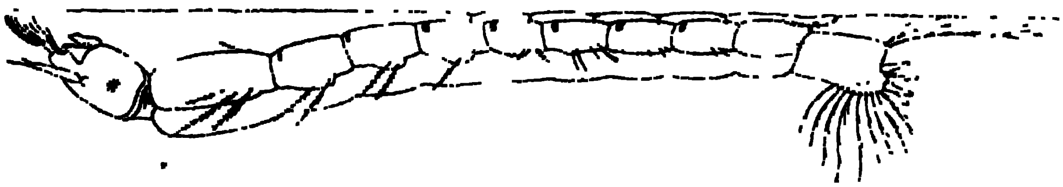

FIG. 389.—LARVA OF AN ANOPHELINE MOSQUITO LYING PARALLEL TO THE WATER

(Modified after Howard.)

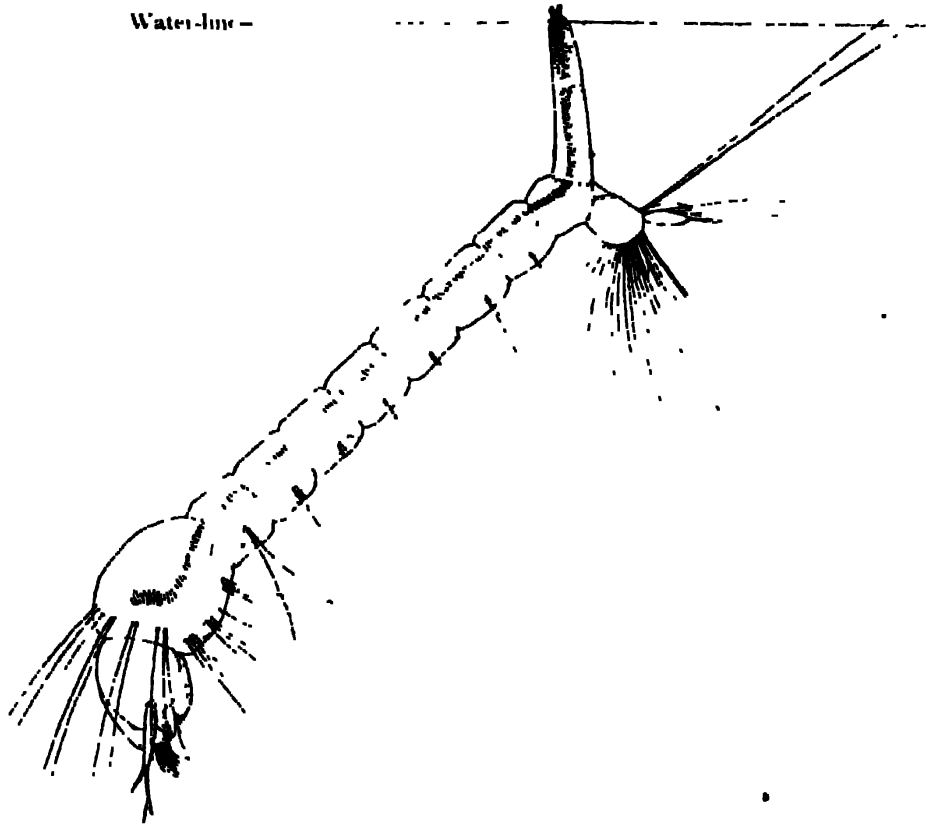

FIG. 390.—LARVA OF A CULICINE MOSQUITO HANGING DOWN FROM THE SURFACE OF THE WATER.

(After Howard.)

The teeth are of great importance, being capable of being approximated so as to close the cavity, and thus protect the two openings of the tracheæ which lie in the anterior portion of the siphon. From these openings the long tracheæ can be seen running from back to front along the larva

The duration of the larval stage varies with food and temperature, being longer in the temperate zone than in the tropics. According to Stephens, it is twelve days in *Cellia argyrotarsis* and eleven days in *Myzomyia rossi*, while it may be eighteen to twenty-one days in *Anopheles maculipennis* in the temperate zone. The larva grows by moulting several times.

Culicine larvæ are easily distinguished from Anopheline larvæ by the fact that the spiracles are carried on a long respiratory siphon, formed by a prolongation of the dorsum of the eighth abdominal segment, which has been used to distinguish the different species (Fig. 390).

Below the siphon on the eighth segment there are spines, forming a comb, while along the length of the siphon there is another comb, distal to which is a tuft of hairs. The variations in these structures, together with those in the length and breadth of the siphon, associated with those of the antennæ and clypeus, afford means of classifying the Culicine larvæ. For further information, consult either Theobald's Monograph, vol iv., p. 6, or Felt's paper, Bulletin 97 of the Division of Entomology of the New York State Museum. The Megarhininæ, Ædinæ, and Uranotæninæ possess larvæ belonging to the Culicine type.

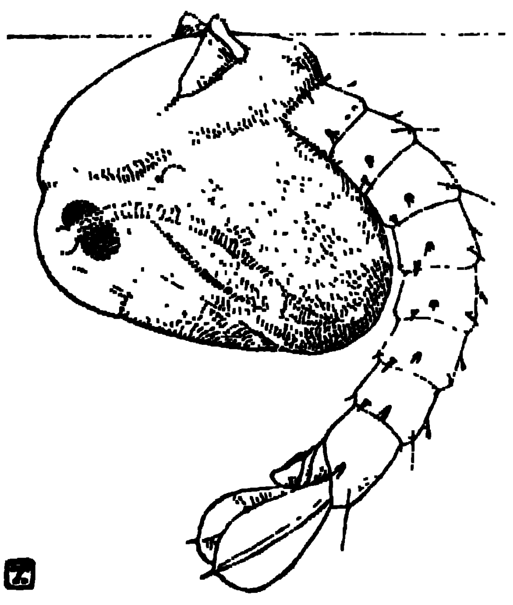

FIG. 391.—PUPA OF *Anopheles maculipennis*.

(After Nuttall and Shipley, *Journal of Hygiene*.)

The pupal stage lasts about forty-eight hours. Towards the end of an afternoon the pupa comes up to the surface, and the dorsal portion of the thorax splits with a T-shaped fissure, and the adult insect or imago emerges. Pupæ do not eat.

Differences between the Anophelinæ and Culicinæ.—The difference between these two important families may popularly be described as follows:

The Anophelinæ, as a rule, project from any plane surface on which they may be resting at a sharply defined angle, owing to their head, thorax, and abdomen forming a more or less straight line; while the Culicinæ, on the other hand, do not make such a well-defined angle, owing to the fact that the abdomen is not in the same straight line as the long axis of the thorax. The eggs of the Anophelinæ are laid singly, while those of the Culicinæ are laid in rafts. The larvæ of the Anophelinæ have no drawn-out siphons, and therefore lie more or less parallel to the surface of the water, while the larvæ of the Culicinæ hang downwards. There are, however, exceptions to these rules—thus, *e.g.*, *Myzomyia culicifacies* rests on a surface like a Culex, not like an Anopheles.

Bionomics.—The imago emerges from the pupa during the late afternoon, after which the females are ready for fertilization by the males. These latter can sometimes be seen in large numbers, while but few females are observed, which is supposed to be characteristic of the breeding period.

The female alone bites man and animals, apparently for the purpose of obtaining rich food for the eggs, while the male feeds on the juices of plants and fruits. The female can also be seen feeding upon vegetable juices, though this is more common in the females of the Culicinæ than in those of the Anophelinæ. It is believed that a female feeds on blood once a day in nature, but this is a difficult matter to be certain about. The mechanism of the bite has already been described in page 223, to which reference should be made. It will also be noted that the structure of the female mouth-parts is adapted for piercing, while that of the male is not. It will also be remembered that only the stylets pierce the skin, and that the labium never does so. Infection of the victim by the malarial germ takes place during the act of biting, as the sporozoites pass down the hypopharyngeal or salivary tube, while the infection of the mosquito is effected by the blood, which passes from the victim along the labial or blood-tube into the mouth. So much blood may be sucked that it may appear *per anum*.

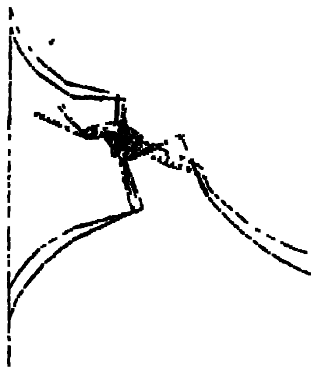

FIG. 392.—DIAGRAM TO SHOW THE POSTURE OF AN ANOPHELINE MOSQUITO ON A WALL.

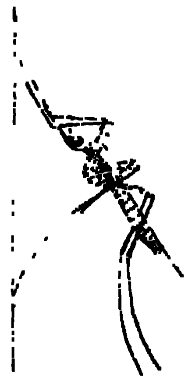

FIG. 393.—DIAGRAM TO SHOW THE POSTURE OF ANOTHER ANOPHELINE MOSQUITO ON A WALL.

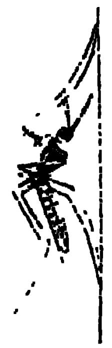

FIG. 394.—DIAGRAM TO SHOW THE POSTURE OF *Culex pipiens* ON A WALL.

(After Sambon, from the *British Medical Journal*.)

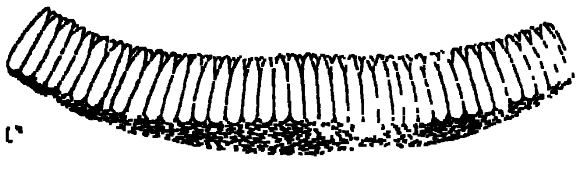

FIG. 395.—RAFT OF CULICINE EGGS. (After Sambon.)

Usually the mosquitoes bite at night, and preferably in the dark, as, for example, they will attack the ankles of people while sitting at dinner at night.

After feeding, the mosquitoes usually retire to a dark portion of the room to digest the food. It is noticeable that they avoid white areas during the daytime, and prefer dark-coloured regions away from the light, and hence are very difficult to find in ill-lighted native huts.

In the early morning the female flies to the nearest water and lays her eggs. Usually she does not travel far, but is believed to be capable of going at least half a mile in case of need.

The females of the Culicinæ do not appear to concern themselves as to the nature of the water in which they lay their eggs, but the female Anophelinæ prefer clean water with a certain amount of weed. This water may be the back eddies of a river, where there is the protection of weeds, or the margins of large lakes, where dense surface vegetation is to be found, or any collection of water which contains green vegetal matter, or, failing these, any collection of fresh or moderately salt water. Small and large wells are a prolific source of mosquitoes, as are puddles, and water in broken bottles, shells, and especially in plants like bamboos, etc. Having laid the eggs, they retire to some dark corner during the daylight, and emerge at night for another feed of blood. How long they live is not known with certainty, and will be discussed, together with other features of their bionomics, in Chapter XL., under Malaria.

Mosquitoes can hibernate during the cold weather of the temperate zone, and æstivate during the dry hot weather of the tropics.

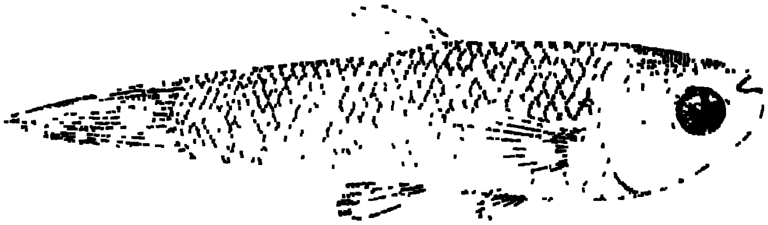

FIG. 300. *Girardinus poeciloides*, DE FILIPPI.
(The tail should have been drawn expanded.)

In this latter condition they bite and suck blood, but apparently do not lay eggs, even if water is provided. The eggs are kept afloat on the surface of the water by their structure, and in due course give rise to the larvæ, which are great eaters, living not merely upon unicellular organisms, such as algæ and diatoms, but also upon their fellows. For purposes of obtaining air they are compelled to come to the surface of the water. The Anopheline larva, not possessing a siphon, has to lie more or less parallel with the surface of the water in order to enable the air to enter the spiracles, and this it is able to do by the aid of the palmate hairs already mentioned: while the Culicine larvæ have merely to bring the apex of the siphon to the surface of the water, from which they apparently hang downwards. Larvæ are certainly able to hibernate, and perhaps eggs also. The pupa does not feed.

Mosquitoes have many enemies and parasites, but the most important from a point of view of the prophylaxis of malaria are those which eat the eggs, the larvæ, and the pupæ, of which fish are the most important.

In 1905 C. K. Gibbons pointed out that a small fish, popularly termed 'millions,' which lived in shallow water, was a voracious feeder on eggs, larvæ, and pupæ of mosquitoes. These fish, which belong to the species *Girardinus pœciloides* de Filippi, are found in Barbados, which is very free from malaria. They are very small, the full-grown female only measuring 1½ inches in length, while the male is smaller. The female is dull in colour, while the male is distinguished by red splashes and a black circular dot on its sides. The great importance of these little fish is that they are able to live in very shallow water, and to work their way in among dense surface vegetation, and thus to gain access to the larvæ, etc., of the mosquitoes, which otherwise are protected by the weeds from attacks by the larger fish. Their classification is Teleostei, Haplomi, Cyprinodontidæ, genus *Haplochilus* McClelland, 1839. The family contains 220 species, of which only 50 live out of America. Haplochilus has 24 species in Africa and 35 in Asia and America. There is no doubt that these small fish should be introduced into malarious places as a prophylactic measure against the disease. Other closely allied species are *G. versicolor* Gunther, found in St. Domingo, and *G. formosus*, found in Florida and South Carolina. With regard to other species, *Gambusca molliensia* is said to be of great value in consuming larvæ, especially when protected by dense surface vegetation. Recently Graham has reported that *Haplochilus grahami* Boulenger, 1911, and *H. bifasciatus* Steindachner, 1881, of the Cyprinodontidæ, eat larvæ greedily, while Gowdey finds the same for *Fundulus tæniopygus* and *Haplochilus pumilus* Boulenger, 1906, in Uganda.

Certain plants, as is well known, collect water, especially the bromelias, the bamboos, and the pitcher plants. In this water Culicine and sometimes Anopheline larvæ can be found. E. E. Green, of Ceylon, has shown that the flowers of the lobster claw plant (*Heliconia brasiliensis*) can hold a considerable amount of water, in which he found Stegomyia and Desvoidea larvæ in large numbers.

Classification. Various methods of classifying mosquitoes have been brought forward. The earliest were based upon the characters of the palpi, but in 1901 Theobald showed that they were useless for anything but specific characteristics, and based his larger divisions on the variations of the scales on the head, body, and wings. Felt brought forward a classification based upon the male genitalia and the wing veins, but, as Theobald remarks, the majority of known mosquitoes being female, it is most undesirable to take only male characters for the classification. Recently Dyar and Knab have issued a classification of the Culicidæ by larval characters, and Eysell has advanced matters considerably by separating the Corethrinæ from the Culicidæ under the term Corethridæ, because the Corethridæ have an entire absence of the long piercing proboscis and of scales in the adults, both of which are marked features of the Culicidæ. It will be evident that this is useful. Lutz has brought forward a classification based upon larval and adult forms, which Theobald has modified and brought into accord with one based upon scales as generic characters, and this classification is followed below.

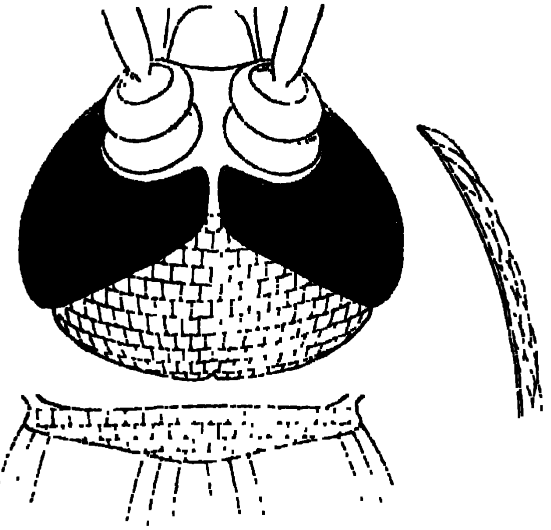

FIG. 407. HEAD AND SCUTELLUM OF MEGARHINUS, TO SHOW THE SCALES. On the right a profile view of the scales (After Theobald, 'Culicidæ of the World

THEOBALD'S CLASSIFICATION.—The Culicidæ may be divided into subfamilies, according to the characters of the scales on the head, body, legs, and wings.

A. Scutellum simple, never trilobed; proboscis straight, palpi long in male and female—*Anophelinæ.*

B. Scutellum trilobed:—

I. Proboscis strongly recurved; first submarginal cell very small—*Megarhininæ.*

II. Proboscis straight: post-scutellum nude:—

1. Wings with six longitudinal scaled veins:—

(1) Antennæ with second joint normal in length:—

(*a*) First submarginal cell as long as or longer than the second posterior cell.

Palpi in the female shorter than the proboscis, long in male—*Culicinæ.*

Palpi short in both sexes—*Ædinæ.*

(*b*) First submarginal cell very small: smaller than second posterior—*Uranotæninæ.*

(2) Antennæ with second joint very long—*Deinoceratinæ*

2. Wings with seven longitudinal scaled veins—*Heptaphlebomyinæ*

III. Proboscis straight: post-scutellum with scales or chætæ:—

1. Palpi long in male, short in female—*Trichoprosoponinæ.*

2. Palpi short in both sexes.—*Dendromyinæ.*

IV. Proboscis elbowed—*Limatinæ.*

Of these, only the Anophelinæ and the Culicinæ, and possibly the Ædinæ, contain species of importance in tropical medicine, and concerning these subfamilies a few details must be given.

ANOPHELINÆ.

Definition.—Culicidæ with straight proboscis; palpi long in both sexes; occiput mostly with upright forked scales, never with flat lateral scales. Thorax with scales or hairs, scutellum never trilobed, with scales or hairs. Postscutellum nude. Abdomen with hairs or scales. Eggs laid singly, and not in rafts. Larvæ without respiratory siphon.

This is a most important subfamily, because it contains the species which are known to carry malaria. The list of known carriers will be found in Chapter XXXV. (p. 883).
